Introduction

The Seventh Conference on Machine Translation (WMT 2022) took place on Wednesday, December 7 and Thursday, December 8, 2022 immediately preceding the 2022 Conference on Empirical Methods in Natural Language Processing (EMNLP 2022).

This is the seventh time WMT has been held as a conference. The first time WMT was held as a conference was at ACL 2016 in Berlin, Germany, the second time at EMNLP 2017 in Copenhagen, Denmark, the third time at EMNLP 2028 in Brussels, Belgium, the fourth time at ACL 2019 in Florence, Italy, the fifth time at EMNLP-2020, which was held as an online event due to the COVID-19 pandemic, and the sixth time at EMNLP 2021 at Punta Cana, Dominican Republic. Prior to being a conference, WMT was held 10 times as a workshop. WMT was held for the first time at HLT-NAACL 2006 in New York City, USA. In the following years the Workshop on Statistical Machine Translation was held at ACL 2007 in Prague, Czech Republic, ACL 2008, Columbus, Ohio, USA, EACL 2009 in Athens, Greece, ACL 2010 in Uppsala, Sweden, EMNLP 2011 in Edinburgh, Scotland, NAACL 2012 in Montreal, Canada, ACL 2013 in Sofia, Bulgaria, ACL 2014 in Baltimore, USA, EMNLP 2015 in Lisbon, Portugal.

The focus of our conference is to bring together researchers from the area of machine translation and invite selected research papers to be presented at the conference.

Prior to the conference, in addition to soliciting relevant papers for review and possible presentation, we conducted 13 shared tasks: General Machine Translation of News, Similar Language Translation, Biomedical Translation, Large-Scale Machine Translation Evaluation for African Languages, Translation Efficiency, Sign Language Translation, Code-mixed Machine Translation, Chat Translation Task, Unsupervised MT and Very Low Resource Supervised Machine Translation, Metrics for Machine Translation, Quality Estimation of Translation, Word-Level Auto-Completion, Translation Suggestion, and the Automatic Post-Editing task.

The results of all shared tasks were announced at the conference, and these proceedings also include overview papers for the shared tasks, summarizing the results, as well as providing information about the data used and any procedures that were followed in conducting or scoring the tasks. In addition, there are short papers from each participating team that describe their underlying system in greater detail.

Like in previous years, we have received a far larger number of submissions than we could accept for presentation. WMT 2022 has received 48 full research paper submissions (not counting withdrawn submissions). In total, WMT 2022 featured 16 full research paper presentations and 96 shared task presentations.

The invited talk entitled was given by Ondřej Bojar from Charles University, Prague, Czech Republic

We would like to thank the members of the Program Committee for their timely reviews. We also would like to thank the participants of the shared task and all the other volunteers who helped with the evaluations.

Keynote Talk: Speech Translation — When Two Superhuman Technologies Combined Fail

Ondrej Bojar
Charles University

Abstract: In my talk, I will describe the challenges we faced in the EU project ELITR when we put together low-latency speech recognition and machine translation, both ’at or above human levels of performance’ in order to simultaneously translate spontaneous speech to 42 languages. I will have to talk about various aspects of quality and I will delve into both source and target multilinguality. Our ongoing quest is to put human interpreters on the same scales as machines, to contrast their virtues, complement them in their service and build upon their output.

Bio: Ondřej Bojar is an associate professor at ÚFAL, Charles University, and a lead scientist in Machine Translation in the Czech Republic. He has been co-organizing WMT shared tasks in machine translation and machine translation evaluation since 2013. His system has dominated English-Czech translation in the years 2013-2015, before deep learning and neural networks fundamentally changed the field. Having taken part and later supervised ÚFAL’s participation in a series of EU projects (EuroMatrix, EuroMatrixPlus, MosesCore, QT21, HimL, CRACKER, Bergamot), he has recently concluded his coordination of the EU project ELITR (http://elitr.eu/) focussed on simultaneous speech translation into over 40 languages. ELITR has also coined the task of project meeting summarization with its AutoMin 2021 shared task.

Table of Contents

Program

Wednesday, December 7, 2022

09:00 - 09:10 *Opening Remarks*

09:10 - 10:30 *Session 1 — Shared Task Overview Papers I*

Findings of the 2022 Conference on Machine Translation (WMT22)
Tom Kocmi, Rachel Bawden, Ondřej Bojar, Anton Dvorkovich, Christian Federmann, Mark Fishel, Thamme Gowda, Yvette Graham, Roman Grundkiewicz, Barry Haddow, Rebecca Knowles, Philipp Koehn, Christof Monz, Makoto Morishita, Masaaki Nagata, Toshiaki Nakazawa, Michal Novák, Martin Popel and Maja Popović

Results of WMT22 Metrics Shared Task: Stop Using BLEU – Neural Metrics Are Better and More Robust
Markus Freitag, Ricardo Rei, Nitika Mathur, Chi-kiu Lo, Craig Stewart, Eleftherios Avramidis, Tom Kocmi, George Foster, Alon Lavie and André F. T. Martins

Findings of the WMT 2022 Shared Task on Quality Estimation
Chrysoula Zerva, Frédéric Blain, Ricardo Rei, Piyawat Lertvittayakumjorn, José G. C. De Souza, Steffen Eger, Diptesh Kanojia, Duarte Alves, Constantin Orăsan, Marina Fomicheva, André F. T. Martins and Lucia Specia

Findings of the WMT 2022 Shared Task on Efficient Translation
Kenneth Heafield, Biao Zhang, Graeme Nail, Jelmer Van Der Linde and Nikolay Bogoychev

Findings of the WMT 2022 Shared Task on Automatic Post-Editing
Pushpak Bhattacharyya, Rajen Chatterjee, Markus Freitag, Diptesh Kanojia, Matteo Negri and Marco Turchi

10:30 - 11:00 *Coffee Break*

11:00 - 12:40 *Session 2 — Research Papers on Evaluation and Bias*

Embarrassingly Easy Document-Level MT Metrics: How to Convert Any Pretrained Metric into a Document-Level Metric
Giorgos Vernikos, Brian Thompson, Prashant Mathur and Marcello Federico

Searching for a Higher Power in the Human Evaluation of MT
Johnny Wei, Tom Kocmi and Christian Federmann

Analyzing the Use of Influence Functions for Instance-Specific Data Filtering in Neural Machine Translation
Tsz Kin Lam, Eva Hasler and Felix Hieber

Wednesday, December 7, 2022 (continued)

Continuous Rating as Reliable Human Evaluation of Simultaneous Speech Translation
Dávid Javorský, Dominik Macháček and Ondřej Bojar

Gender Bias Mitigation for NMT Involving Genderless Languages
Ander Corral and Xabier Saralegi

12:40 - 14:00 *Lunch Break*

14:00 - 15:20 *Session 3 — Research Papers on Multilingual, Multimodal, Multidomain Translation*

Exploring the Benefits and Limitations of Multilinguality for Non-autoregressive Machine Translation
Sweta Agrawal, Julia Kreutzer and Colin Cherry

Learning an Artificial Language for Knowledge-Sharing in Multilingual Translation
Danni Liu and Jan Niehues

Don't Discard Fixed-Window Audio Segmentation in Speech-to-Text Translation
Chantal Amrhein and Barry Haddow

Additive Interventions Yield Robust Multi-Domain Machine Translation Models
Elijah Rippeth and Matt Post

Test Set Sampling Affects System Rankings: Expanded Human Evaluation of WMT20 English-Inuktitut Systems
Rebecca Knowles and Chi-kiu Lo

Can Domains Be Transferred across Languages in Multi-Domain Multilingual Neural Machine Translation?
Thuy-trang Vu, Shahram Khadivi, Xuanli He, Dinh Phung and Gholamreza Haffari

15:20 - 16:00 *Coffee Break*

16:00 - 17:30 *Session 4 — Shared Task Sytem Description Posters I*

Wednesday, December 7, 2022 (continued)

16:00 - 17:30 *News Translation Task*

Inria-ALMAnaCH at WMT 2022: Does Transcription Help Cross-Script Machine Translation?
Jesujoba Alabi, Lydia Nishimwe, Benjamin Muller, Camille Rey, Benoît Sagot and Rachel Bawden

NAIST-NICT-TIT WMT22 General MT Task Submission
Hiroyuki Deguchi, Kenji Imamura, Masahiro Kaneko, Yuto Nishida, Yusuke Sakai, Justin Vasselli, Huy Hien Vu and Taro Watanabe

Samsung R&D Institute Poland Participation in WMT 2022
Adam Dobrowolski, Mateusz Klimaszewski, Adam Myśliwy, Marcin Szymański, Jakub Kowalski, Kornelia Szypuła, Paweł Przewłocki and Paweł Przybysz

Tencent AI Lab - Shanghai Jiao Tong University Low-Resource Translation System for the WMT22 Translation Task
Zhiwei He, Xing Wang, Zhaopeng Tu, Shuming Shi and Rui Wang

Lan-Bridge MT's Participation in the WMT 2022 General Translation Shared Task
Bing Han, Yangjian Wu, Gang Hu and Qiulin Chen

Manifold's English-Chinese System at WMT22 General MT Task
Chang Jin, Tingxun Shi, Zhengshan Xue and Xiaodong Lin

CUNI-Bergamot Submission at WMT22 General Translation Task
Josef Jon, Martin Popel and Ondřej Bojar

KYB General Machine Translation Systems for WMT22
Shivam Kalkar, Yoko Matsuzaki and Ben Li

The AISP-SJTU Translation System for WMT 2022
Guangfeng Liu, Qinpei Zhu, Xingyu Chen, Renjie Feng, Jianxin Ren, Renshou Wu, Qingliang Miao, Rui Wang and Kai Yu

NT5 at WMT 2022 General Translation Task
Makoto Morishita, Keito Kudo, Yui Oka, Katsuki Chousa, Shun Kiyono, Sho Takase and Jun Suzuki

Wednesday, December 7, 2022 (continued)

Adam Mickiewicz University at WMT 2022: NER-Assisted and Quality-Aware Neural Machine Translation
Artur Nowakowski, Gabriela Pałka, Kamil Guttmann and Mikołaj Pokrywka

Evaluating Corpus Cleanup Methods in the WMT'22 News Translation Task
Marilena Malli and George Tambouratzis

PROMT Systems for WMT22 General Translation Task
Alexander Molchanov, Vladislav Kovalenko and Natalia Makhamalkina

eTranslation's Submissions to the WMT22 General Machine Translation Task
Csaba Oravecz, Katina Bontcheva, David Kolovratnìk, Bogomil Kovachev and Christopher Scott

CUNI Systems for the WMT 22 Czech-Ukrainian Translation Task
Martin Popel, Jindřich Libovický and Jindřich Helcl

The ARC-NKUA Submission for the English-Ukrainian General Machine Translation Shared Task at WMT22
Dimitrios Roussis and Vassilis Papavassiliou

The NiuTrans Machine Translation Systems for WMT22
Weiqiao Shan, Zhiquan Cao, Yuchen Han, Siming Wu, Yimin Hu, Jie Wang, Yi Zhang, Hou Baoyu, Hang Cao, Chenghao Gao, Xiaowen Liu, Tong Xiao, Anxiang Ma and Jingbo Zhu

Teaching Unseen Low-resource Languages to Large Translation Models
Maali Tars, Taido Purason and Andre Tättar

DUTNLP Machine Translation System for WMT22 General MT Task
Ting Wang, Huan Liu, Junpeng Liu and Degen Huang

HW-TSC's Submissions to the WMT 2022 General Machine Translation Shared Task
Daimeng Wei, Zhiqiang Rao, Zhanglin Wu, Shaojun Li, Yuanchang Luo, Yuhao Xie, Xiaoyu Chen, Hengchao Shang, Zongyao Li, Zhengzhe Yu, Jinlong Yang, Miaomiao Ma, Lizhi Lei, Hao Yang and Ying Qin

Vega-MT: The JD Explore Academy Machine Translation System for WMT22
Changtong Zan, Keqin Peng, Liang Ding, Baopu Qiu, Boan Liu, Shwai He, Qingyu Lu, Zheng Zhang, Chuang Liu, Weifeng Liu, Yibing Zhan and Dacheng Tao

No Domain Left behind
Hui Zeng

GTCOM Neural Machine Translation Systems for WMT22
Hao Zong and Chao Bei

16:00 - 17:30 *Test Suites*

Linguistically Motivated Evaluation of the 2022 State-of-the-art Machine Translation Systems for Three Language Directions
Vivien Macketanz, Shushen Manakhimova, Eleftherios Avramidis, Ekaterina Lapshinova-koltunski, Sergei Bagdasarov and Sebastian Möller

Automated Evaluation Metric for Terminology Consistency in MT
Kirill Semenov and Ondřej Bojar

Test Suite Evaluation: Morphological Challenges and Pronoun Translation
Marion Weller-di Marco and Alexander Fraser

16:00 - 17:30 *Metrics Task*

Robust MT Evaluation with Sentence-level Multilingual Augmentation
Duarte Alves, Ricardo Rei, Ana C Farinha, José G. C. De Souza and André F. T. Martins

ACES: Translation Accuracy Challenge Sets for Evaluating Machine Translation Metrics
Chantal Amrhein, Nikita Moghe and Liane Guillou

Linguistically Motivated Evaluation of Machine Translation Metrics Based on a Challenge Set
Eleftherios Avramidis and Vivien Macketanz

Exploring Robustness of Machine Translation Metrics: A Study of Twenty-Two Automatic Metrics in the WMT22 Metric Task
Xiaoyu Chen, Daimeng Wei, Hengchao Shang, Zongyao Li, Zhanglin Wu, Zhengzhe Yu, Ting Zhu, Mengli Zhu, Ning Xie, Lizhi Lei, Shimin Tao, Hao Yang and Ying Qin

MS-COMET: More and Better Human Judgements Improve Metric Performance
Tom Kocmi, Hitokazu Matsushita and Christian Federmann

Wednesday, December 7, 2022 (continued)

Partial Could Be Better than Whole. HW-TSC 2022 Submission for the Metrics Shared Task
Yilun Liu, Xiaosong Qiao, Zhanglin Wu, Su Chang, Min Zhang, Yanqing Zhao, Song Peng, Shimin Tao, Hao Yang, Ying Qin, Jiaxin Guo, Minghan Wang, Yinglu Li, Peng Li and Xiaofeng Zhao

Unsupervised Embedding-based Metric for MT Evaluation with Improved Human Correlation
Ananya Mukherjee and Manish Shrivastava

REUSE: REference-free UnSupervised Quality Estimation Metric
Ananya Mukherjee and Manish Shrivastava

MaTESe: Machine Translation Evaluation as a Sequence Tagging Problem
Stefano Perrella, Lorenzo Proietti, Alessandro Scirè, Niccolò Campolungo and Roberto Navigli

COMET-22: Unbabel-IST 2022 Submission for the Metrics Shared Task
Ricardo Rei, José G. C. De Souza, Duarte Alves, Chrysoula Zerva, Ana C Farinha, Taisiya Glushkova, Alon Lavie, Luisa Coheur and André F. T. Martins

Alibaba-Translate China's Submission for WMT2022 Metrics Shared Task
Yu Wan, Keqin Bao, Dayiheng Liu, Baosong Yang, Derek F. Wong, Lidia S. Chao, Wenqiang Lei and Jun Xie

16:00 - 17:30 *Quality Estimation Task*

Quality Estimation via Backtranslation at the WMT 2022 Quality Estimation Task
Sweta Agrawal, Nikita Mehandru, Niloufar Salehi and Marine Carpuat

Alibaba-Translate China's Submission for WMT 2022 Quality Estimation Shared Task
Keqin Bao, Yu Wan, Dayiheng Liu, Baosong Yang, Wenqiang Lei, Xiangnan He, Derek F. Wong and Jun Xie

KU X Upstage's Submission for the WMT22 Quality Estimation: Critical Error Detection Shared Task
Sugyeong Eo, Chanjun Park, Hyeonseok Moon, Jaehyung Seo and Heuiseok Lim

NJUNLP's Participation for the WMT2022 Quality Estimation Shared Task
Xiang Geng, Yu Zhang, Shujian Huang, Shimin Tao, Hao Yang and Jiajun Chen

BJTU-Toshiba's Submission to WMT22 Quality Estimation Shared Task
Hui Huang, Hui Di, Chunyou Li, Hanming Wu, Kazushige Ouchi, Yufeng Chen, Jian Liu and Jinan Xu

Papago's Submission to the WMT22 Quality Estimation Shared Task
Seunghyun Lim and Jeonghyeok Park

CometKiwi: IST-Unbabel 2022 Submission for the Quality Estimation Shared Task
Ricardo Rei, Marcos Treviso, Nuno M. Guerreiro, Chrysoula Zerva, Ana C Farinha, Christine Maroti, José G. C. De Souza, Taisiya Glushkova, Duarte Alves, Luisa Coheur, Alon Lavie and André F. T. Martins

CrossQE: HW-TSC 2022 Submission for the Quality Estimation Shared Task
Shimin Tao, Su Chang, Ma Miaomiao, Hao Yang, Xiang Geng, Shujian Huang, Min Zhang, Jiaxin Guo, Minghan Wang and Yinglu Li

Welocalize-ARC/NKUA's Submission to the WMT 2022 Quality Estimation Shared Task
Eirini Zafeiridou and Sokratis Sofianopoulos

16:00 - 17:30 *Efficient Translaton Task*

Edinburgh's Submission to the WMT 2022 Efficiency Task
Nikolay Bogoychev, Maximiliana Behnke, Jelmer Van Der Linde, Graeme Nail, Kenneth Heafield, Biao Zhang and Sidharth Kashyap

CUNI Non-Autoregressive System for the WMT 22 Efficient Translation Shared Task
Jindřich Helcl

The RoyalFlush System for the WMT 2022 Efficiency Task
Bo Qin, Aixin Jia, Qiang Wang, Jianning Lu, Shuqin Pan, Haibo Wang and Ming Chen

HW-TSC's Submission for the WMT22 Efficiency Task
Hengchao Shang, Ting Hu, Daimeng Wei, Zongyao Li, Xianzhi Yu, Jianfei Feng, Ting Zhu, Lizhi Lei, Shimin Tao, Hao Yang, Ying Qin, Jinlong Yang, Zhiqiang Rao and Zhengzhe Yu

16:00 - 17:30 *Automatic Post-Editing Task*

IIT Bombay's WMT22 Automatic Post-Editing Shared Task Submission
Sourabh Deoghare and Pushpak Bhattacharyya

LUL's WMT22 Automatic Post-Editing Shared Task Submission
Xiaoying Huang, Xingrui Lou, Fan Zhang and Tu Mei

16:00 - 17:30 *Papers from the Findings of the EMNLP*

Translating Hanja Historical Documents to Contemporary Korean and English
Alice Oh, Kyunghyun Cho, JinYeong Bak, Haneul Yoo, Jiho Jin and Juhee Son

Data Selection Curriculum for Neural Machine Translation
Shafiq Joty, Shruti Bhosale, James Cross, Vishrav Chaudhary, Philipp Koehn and Tasnim Mohiuddin

Bitext Mining Using Distilled Sentence Representations for Low-Resource Languages
Holger Schwenk, Onur Çelebi and Kevin Heffernan

m^4 Adapter: Multilingual Multi-Domain Adaptation for Machine Translation with a Meta-Adapter
Alexander Fraser, Alexandra Chronopoulou and Wen Lai

What Do Compressed Multilingual Machine Translation Models Forget?
Laurent Besacier, James Henderson, Caroline Brun, Alexandre Berard, Vassilina Nikoulina and Alireza Mohammadshahi

Improving HowNet-Based Chinese Word Sense Disambiguation with Translations
Grzegorz Kondrak, Bradley Hauer and Xiang Zhang

Finding Memo: Extractive Memorization in Constrained Sequence Generation Tasks
Arul Menezes and Vikas Raunak

SALTED: A Framework for SAlient Long-tail Translation Error Detection
Arul Menezes, Matt Post and Vikas Raunak

SALTED: A Framework for SAlient Long-tail Translation Error Detection
Arul Menezes, Matt Post and Vikas Raunak

Wednesday, December 7, 2022 (continued)

Data Cartography for Low-Resource Neural Machine Translation
Marine Carpuat and Aquia Richburg

Improving Zero-Shot Multilingual Translation with Universal Representations and Cross-Mapping
Yang Feng and Shuhao Gu

Guiding Neural Machine Translation with Semantic Kernels
Yuqiang Xie, Luxi Xing, Yunpeng Li, Yubing Ren, Xiangpeng Wei, Yue Hu and Ping Guo

Does Simultaneous Speech Translation need Simultaneous Models?
Marco Turchi, Matteo Negri, Marco Gaido and Sara Papi

Utilizing Language-Image Pretraining for Efficient and Robust Bilingual Word Alignment
Kangwook Lee, Dimitris Papailiopoulos, Junjie Hu, Yifei Ming, Timothy Ossowski, Shashank Rajput, Jy-yong Sohn and Tuan Dinh

11:00 - 12:40 *Session 6 — Research Papers on Practical Aspects of Machine Translation*

Focused Concatenation for Context-Aware Neural Machine Translation
Lorenzo Lupo, Marco Dinarelli and Laurent Besacier

Does Sentence Segmentation Matter for Machine Translation?
Rachel Wicks and Matt Post

Revisiting Locality Sensitive Hashing for Vocabulary Selection in Fast Neural Machine Translation
Hieu Hoang, Marcin Junczys-dowmunt, Roman Grundkiewicz and Huda Khayrallah

Too Brittle to Touch: Comparing the Stability of Quantization and Distillation towards Developing Low-Resource MT Models
Harshita Diddee, Sandipan Dandapat, Monojit Choudhury, Tanuja Ganu and Kalika Bali

Data Augmentation for Inline Tag-Aware Neural Machine Translation
Yonghyun Ryu, Yoonjung Choi and Sangha Kim

Wednesday, December 7, 2022 (continued)

12:40 - 14:00	*Lunch Break*
14:00 - 15:30	*Session 7 — Invited Talk by Ondrej Bojar*

Thursday, December 8, 2022

09:00 - 09:10 *Session 5 — Shared Task Overview Papers II*

Findings of the WMT 2022 Biomedical Translation Shared Task: Monolingual Clinical Case Reports
Mariana Neves, Antonio Jimeno Yepes, Amy Siu, Roland Roller, Philippe Thomas, Maika Vicente Navarro, Lana Yeganova, Dina Wiemann, Giorgio Maria Di Nunzio, Federica Vezzani, Christel Gerardin, Rachel Bawden, Darryl Johan Estrada, Salvador Lima-lopez, Eulalia Farre-maduel, Martin Krallinger, Cristian Grozea and Aurelie Neveol

Findings of the WMT 2022 Shared Task on Chat Translation
Ana C Farinha, M. Amin Farajian, Marianna Buchicchio, Patrick Fernandes, José G. C. De Souza, Helena Moniz and André F. T. Martins

Findings of the First WMT Shared Task on Sign Language Translation (WMT-SLT22)
Mathias Müller, Sarah Ebling, Eleftherios Avramidis, Alessia Battisti, Michèle Berger, Richard Bowden, Annelies Braffort, Necati Cihan Camgöz, Cristina España-bonet, Roman Grundkiewicz, Zifan Jiang, Oscar Koller, Amit Moryossef, Regula Perrollaz, Sabine Reinhard, Annette Rios, Dimitar Shterionov, Sandra Sidler-miserez and Katja Tissi

Findings of the WMT'22 Shared Task on Large-Scale Machine Translation Evaluation for African Languages
David Adelani, Md Mahfuz Ibn Alam, Antonios Anastasopoulos, Akshita Bhagia, Marta R. Costa-jussà, Jesse Dodge, Fahim Faisal, Christian Federmann, Natalia Fedorova, Francisco Guzmán, Sergey Koshelev, Jean Maillard, Vukosi Marivate, Jonathan Mbuya, Alexandre Mourachko, Safiyyah Saleem, Holger Schwenk and Guillaume Wenzek

Findings of the WMT 2022 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT
Marion Weller-di Marco and Alexander Fraser

Overview and Results of MixMT Shared-Task at WMT 2022
Vivek Srivastava and Mayank Singh

Findings of the Word-Level AutoCompletion Shared Task in WMT 2022
Francisco Casacuberta, George Foster, Guoping Huang, Philipp Koehn, Geza Kovacs, Lemao Liu, Shuming Shi, Taro Watanabe and Chengqing Zong

Findings of the WMT 2022 Shared Task on Translation Suggestion
Zhen Yang, Fandong Meng, Yingxue Zhang, Ernan Li and Jie Zhou

10:30 - 11:00 *Coffee Break*

15:30 - 16:00 *Coffee Break*

16:00 - 17:30 *Session 8 — Shared Task Sytem Description Papers II*

16:00 - 17:30 *Biomedical Translation Task*

The SPECTRANS System Description for the WMT22 Biomedical Task
Nicolas Ballier, Jean-baptiste Yunès, Guillaume Wisniewski, Lichao Zhu and Maria Zimina

SRT's Neural Machine Translation System for WMT22 Biomedical Translation Task
Yoonjung Choi, Jiho Shin, Yonghyun Ryu and Sangha Kim

Examining Large Pre-Trained Language Models for Machine Translation: What You Don't Know about It
Lifeng Han, Gleb Erofeev, Irina Sorokina, Serge Gladkoff and Goran Nenadic

Summer: WeChat Neural Machine Translation Systems for the WMT22 Biomedical Translation Task
Ernan Li, Fandong Meng and Jie Zhou

Optum's Submission to WMT22 Biomedical Translation Tasks
Sahil Manchanda and Saurabh Bhagwat

Huawei BabelTar NMT at WMT22 Biomedical Translation Task: How We Further Improve Domain-specific NMT
Weixuan Wang, Xupeng Meng, Suqing Yan, Ye Tian and Wei Peng

HW-TSC Translation Systems for the WMT22 Biomedical Translation Task
Zhanglin Wu, Jinlong Yang, Zhiqiang Rao, Zhengzhe Yu, Daimeng Wei, Xiaoyu Chen, Zongyao Li, Hengchao Shang, Shaojun Li, Ming Zhu, Yuanchang Luo, Yuhao Xie, Miaomiao Ma, Ting Zhu, Lizhi Lei, Song Peng, Hao Yang and Ying Qin

16:00 - 17:30 *Chat Translation Task*

Unbabel-IST at the WMT Chat Translation Shared Task
João Alves, Pedro Henrique Martins, José G. C. De Souza, M. Amin Farajian and André F. T. Martins

Investigating Effectiveness of Multi-Encoder for Conversational Neural Machine Translation
Baban Gain, Ramakrishna Appicharla, Soumya Chennabasavaraj, Nikesh Garera, Asif Ekbal and Muthusamy Chelliah

BJTU-WeChat's Systems for the WMT22 Chat Translation Task
Yunlong Liang, Fandong Meng, Jinan Xu, Yufeng Chen and Jie Zhou

Thursday, December 8, 2022 (continued)

HW-TSC Translation Systems for the WMT22 Chat Translation Task
Jinlong Yang, Zongyao Li, Daimeng Wei, Hengchao Shang, Xiaoyu Chen, Zhengzhe Yu, Zhiqiang Rao, Shaojun Li, Zhanglin Wu, Yuhao Xie, Yuanchang Luo, Ting Zhu, Yanqing Zhao, Lizhi Lei, Hao Yang and Ying Qin

16:00 - 17:30 *Sign Language Translation Task*

Clean Text and Full-Body Transformer: Microsoft's Submission to the WMT22 Shared Task on Sign Language Translation
Subhadeep Dey, Abhilash Pal, Cyrine Chaabani and Oscar Koller

Spatio-temporal Sign Language Representation and Translation
Yasser Hamidullah, Josef Van Genabith and Cristina España-bonet

Experimental Machine Translation of the Swiss German Sign Language via 3D Augmentation of Body Keypoints
Lorenz Hufe and Eleftherios Avramidis

TTIC's WMT-SLT 22 Sign Language Translation System
Bowen Shi, Diane Brentari, Gregory Shakhnarovich and Karen Livescu

Tackling Low-Resourced Sign Language Translation: UPC at WMT-SLT 22
Laia Tarres, Gerard I. Gállego, Xavier Giro-i-nieto and Jordi Torres

16:00 - 17:30 *African Languages Translation Task*

Separating Grains from the Chaff: Using Data Filtering to Improve Multilingual Translation for Low-Resourced African Languages
Idris Abdulmumin, Michael Beukman, Jesujoba Alabi, Chris Chinenye Emezue, Everlyn Chimoto, Tosin Adewumi, Shamsuddeen Muhammad, Mofetoluwa Adeyemi, Oreen Yousuf, Sahib Singh and Tajuddeen Gwadabe

Language Adapters for Large-Scale MT: The GMU System for the WMT 2022 Large-Scale Machine Translation Evaluation for African Languages Shared Task
Md Mahfuz Ibn Alam and Antonios Anastasopoulos

Samsung Research Philippines - Datasaur AI's Submission for the WMT22 Large Scale Multilingual Translation Task
Jan Christian Blaise Cruz and Lintang Sutawika

University of Cape Town's WMT22 System: Multilingual Machine Translation for Southern African Languages
Khalid Elmadani, Francois Meyer and Jan Buys

Abstract

This paper presents the results of the General Machine Translation Task organised as part of the Conference on Machine Translation (WMT) 2022. In the general MT task, participants were asked to build machine translation systems for any of 11 language pairs, to be evaluated on test sets consisting of four different domains. We evaluate system outputs with human annotators using two different techniques: reference-based direct assessment and (DA) and a combination of DA and scalar quality metric (DA+SQM).

1 Introduction

The Seventh Conference on Machine Translation (WMT22)[1] was held online with EMNLP 2022 and hosted a number of shared tasks on various aspects of machine translation. This conference built on 15 previous editions of WMT as workshops and conferences (Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Bojar et al., 2013, 2014, 2015, 2016, 2017, 2018; Barrault et al., 2019, 2020; Akhbardeh et al., 2021).

For more than a decade, the machine translation (MT) community has focused on the news domain, which has many desirable features for MT evaluation, such as sufficiently long and grammatically correct sentences that are easy for both professionals to translate (to produce references) and for human raters to evaluate without specific in-domain knowledge. However, with recent advances in MT and potential overfitting on the news domain (with methods such as fine-tuning on past WMT testsets), we decided to open a fresh research direction of testing the "General Machine Translation" capabilities.

How to test general MT capabilities is a research question in itself. Countless phenomena could be evaluated, the most important being:

- various domains (news, medicine, IT, patents, legal, social, gaming, etc.)
- style of text (formal or spoken language, fiction, technical reports, etc.)
- noisy or robust user-generated content (grammatical errors, code-switching, abbreviations, etc.)

Evaluating all possible phenomena is near impossible and creates many unforeseen problems. Therefore, we decided to simplify the problem and start with an evaluation of different domains. We select the following four domains: news, e-commerce, social, and conversational, chosen to represent various topics with different content

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1 - 45
December 7-8, 2022 ©2022 Association for Computational Linguistics

styles. Additionally, these domains are understandable for humans without special in-domain knowledge, thus not requiring specialized translators or human raters for evaluation.

Another significant change for this year is the redesign of our human evaluation procedure for English→X and non-English language pairs. We introduce SQM-style DA rating, improved sampling of sentences for human judgements, and we opt in for using professional raters.

In addition to language pairs evaluated yearly, we introduce several new language pairs that have never been evaluated at WMT or other venues: Ukrainian↔English, Ukrainian↔Czech, Livonian↔English, Yakut↔Russian and English→Croatian.

Lastly, with multiple different shared tasks run at WMT evaluating different phenomena over the same language pairs, we proposed to aggregate test sets and ask participants of different shared tasks to also translate test sets from other shared tasks (for shared language pairs), allowing cross-task evaluation of systems on various phenomena. More details are in Section 4.2.

General MT task submissions and human judgements are available at `https://github.com/wmt-conference/wmt22-news-systems`. The interactive visualization and comparison of differences between systems is at `http://wmt.ufal.cz` using MT-ComparEval (Sudarikov et al., 2016).

The structure of the findings is as follows. We describe process of collecting, cleaning and translating of test sets in Section 2 followed by summary of allowed training data for constrained track Section 3. We list all submitted systems in Section 4. We use two different techniques for human evaluation. Reference-based DA is used to evaluate languages into English and described in Section 5. DA+SQM technique used for non-English and from English translation directions is described in Section 6. In Section 7, we describe our analysis of English→Croatian, translation direction containing professional and student produced references. We conclude the findings in Section 8.

2 Test Data

In this section, we describe the process of collecting data in Section 2.1, followed by the explanation of preprocessing steps in Section 2.2. Producing human references is summarized in Section 2.3 and test set analysis is conducted in Section 2.5. Lastly, Section 2.4 describes specific language pairs that are prepared differently.

2.1 Collecting test data

As in the news shared tasks in previous years, the test sets consist of unseen translations prepared specially for the task. However, in contrast, we introduce several domains instead of only the news domain. The test sets are publicly released to be used as translation benchmarks. Here we describe the production and composition of the test sets.

With the new direction towards testing general MT capabilities, we redesign the content of the test sets. We decided to collect data from four domains (news, social, e-commerce, and conversation). For all language pairs, we aimed for a test set size of 2000 sentences and to ensure that the test sets were "source-original", namely that the source text is written in the source language, and the target text is the human translation. This is to avoid "translationese" effects on the source language, which can have a detrimental impact on the accuracy of evaluation (Freitag et al., 2019; Läubli et al., 2020; Graham et al., 2020). We collected roughly the same number of sentences (around 500 sentences with document context) for each domain. For some languages, we could not locate high-quality data and therefore selected more sentences from other domains.

News domain - This domain contains data prepared in the same way as in previous years (Akhbardeh et al., 2021). We collect news articles from the second half of 2021 extracted from online news sites, keeping document information. The news domain is mainly of the highest quality.

Social domain - For most languages (Czech, English, French, German, and Japanese), we extract data from public Reddit discussions, keeping separate posts as a single document. We target subreddits that come from countries speaking a given language. We remove all posts marked by Reddit as inappropriate.

We use different data source for Chinese and Russian social domain as there is not enough Reddit content. For Chinese, we collected posts from various social media webpages used in China, a list provided by our Chinese colleague. For Russian, we took data from Zen, one of the most popular blog platforms among Russian-speaking users.

E-commerce domain - Contains product descriptions donated by individual companies.

			#segments			
Source / Domain	conversation	ecommerce	news	social	other	total
Chinese	349	518	505	503	-	1875
Czech	-	-	957	491	-	1448
Czech (to Ukrainian)	-	-	-	-	1930	1930
English	484	530	511	512	-	2037
English (to Croatian)	-	1015	656	-	-	1671
French	501	524	504	477	-	2006
German	462	501	506	515	-	1984
Japanese	502	503	505	498	-	2008
Livonian	-	-	-	-	420	420
Russian	-	508	1004	-	504	2016
Russian (to Yakut)	-	-	-	-	1123.0	1123
Ukrainian	-	-	-	-	2018	2018
Ukrainian (to Czech)	-	-	-	-	2812	2812
Yakut	-	-	-	-	1123	1123

Table 1: Number of segments for individual source languages used in the general translation test sets.

For Japanese e-commerce domain, we used search advertising text ads provided by an advertising company with their client's prior consent. Defining documents and sentences in search ads is tricky. Clients define multiple titles and multiple descriptions, called assets. We defined a document as the longest possible combination of assets. We also defined a sentence as either an asset or a unit separated by sentence-ending punctuations within an asset. Since the diversity of Japanese ad sentences is small, we chose the test sentences greedily to minimize the test set's self-BLEU.

Conversational domain - data for English, German, French, and Chinese are provided by the Chat Shared Task organizers (Farinha et al., 2022). These data contain a discussion between an agent, talking in English, and a customer, each of them talking in a different language. To avoid the effects of translationese, we split conversations into individual messages and handled each as a separate document, only using messages written in the original language (therefore, the English side only contains messages from agents) resulting in often short documents.

For Japanese conversational domain, We used question-answer pairs from a community question-answering website, *Oshiete!goo*[2]. The operator provided us with a dump as of March 2022. Topics are diverse, ranging from life advice to entertainment. Since there were usually many answers to a question, we extracted question-answer pairs whose answers were marked as the best answer. We considered a question-answer pair as a document and randomly sampled test data from question-answer pairs with a total length of 180 characters or fewer. We did not indicate the boundary between them.

After collecting all data, we applied several steps to filter out documents of lower-quality, see Section 2.2. Specifically paying attention to short documents. Whenever we had enough data, we removed the shortest documents, usually a single or two sentences. We advised linguists who were checking the data to further remove short documents. This helped us to add document context to the test set.

2.2 Human preprocessing of test data

In the News task of previous years, we asked humans to check collected data and carry out minor corrections (mainly checking sentence splits and discarding similar or repeated content), which was sufficient for the news domain because is often clean and without serious problems. However, with the expansion towards general MT, we run into an issue of source data being noisier and not well formatted that needs to be handled before translation.

Although testing of robustness of MT is an important task, the noisy data introduces problems for human translators and annotators. Therefore, we decided to discard data that are considered too noisy. Furthermore, publicly available data often contains inappropriate content, which can stress either human translators or human annotators, leading to a decrease in the quality (for example, translators refuse to translate political content considered censored in their countries).

Therefore, the source data for test sets[3] goes

[2] https://oshiete.goo.ne.jp

[3] Except for sources from the following translation directions: English→Croatian, Livonian↔English, Yakut↔Russian, Ukrainian→English, Ukrainian↔Czech. Data for these directions have been checked differently and should not contain noisy or inappropriate content.

through human validation checks involving linguists discarding inappropriate content altogether or carrying out minor textual corrections to the data. You can find the linguistic brief for prepossessing in Appendix C.

2.3 Test set translation

The translation of the test sets was performed by professional translation agencies, according to the brief in Appendix D. Different partners sponsored each language pair and various translation agencies were therefore used, which may affect the quality of the translation. The exception is that Chinese↔English, German↔English, Ukrainian↔English and reference-B for Czech↔English were translated by the same agency. These languages also received a special treatment of being translated by one translator and checked by a second different translator.

Several language pairs received special attention. For Chinese↔English, Czech↔English, German↔English, and English→Croatian, we obtained a second reference in each direction from different translators.

For Czech↔English, our partner paid professional agency to provide high-quality translations. However, as it turned out, the quality is rather low. We fixed manually the reference with grammar correction tools, however, that isn't sufficient. We provide this reference as reference–C. There is no issue with reference-B as that was provided by different partner.

Human translations would not be possible without the sponsorship of our partners. We are thankful for the support from: Microsoft, Charles University, LinguaCustodia, NTT, Dublin City University, Google, and Phrase.

2.4 Language pairs prepared differently

English→Croatian The English-Croatian test data is a sub-corpus of the DiHuTra corpus[4] (Lapshinova-Koltunski et al., 2022). The English source texts include Amazon product reviews and news articles. The document information is available for both domains.

The *reviews* were selected from the publicly available **Amazon product reviews**[5,6] containing reviews divided into 24 categories (topics). The selected corpus covers fourteen categories, paying attention to the data balance: an equal number of positive and negative reviews and a balanced distribution of categories (topics). In total, 196 reviews (1015 sentences) were included, fourteen from each of the fourteen selected topics: 'Beauty', 'Books', 'CDs and Vinyl', 'Cell Phones and Accessories', 'Grocery and Gourmet Food', 'Health and Personal Care', 'Home and Kitchen', 'Movies and TV', 'Musical Instruments', 'Patio, Lawn and Garden', 'Pet Supplies', 'Sports and Outdoors', 'Toys and Games' and 'Video Games'.

The *news articles* were selected from the News test corpus of the WMT (2019 and 2020) shared task.[7] In total, 68 news articles (656 sentences) from different sources are included.

These English texts were then translated into Croatian by professional translators and by translation students, thus providing two reference translations. Both professional and student translations were produced in cooperation with the University of Zagreb and the University of Rijeka in Croatia. In total, four professional translators and twenty translation students participated, all native speakers of Croatian and fluent in English. Translation experience of professional translators ranges between five and ten years, while for students the range is from zero to five years, the majority being in the range between two and four years. The two students who indicated no experience (zero years) also indicated that they had no real professional experience yet, only work in the framework of their studies. All students were in their first or second year of master's studies.

The translators were asked too keep the sentence (segment) alignment (not to merge or to split segments so that each English segment corresponds to one translated segment) and not to use any kind of machine translation in the process. No further restrictions were given to the translators.

Yakut↔Russian Source texts for Yakut↔Russian translation were selected from Ulus media, which is Yakutia's official news aggregator. The majority of the data are local news.[8] The professional translators were asked to translate 42 news texts for the test set. Yakut is one of the minor languages spoken by around

[8] https://ulus.media/

450,000 native speakers. It is one of the official languages of Sakha (Yakutia), a federal republic in the Russian Federation.

Livonian↔English The source language for Livonian↔English was English, since the amount of Livonian monolingual and parallel data is severely limited. The source texts were selected from various news articles published in 2022; politically neutral topics were selected. One addition to the set was the text describing the addition of WMT'22 Livonian↔English shared task itself. Translations were done by two professionals. Livonian is a critically endangered language spoken in Latvia but belonging to the Finno-ugric language family. Its last native speaker passed in 2013 and currently there are about 20 near-native speakers; however, there is an Institute of the Livonian Language at the University of Latvia that leads efforts on collecting and preserving Livonian texts as well as other materials (audio, video, hand-written, etc).

Ukrainian↔Czech and Ukrainian→English Source texts for Ukrainian↔Czech and Ukrainian→English translation were selected from the inputs collected through the Charles Translator for Ukraine.[9] Charles Translator for Ukraine is an online translation service that has been developed by the team from the Charles University, Prague[10] as a response to the wave of Ukrainian refugees coming to the Czech Republic after the 2022 Russian invasion of Ukraine.[11] The service is powered by a model trained with Block Backtranslation (Popel et al., 2020b). With users' consent, the service can log their inputs for the purpose of creating a dataset of real use cases. The datasets are extracted from the inputs collected in March and April 2022.

After automatic filtering,[12] we asked linguistically-educated annotators to filter and preprocess the source data manually. The filtering aimed at obtaining a data sample with diverse examples. The preprocessing was performed according to the brief in Appendix C with the following modifications. First, as the content is closely related to the war, someone may always find it polarizing or controversial. We did not filter out texts based on this criterion. Second, we asked the annotators not to delete or fix noisy inputs as long as they are comprehensible. This concerns, for instance, errors in casing, punctuation, diacritics, grammar and typos. Furthermore, all emojis are kept. Third, our annotators were instructed to join multiple related sentences to the same line whenever they found them too short compared to the rest of the dataset. The dataset thus does not satisfy the rule that each line contains a single sentence. Finally, any personal data related to people other than well-known people was pseudonymized.

The user inputs cover three broader domains: (1) personal communication, (2) news, and (3) formal communication. Our annotators assigned these categories (often accompanied by a finer subcategory) to every data example. If none of the above categories fit, they labeled the example with the "other" tag.

The source texts were translated by professional translation agencies principally following the brief in Appendix D. A sample of translated sentences were checked by native speakers of the target language. It revealed that post-edited MT had allegedly been used for parts of the Ukrainian→Czech test set, although this was denied by the translator. Therefore, we decided to add additional data to the test set for this direction translated by a different translation agency. This extra data consists of about 600 segments downloaded from the web (news, example CV) and about 200 segments from the Charles Translator inputs logs. It was pre-processed similarly as described above except for the domain annotation (all segments have the "unknown" tag assigned).

2.5 Test set analysis

As described previously, the aim was for the test sets to be composed of approximately 500 sentences per domain, although this depended on the language pair. The number of segments for each domain (including unspecified domain 'other') is given in Table 1 per source language, with the target language being specified where the composition differs. All four domains are available for Chinese, English, French, German and Japanese source texts, whereas only certain domains are available

[9] http://translate.cuni.cz

[10] http://ufal.mff.cuni.cz/u4u

[11] At that time, the most popular online MT services either did not support translation between Czech and Ukrainian (e.g. DeepL) or they seemed to pivot the translation for the language pair via English (e.g. Google Translate, Microsoft Translator).

[12] This includes the removal of intermediate inputs, HTML-tagged inputs, inputs identified as written in a language other than the source language, and backtranslated inputs.

for Czech, Russian and English into Croatian.

Document context Document context is available for most language pairs (the exception being Livonian↔English). The length of documents varies considerably by domain but also by language pair. As can be see in Table 2, e-commerce documents tend to be longest, followed by news and social (together), with conversational documents being shortest, although this does not hold for all languages. For example, the Ukrainian test set has short documents (2.28 segments on average), whereas Yakut↔Russian has very long ones (26.12 segments on average).

Lexical diversity We can compare the type-token ratio (TTR) to get an idea of the relative lexical diversity of (i) domains and (ii) original vs. translated sentences.[13],[14] Raw TTRs for each language pair and domain are given in Table 28 in Appendix E. Regarding domains, the TTR is generally lowest for conversations, whereas e-commerce and news are most diverse, followed by social. Translated texts appear to show a lower lexical diversity than original texts. If we look at the ratio between the TTRs of a language A and a language B (i.e. the diversity of A with respect to B), this ratio is higher when A is the source and B the target than when B is the source and A the target. For example, given the language pair Czech↔English, the ratio of the TTRs of Czech and English (i.e. $\frac{\text{TTR}_{\text{cs}}}{\text{TTR}_{\text{en}}}$ is higher when Czech is the original text and lower when it is the translation. This can be seen in Table 3 comparing for individual domains.

Anonymisation One characteristic that stands out is the presence of placeholders for anonymised elements in the conversation and social domains. There are a total of 17 difference placeholders, indicated by the entity type surrounded by #, e.g. #NAME#, #EMAIL#, #Product1#, #Product2#, etc. The entities are identical in the reference translation (where there is a direct translation), rather than the entity being translated (e.g. #NAME# and not #NOM# for French). Manual corrections were carried out to homogenise variants in terms of capitals, space issues and placeholders that were translated rather than copied by the professional translators.

Translation quality As mentioned previously, the quality of the human references differed according to the agency used. A few translations were erroneous due to problems with anonymisation, where some overzealous anonymisation added entity tags within non-entity words, therefore making the source sentence non-sensical. However this affected only one or two sentences, and some minor corrections were introduced. There were some particular problems with the quality of Czech→English translations, including wrong quote marks, grammatical and spelling mistakes and unnatural translations as mentioned in Section 2.3.

3 Training Data

Similar to previous years, we provide a selection of parallel and monolingual corpora for model training. The provenance and statistics of the selected parallel datasets are provided in Appendix in Table 20 and Table 19. Specifically, our parallel data selection include large multilingual corpora such as Europarl-v10 (Koehn, 2005), Paracrawl-v9 (Bañón et al., 2020), CommonCrawl, NewsCommentary-v16, WikiTitles-v3, WikiMatrix (Schwenk et al., 2021), TildeCorpus (Rozis and Skadiņš, 2017), OPUS (Tiedemann, 2012), UN Parallel Corpus (Ziemski et al., 2016), and language specific corpora such as CzEng-v2.0 (Kocmi et al., 2020), YandexCorpus,[15] ELRC EU Acts, YakutCorpus [16], JParaCrawl (Morishita et al., 2020), Japanese-English Subtitle Corpus (Pryzant et al., 2018), Livonian multiparallel corpus Liv4ever (Rikters et al., 2022),[17] KFTT(Neubig, 2011), TED (Cettolo et al., 2012), CCMT, and back-translated news. Similar to previous years, we provided links to these datasets on the task web page.[18] However, new to this year, we automate the data preparation pipeline using a tool named MTDATA (Gowda et al., 2021).[19] MTDATA downloads all available datasets, except

[13] The TTR is the ratio of unique tokens to total tokens, and it is higher the diverse the vocabulary of a text is. It is dependent on the morphological complexity of a language, but can also vary due to other factors.

[14] Texts are tokenised using the language-specific Spacy models (Honnibal and Montani, 2017) where available. For Czech, Livonian and Yakut, for which Spacy models are not available, we took as a rough approximation models for Croatian, Finnish and Russian respectively.

Table 3: For each language pair A–B, the ratio of the TTRs of A and B, for the A→B test set (→; i.e. A is the original text) and for the B→A test set (←, i.e. A is the translated text).

the two which required user authentication: CCMT and CzEng-v2.0.

4 System submissions

In 2022, we received a total of 107 primary submissions[20] and 82 online systems. The participating institutions are listed in Table 4 and detailed in the rest of this section. Each system did not necessarily appear in all translation tasks. We also included online MT systems (originating from 5 services), which we anonymized as ONLINE-A,B,G,W,Y. All submissions, sources and references are made available via github.

For presentation of the results, systems are treated as either constrained or unconstrained. When the system submitters report that they were only trained on our provided data, we class them as constrained. The online systems are treated as unconstrained during the automatic and human evaluations, since we do not know how they were built. In Appendix F, we provide brief details of the submitted systems, for those where the authors provided such details.

4.1 OCELoT

To collect submissions, we used the open-source OCELoT platform[21] again, which provides anonymized public leaderboards for several WMT22 shared tasks.[22] Similarly to the setup from the previous year, only registered and verified teams with correct contact information were allowed to submit their system outputs and each

[20] GTCOM was removed from human evaluation, however, we calculate automatic scores in Appendix G.

Table 4: Participants in the shared translation task. The translations from the online systems were not submitted by their respective companies but were obtained by us, and are therefore anonymized in a fashion consistent with previous years of the workshop.

verified team was limited to 7 submissions per test set. Submissions on leaderboards with BLEU and CHRF scores from SacreBLEU (Post, 2018) were displayed anonymously to avoid publishing rankings based on automatic scores during the submission period. Until one week after the submission period, teams could select a single primary submission per test set, specify if the primary submission followed a constrained or unconstrained setting, and submit a system description paper abstract. All entries were mandatory for a system submission to be included in the human evaluation campaign.

OCELoT has helped to simplify the submission process—from collecting submissions to gathering system information—and it supported the multi-domain shift introduced in the general task this year. The platform was also used for the Biomedical Shared Task (Neves et al., 2022). This made it easier to include the biomedical test set as another domain data in the test sets of the general task for languages that overlapped between the two tasks, which made it possible to collect outputs from the general domain systems for the biomedical domain.

4.2 Collaboration across WMT shared tasks

There are various shared tasks at WMT evaluating same language pairs but with different participants. This leads into inability to compare systems specialized for a particular task with participants of other tasks.

Therefore, we decided to open a collaboration across WMT shared tasks by asking participants to translate test sets from other shared tasks as well. This open the possibility to see how general MT systems compete for example in biomedical domain, or what is the general translation quality of specialized systems.

We set up a collaboration with Biomedical Shared Task (Neves et al., 2022) on all shared language pairs (Chinese-English, German-English, Russian-English).

This effort did not increase the number of participants for General MT Task because all participants of Biomedical Shared Task also participated in General MT. However, other participants of General MT have been evaluated on biomedical domain, too. For details, see Neves et al. (2022).

Language Pair	Sys.	Assess.	Assess/Sys
Czech→English	12	20,094	1,674.5

Table 6: Number of crowd-sourced workers taking part in the reference-based SR+DC campaign; (A) those whose scores for bad reference items were significantly lower than corresponding MT outputs; those of (A) whose scores also showed no significant difference for exact repeats of the same translation; note: many workers evaluated more than one language pair.

5 Human Evaluation of Translation into English

As in previous years, reference-based Direct Assessment (DA, Graham et al., 2013, 2014, 2016) was employed as the primary method of evaluation for translation into English. DA human evaluation has several important features including accurate quality control of crowd-sourcing and standard methods of significance testing differences in ratings for systems. Human assessors are asked to rate a given translation by how adequately it expresses the meaning of the corresponding reference translation or source language input on an analogue scale, which corresponds to an underlying absolute 0–100 rating scale.[23] Direct Assessment is also employed for evaluation of video captioning systems at TRECvid (Graham et al., 2018; Awad et al., 2019) and multilingual surface realisation (Mille et al., 2018, 2019, 2020).

For evaluation of translation into-English, we

[23] No sentence or document length restriction is applied during manual evaluation.

use the monolingual configuration of DA, where the human evaluator reads and rates the system output translation and compares its meaning to an English reference translation, which was manually translated by a human translator. As recommended in Graham et al. (2020), we only employ forward-created test data to avoid potential bias. Since evaluating segments without their context (i.e. the surrounding document) can cause further bias (Läubli et al., 2018; Toral et al., 2018), we evaluate sentences in turn taken from a single document and system (described as "SR+DC" in previous WMT reports).[24] Similarly to last year, for all language pairs for which document context was available, we include it when evaluating translations. Note that the ratings are nevertheless collected on the segment level, motivated by the power analysis described in Graham et al. (2020), as well as better inter-annotator agreement and lower effort described in Castilho (2020).

In terms of the manual evaluation for the translation task for into-English language pairs, a total of 428 Turker accounts were involved.[25] 510,451 translation assessment scores were submitted in total by the crowd, of which 187,922 were provided by workers who passed quality control.[26]

System rankings are produced from a large set of human assessments of translations, each of which indicates the absolute quality of the output of a system. Table 5 shows total numbers of human assessments collected in WMT22 for into-English language pairs contributing to final scores for systems.[27]

Quality control was carried out exactly as described in last year's WMT for crowd-sourcing into-English translation assessments on Amazon Mechanical Turk (see Akhbardeh et al. (2021) for full details). Table 6 shows results of workers who passed quality control (by showing significant differences in scores attributed to translations of known to be of distinct qualities) and numbers of workers who also showed no significant difference for ratings of identical pairs of translations judged separately in repeat tests. Data from the non-reliable workers in all language pairs were removed prior to calculation of results.

Similar to last year, all rankings for to-English translation were reached through segment ratings presented one at a time in their original document order (SR+DC). As is usual with DA assessments, human assessment scores for translations were first standardized according to each individual human assessor's overall mean and standard deviation score. Average standardized scores for individual segments belonging to a given system were then computed, before the final overall DA score for a given system is computed as the average of its segment scores (Ave z in Table 7). Results are also reported for average scores for systems, computed in the same way but without any score standardization applied (Ave % in Table 7).

Human performance estimates calculated through the evaluation of human-produced reference translations are denoted by "HUMAN" in all tables. Translations HUMAN-C in Czech→English are known to be of lower quality than usual for manual translations.

Clusters are identified by grouping systems together according to which systems significantly outperform all others in lower ranking clusters, according to Wilcoxon rank-sum test.

All data collected during the human evaluation is available at `http://www.statmt.org/wmt22/results.html`. Appendix B shows the official results for the underlying head-to-head significance test for all pairs of systems.

6 Human Evaluation of Translation out of English and without English

Human evaluation for out-of-English and non-English translation directions[28] was performed with source-based ("bilingual") direct assessment of individual segments in context similar to the approach described in Akhbardeh et al. (2021). We use open-source framework Appraise for the evaluation (Federmann, 2018).

This year, several changes were made to the annotation procedure, the data sampling, and the interface display. In contrast to the standard DA (sliding scale from 0-100) used in 2021, this year annotators performed DA+SQM (Direct Assessment + Scalar Quality Metric). In DA+SQM, the annotators still provide a raw score between 0 and 100, but also

[24] The implementation still has the limitation that the assessors cannot go back to the previous segment.

[25] Numbers do not include the 988 workers on Mechanical Turk who did not pass quality control.

[26] Both numbers include quality control segments.

[27] Number of systems for WMT22 includes "human" systems comprising human-generated reference translations used to provide human performance estimates.

[28] We decided not to run human evaluation for French↔German due to the small number of system submissions this year.

Table 7: Official results of WMT22 General Translation Task for translation into-English (SR+DC). Systems ordered by DA score z-score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$; rank ranges are based on the same test; grayed entry indicates resources that fall outside the constraints provided.

are presented with seven labeled tick marks, as visible in Figure 1. Discrete SQM (0-6) was found to correlate well with MQM (Multidimensional Quality Metrics) annotations by Freitag et al. (2021), while internal preliminary experiments suggested that DA+SQM helps to stabilize scores across annotators (as compared to DA). Annotators performing DA+SQM annotations at IWSLT 2022 human evaluation campaign (Anastasopoulos et al., 2022) also provided positive feedback about the annotation format. In previous years, full documents were sampled for annotation. This year we sampled a maximum of 10 consecutive segments from a document (a document "snippet") for annotation. This provides the potential to annotate segments from a more diverse range of documents while still maintaining a similar number of total annotations. Up to 10 source segments preceding and following the snippet being evaluated are displayed as static extra context for the annotator in the interface, as presented in Figure 1. As in past years, annotators provide both segment-level scores and document-level scores (in this case it is more accurate to call them snippet-level scores), however only the segment-level scores were used to compute the official rankings. As the English–Livonian data was not document-level, those annotations are run with segment-level-only DA+SQM. HITs (using the Amazon terminology of "Human Intelligence Task" to describe an annotation task) contained quality control segments, as described in Section 6.2. Rankings are computed as described in Section 6.4 based on segment-level scores.

6.1 Human Annotators

All annotations in the bilingual human evaluation campaign were carried out by hired professional annotators. This year, for the first time, we did not ask participants of the general task to contribute to human evaluation, but instead made it voluntary. The main motivations for this change were the attempt to increase the reliability and consistency of the judgements and the immense amount of time that was needed to be devoted to the process of collecting annotations from participating teams. Annotations for different language pairs were provided by different parties with their pool of annotators of distinct profiles as summarized in Table 8.

Charles University provided annotators for language pairs involving the Czech language, i.e. English→Czech and Ukrainian↔Czech. Their annotators were linguists, translators, researchers and students who are native speakers of the target language[29] with high proficiency in the source language.

University of Tartu provided the annotations for Livonian↔English, with 15% of the Livonian-speaking population participating in the annotation efforts. All three participants were near-native speakers of Livonian and participated in source-based Livonian-English and English-Livonian annotations, as well as reference-based Livonian annotation.

The second annotator group was provided by Toloka AI,[30] who collected annotations for English→Russian and Russian↔Yakut. Toloka AI is a global data labeling company that helps its customers to generate machine learning data at scale by harnessing the wisdom of the crowd from around the world. It relies on a geographically diverse crowd of several million registered users[31] (Pavlichenko et al., 2021). Toloka tests proficiency of their annotator crowd and excludes from future annotations anyone who does not pass quality control in the Appraise tool.

The last part of annotations was sponsored by Microsoft, who contributed with their pool of qualified paid bilingual speakers experienced in the MT evaluation process. Microsoft provided annotations for English into Chinese, Croatian, German, and Japanese, as well as Chinese→English as a comparison for reference-based evaluation described above and MQM evaluated in Metrics shared task (Freitag et al., 2022). For this pool of annotators, their performance is tracked over time, and those who fail quality control are permanently removed from the pool. This process increases the overall quality of the human assessment.

6.2 Sampling and Quality Control

In past WMT annotations, document-system pairs were sampled randomly for annotation, resulting in different subsets of the test set being annotated for each system. This year we first randomly sample a subset of document snippets from each of the domains for annotations, sampling the domains

[29] Some of Ukrainian→Czech annotators were not native Czechs, but native Ukrainians with near-native knowledge of Czech.

WMT22TolokaA #864:Document #ecommerce_en_13#3-13-0

English → Ukrainian (українська)

Below you see a document with 11 sentences in English (left columns) and their corresponding candidate translations in Ukrainian (українська) (right columns). Score each candidate sentence translation in the document context. You may revisit already scored sentences and update their scores at any time by clicking at a source text.

Assess the translation quality on a continuous scale using the quality levels described as follows:

0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Grammar is irrelevant.
2: Some meaning preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Grammar may be poor.
4: Most meaning preserved and few grammar mistakes: The translation retains most of the meaning of the source. It may have some grammar mistakes or minor contextual inconsistencies.
6: Perfect meaning and grammar: The meaning of the translation is completely consistent with the source and the surrounding context (if applicable). The grammar is also correct.

Plus Muscle Maintenance to support muscular structure and activity Joint Aid for Dogs is a high specification joint and muscle supplement with glucosamine for dogs, designed to aid freedom of movement. *- Additional source context*	*Plus Muscle Maintenance для підтримки м'язової структури та діяльності Joint Aid for Dogs – це високоякісна собача добавка для суглобів та м'язів із глюкозаміном, розроблена для сприяння свободі рухів.* *- Additional target context*
Joint Aid for Dogs can be fed to all dogs from any age at the 'General Support' level to maintain freedom of movement and muscle condition throughout their lives.	**Joint Aid for Dogs можна давати всім собакам будь-якого віку з метою загальної підтримки свободи рухів та стану м'язів протягом усього життя.**
For elderly and working dogs or those showing reduced muscle mass, Joint Aid for Dogs is recommended to be fed at the 'Full Support' level.	**Для старих та працюючих собак, а також собак із зниженою м'язовою масою Joint Aid for Dogs рекомендується в якості повної підтримки.**
What are the key benefits of using Joint Aid for Dogs?	**Які основні переваги використання Joint Aid for Dogs?**
-Maintains flexibility of movement in all working and pet dogs regardless of age, size and level of exercise.	**- Підтримує свободу рухів у всіх працюючих та домашніх собак незалежно від віку, розміру та рівня фізичного навантаження.**
-Supports the formation of cartilage, tendons, ligaments, synovial fluid and muscles.	**- Сприяє формуванню хрящів, сухожиль, зв'язок, синовіальної рідини та м'язів.**
-Contains the unique Oatinol™ Delivery System to maintain a high rate of nutrient absorption.	**- Містить унікальну систему доставки Oatinol™, яка забезпечує високу швидкість поглинання поживних речовин.**
-Contains high levels of Omega 3 to support optimum health and performance.	**- Містить високі рівні Omega 3 для підтримки оптимального здоров'я та ефективності.**
-Manufactured as palatable and easy-to-feed 2mm pellets.	**- Виготовляється у вигляді смачних і зручних гранул діаметром 2 мм.**
-Can be fed to all dogs regardless of age, size or level of exercise.	**- Підходить для всіх собак незалежно від віку, розміру та рівня фізичного навантаження.**
-For continued support, Joint Aid is recommended to be fed on a daily basis. A measure is included in the pack. Nutraceuticals are nutritional substances that provide additional health benefits. Through the addition of the following nutraceuticals, Joint Aid provides a complementary support for all dogs. High levels of 5 particular dietary amino acids, essential for the production of muscle tissue. Chondroitin is essential for the resilience of cartilage. It maintains normal enzymatic activity and water-holding capacity to provide healthy resistance to compression. Collagen possesses great tensile strength and provides the framework that gives tissues their firmness and resilience. *- Additional source context*	*- Для постійної підтримки рекомендується давати Joint Aid щоденно. В упаковці є мірна ємність. Нутрицевтики – це поживні речовини, які забезпечують додаткову користь для здоров'я. Завдяки додаванню перелічених нижче нутрицевтиків Joint Aid забезпечує додаткову підтримку для всіх собак. Високий вміст 5 конкретних дієтичних амінокислот, які потрібні для формування м'язової тканини. Хондроїтин необхідний для еластичних хрящів. Він підтримує нормальну ферментативну активність і здатність утримувати воду, забезпечуючи здорову стійкість до стиснення. Колаген забезпечує чудову міцність на розрив та є основою для цупких та пружних тканин.* *- Additional target context*

Please score the overall document translation quality (you can score the whole document only after scoring all individual sentences first).

Assess the translation quality on a continuous scale using the quality levels described as follows:

0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Grammar is irrelevant.
2: Some meaning preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Grammar may be poor.
4: Most meaning preserved and few grammar mistakes: The translation retains most of the meaning of the source. It may have some grammar mistakes or minor contextual inconsistencies.
6: Perfect meaning and grammar: The meaning of the translation is completely consistent with the source and the surrounding context (if applicable). The grammar is also correct.

This is the GitHub version #wmt22dev of the Appraise evaluation system. Some rights reserved. Developed and maintained by Christian Federmann and the Appraise Dev team.

(a) Top part of the screen with segment-level scoring. **(b)** Bottom part of the screen with document-level scoring.

Figure 1: Screen shot of the document-level DA+SQM configuration in the Appraise interface for an example assessment from the human evaluation campaign for out of English language pairs. The annotator is presented with the entire translated document snippet randomly selected from competing systems (anonymized) with preceding and following contexts and is asked to rate the translation of individual segments and then the entire document on sliding scales.

Language pairs	Annotators' profile
English→Chinese/Croatian/German/Japanese	Microsoft annotators: bilingual target-language native speakers, professional translators or linguists, experienced in MT evaluation
English→Czech	Czech paid linguists, annotators, researchers, students with high proficiency in English
English→Livonian	Livonian speakers
English→Russian/Ukrainian, Russian↔Yakut	Toloka paid crowd: bilingual target-language native speakers
Ukrainian↔Czech	Paid translators and target-language native speakers

Table 8: Human annotator types for each language pair in bilingual human evaluation.

with approximately the same number of segments per domain. We use document snippets with 10 consecutive segments, or fewer in the case of short documents. In this way, all systems are annotated over almost exactly the same subset of document snippets.[32] All HITs consists of exactly 100 segments and are generated as in the past: (1) first snippet-system pairs are randomly sampled (from the restricted set of pre-sampled snippets) with up to 80 segments; (2) then random snippets with the remaining 20 (or more) segments are duplicated to serve as quality control items; (3) BAD references are introduced to the random segments in the duplicated snippets to have about 12-14% of quality control segments per HIT.[33] BAD references consist of segments in which an embedded sequences of tokens is replaced from a randomly placed phrase of the same length, sampled from a different reference segment.

We perform quality control by measuring an annotator's ability to reliably score BAD translations significantly lower than corresponding original system outputs using a paired significance test with $p < 0.05$. We pair two HITs into a single annota-

[32] For English→{Czech, German, Japanese, Russian, Ukrainian, Chinese} and the additional Chinese→English collection, all systems received annotations for all the sampled snippets. For Czech→Ukrainian, Ukrainian→Czech, English→Croatian, Yakut→Russian, and pairs including Livonian, annotation coverage of sampled snippets was incomplete; not all systems were scored over exactly the same set of segments.

[33] For full details, see the HIT and batch generation code: https://github.com/wmt-conference/wmt22-news-systems

Language Pair	Sys.	Assess.	Assess/Sys
Chinese→English	14	26,800	1,914.3
Czech→Ukrainian	12	21,285	1,773.8

tion task with about 24-28 quality control segments to ensure a sufficient sample size for the statistical test. If an annotator is not able to demonstrate reliability on BAD references, they are excluded from further annotations, the HITs are reset and annotated from scratch by another annotator.[34]

In addition to the quality control items, because this annotation is performed bilingually, reference translations are also evaluated as though they were submitted systems.

For language pairs where there was a concern about having sufficient annotations, two smaller batches of HITs were generated (such that at least all segments in the first batch could be covered for all systems, with the second campaign completed if possible; in the case of translation between Czech and Ukrainian, due to a large number of single-sentence documents, larger documents were sampled first).

Language Pair	Min.	Max.	Med.

Table 12: Three rankings for systems translating between English and Livonian.

6.3 Calibration HITs

For several language pairs (English→{Chinese, Croatian, Czech, German, Japanese} and Chinese→English), we collect calibration HITs in the DA+SQM interface: one identical HIT with 100 randomly selected segments completed by all annotators, in addition to their regular annotation HITs. By providing a small set of sentences annotated by all annotators, we are better able to examine questions about inter-annotator consistency. We release these alongside the other annotations and the anonymized mapping between annotators and HITs in order to enable additional analysis.

Table 10 shows the number of unique annotators for these languages, along with the total number of HITs and average number of HITs per annotator. For all pairs of annotators who completed both a calibration HIT and additional HIT(s) within a given language pair, we compute the Spearman's rank correlation coefficient between the two an-

[34] The quality control in bilingual human evaluation excluded 17 HITs in total: 1 Yakut→Russian, 2 English→Russian, 3 English→Ukrainian, 7 English→Livonian, 4 Czech↔Ukrainian.

notators' scores of the segments in the calibration HIT. Table 11 shows the minimum, maximum, and median correlations obtained by pairs of annotators for each language. These vary quite widely between languages, and we also note that across the calibration HITs, annotators vary widely in their use of the scoring space and the shape of their score distributions. Even within the same language pair (i.e., scoring the exact same set of segments in the calibration HIT), some annotators' scores are distributed across most of the 0-100 scoring space, some only produce scores above a certain threshold, and some treat the scale as though it were discretized according to the numerical scale shown in the interface (clustering most of their scores at the numerical marks the one can see in Figure 1).

6.4 Human Ranking Computation

The official rankings shown in Table 13 are generated on the basis of the segment-level DA+SQM scores that are collected within document snippet context for all language pairs.[35] The quality control (BAD) segments and any HITs that failed to pass quality control are removed prior to computing the rankings. Means and standard deviations for computing z-scores are computed at the HIT level. To compute system-level averages (both raw and z-score), any instances of multiple scores for the same segment are first averaged together, then all segment-level scores are averaged per system to compute the system-level scores. The clusters are computed using the Wilcoxon rank-sum test with $p < 0.05$. Rank ranges indicate the number of systems a particular system underperforms or outperforms (i.e., the top end of the rank range is $l + 1$ where l is the number of losses, while the bottom is $n - w$ where n is the total number of systems and w is the number of systems that the system in questions significantly wins against).

The rankings for translation between Livonian and English shown in Table 12 are computed in the same manner described above, but because the test set does not include document boundaries the data was collected without document context and some of the data collection was source-based while other portions were reference-based. As the official ranking for English→Livonian we consider the ranking computed from source-based human evaluation.

6.5 Comparison of Human Evaluation Methods

In collaboration with the metrics shared task (Freitag et al., 2022), human annotation data for the Chinese→English direction was collected using three different approaches: the official monolingual reference-based SR+DC DA (Section 5, Table 7), the source-based fully document-level DA+SQM approach used for out-of-English and non-English directions (Section 6), and the Multidimensional Quality Metrics (MQM) framework (Freitag et al., 2021, 2022). We present the rankings produced by the three approaches in Table 14.

The DA rankings produced large clusters only for this language pair; that is, it was not possible to separate the performance into many system clusters with statistical significance. It is also important to note that the set of data over which each of these rankings was produced may have differed (e.g., the distribution over topic domains or the amount of coverage of the full test set), making it difficult to determine whether these differences in rankings represent differences due to data or due to different annotation methods.

7 Manual Error Analysis of English→Croatian translations

In addition to the official human evaluation by assigning DA scores, an analysis of errors in English→Croatian translations was carried out by an MT researcher with experience in human translation. The evaluation was carried out bilingually, while looking at the original English segment and all of its translations, both machine and human, all mixed together in a random order. The segments were presented in the natural order in the document, and the entire document (news article or review) was available by scrolling down or up.

The analysis was performed on the first 100 documents (80 reviews and 20 news articles), containing 603 segments (416 in reviews and 187 in news). All 14 review topics mentioned in Section 2.4 are included, although not uniformly distributed. The annotations are publicly available at https://github.com/wmt-conference/wmt22-news-systems/humaneval/en-hr/.

The errors were not coupled to any quality criterion (adequacy, fluency, readability) – all problematic words found in the translations were tagged as errors, no matter whether they are related to the source language, or are specific to the target lan-

[35] The code used to generate the rankings in Table 13 can be found here: https://github.com/AppraiseDev/Appraise/blob/main/Campaign/management/commands/ComputeWMT21Results.py

Table 13: Official results of WMT22 General Translation Task for translation out of English or without English. Systems ordered by DA score z-score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$; rank ranges indicate the number of systems a system significantly underperforms or outperforms; grayed entry indicates resources that fall outside the constraints provided. All language pairs except English→Livonian used document-level evaluation.

guage, or both. There was no distinction of error severity (“major”, “minor” or similar).

All identified errors (issues) were tagged by their possible causes and/or plausible explanations of their origin, as in (Popovic, 2021). Some of the identified “issue types" are equivalent to the typical error classes that can be found in MQM or similar schemes (such as “mistranslation”, “gender”, etc.), while some go beyond that, often including several different intertwining types of errors. Some of them involve single words, while others might involve a large group of words. The main difference between such tags in comparison to MQM or similar tags is that they are related to (linguistically motivated) causes of errors, also taking into account differences between source and target language as well as the translation process, and not only to the “symptoms” manifested in the MT output.

For example, the most frequent issue is related to “rephrasing”, and refers to a sequence of words that is not translated properly for some of the following reasons: 1) the translation of the source words follows the structure of the source language although it should be expressed differently in the target language (rephrasing is needed); 2) rephrasing is needed but incorrectly applied; 3) rephrasing is not needed but is applied, and/or 4) the choice of target words is related to source words but seems random, both in lexical as well as grammatical terms. The issue is manifested by several consecutive different but intertwined types of errors such as case, gender, verb form, mistranslation, function word, omission, addition, word order, etc. Incorrect translation of multi-word expressions and collocations falls under this type.

Overall error rates Table 15 presents the aggregated error rates for each translation, calculated as the number of words which were tagged as any type of error divided by the total number of words in the text. Thus, the interpretation of, for example, the overall error rate of 12.76% for the MT system ONLINE-B is that about 12-13 incorrect words were found in each group of 100 words. The error rates are presented for the entire analysed text, as well as separately for the two domains. The translations are ranked from the lowest to the highest overall error rate.

The ranking is similar to the official direct assessment results presented in Table 13, however there are some different tendencies. The main difference is the preference for human translations – error rates exhibit a clear preference for human translations over MT outputs. While both scores agree on the four best translations (two human and two MT outputs), error rates clearly distinguish the two human translations with about 10% less errors than in the best MT output. Direct assessment scores, however, are all close, ranging from 93.7 to 91.2, and even put student translations at the same rank as the best MT output. The same tendency has been reported in Freitag et al. (2021), where the MQM error annotation on English→German and Chinese→English translations clearly distinguished human translations from MT outputs, contrary to direct assessment scores. These findings indicate that for evaluating human translations in any context (comparing different human translations, comparing with MT outputs), some kind of error annotation should be performed.

Another potentially interesting difference is the system ONLINE-G, which is clearly ranked as second worst by direct assessment, but less clearly as third worst by error annotation. A potential reason is the different nature of errors in different MT systems discussed below. Other differences between the two rankings affect only the mid-range systems which have very close scores in both set-ups.

It can be seen that errors were detected both in human and in machine translations, although the error rates are notably lower in human translations. Overall error rate is lower than 1% for professional translations and lower than 3% for students’ translations, while in MT outputs, the overall error rates range from 12 to 22%.

In human translations, error rates are similar for both domains. In MT outputs, however, the error rates are notably higher for reviews than for news, which is not surprising given that there are much less training resources for reviews. Furthermore, it can be noted that the rankings would be slightly different if only one of the domains were used: NIUTRANS would be ranked higher on news while ONLINE-G would be ranked higher on reviews and HUAWEITSC would be ranked lower. Nevertheless, those variations in rankings can be observed only for the mid-ranged systems where differences in error rates are small anyway.

Comparing machine and human translations Table 16 presents issue types identified in machine and in human translations and their corresponding error rates. In addition, the distribution between the two domains is presented for each, meaning

Table 15: Percentage of words marked as errors (error rate) in all translations: two human translations (by professional translators and by students) and eight machine translation hypotheses. The percentages are presented for the entire text (overall) and separately for news and for reviews. The translations are ranked from best to worst according to the overall error rate. Bold values indicate domain-specific ranks which are different from the overall rank.

that, for example, 32.2% of all rephrasing errors are found in news and 67.8% in reviews. Issue types are ranked according to their percentage in MT outputs.

The most prominent issues in MT outputs are similar to those reported in in (Popovic, 2021): rephrasing (described at the beginning of the section), ambiguity (different meanings of a word in different contexts), noun phrases (sequences of nouns and possibly adjectives) and omissions (either a part of the source text is omitted or something is missing in the target language), with the error rates ranging from 1% to 5%. Interestingly, the same issue types are the most frequent issues in human translations, too, although with much smaller error rates (less than 0.4%).

The majority of issue types in MT outputs is found more frequently in reviews than in news, although the differences vary. From the most prominent issues, only noun phrase errors are slightly more frequent in news. In human translations, the distribution of issue types between the two domains is more even, although the most prominent four are more frequent in reviews.

Somewhat surprisingly, hallucination errors were identified in the human translation of news. Further manual inspection revealed that in one sentence, a phrase not related to any part of the source text indeed appears in the professional translation. The probable reason is a somewhat specific financial term "like-for-like" meaning "financial growth". The source sentence "Drink-led pubs and bars performed by far the strongest with *like-for-likes* up more than restaurants were down." ended up translated as "Drink-led pubs and bars performed by far the strongest, *while pubs and bars selling both drinks and food had* more up than restaurants were down". The translator probably did not recognise the term and assumed that it refers to something similar to the previously mentioned "drink-led pubs and bars", so they added the phrase about 'pubs and bars selling both drinks and food' which were not mentioned whatsoever in the source. Without this hallucination, all error rates (overall, news and reviews) for professional translations presented in Table 15 would be 0.60%.

Comparing MT systems Table 17 presents the most frequent issue types (with error rate greater than 1%, or, in other words, which were found at least once in each 100 words) in each of the eight MT outputs. The outputs are ranked from best to worst according to the overall error rate (Table 15). For each issue type, its overall error rate together with the separated error rates in news and reviews

Table 16: Identified issues in all MT hypotheses and in both HT references: error rate together with the distribution between news and reviews. The issue types are ordered by their percentage in MT hypotheses. Bold values indicate the domain with the higher amount of a particular issue type.

is shown.

First, it can be noted that in the two best-ranked systems, there are three clearly predominant issue types for both domains: rephrasing, ambiguity and noun phrase. These three issue types are predominant in other systems, too, however with higher error rates.

Furthermore, for all systems, rephrasing errors and ambiguity problems are more frequent in reviews, whereas noun phrase errors are more frequent in news. Also in all systems, there are slightly more omissions in news than in reviews.

When looking at lower ranked systems, it can be noted that not only the error rates for the generally most prominent issue types increase, but also more error types emerge: incorrect verb forms, incorrect gender and problems with pronouns or determiners in reviews.

The most interesting system is ONLINE-G: while the rephrasing error rate is only slightly worse than the two best-ranked systems, and ambiguity and noun phrase errors are also not much worse than some of the higher-ranked systems, it is the only system with notable problems with named entities (more than 2%) and mistranslations (more than 1%) in both domains, as well as generating non-existing words in reviews (more than 1%). This specific distribution of error types could be the reason that this system was clearly ranked as the second worst by direct assessment, although it has similar error rate as some other systems.

In the lowest-ranked systems, apart from the higher error rates for all common issue types, the appearance of untranslated words in reviews can be noted in NIUTRANS, and problems with named entities in news in ONLINE-Y.

Apart from the described quantitative analysis, a qualitative inspection of the translation showed, as can be expected, that the MT outputs generally are close to the source language, without divergences. Nevertheless, some very creative and very nice machine translations were found, too.

Comparing human translations Table 18 presents the most frequent issue types (with error rate greater than 0.1%, or in other words, that were found at least once in each 1000 words) in each of the two human translations. The translations are ranked from best to worst according to the overall error rate (Table 15). For each issue type, its overall error rate together with the separated error rates in news and reviews is shown.

First, it can be noted that the most frequent error in both human translations in omission, being more frequent in student translations. The second issue

Table 18: The most frequent issue types (error rate ≥ 0.1%) in each of the two human reference translations separately, overall as well as separately for news and reviews. The translations are ranked from best to worst according to the overall error rate (Table 15).

type is rephrasing, also more frequent in student translations. The third ranked issue in professional translations are hallucinations, which is discussed in one of the previous paragraphs. For students, the third ranked issue are ambiguous words, apparently more problematic in reviews.

Furthermore, a number of issue types with error rate larger than 0.1% in student translations are less frequent or even not appearing at all in professional translations.

Apart from the described quantitative analysis, a qualitative inspection of the translation showed that students generally diverged more from the source language than professionals, which is the opposite of what could be intuitively expected. This is the probable reason that for all MT outputs, both automatic metrics, COMET and CHRF, are lower when calculated using student references.

8 Conclusions

The General Machine Translation Task at WMT 2022 covered 21 translation pairs, 15 of which had English on the source or target side and 6 were without English. Direct assessment (DA) was the main golden truth, although the style varied across language pairs. Into-English translation was evaluated against human reference translation, preserving the order of sentences in a document but not presenting the whole document at once (SR+DC). Out-of-English and non-English pairs offered the context to the annotators and allowed them to revisit the scores assigned to individual segments (DA+SQM), evaluating against the source.

9 Limitations

We opened a research question of testing general capabilities of MT systems. However, we have simplified this approach. Firstly, we only used four domains that are not specialized. Secondly, we used only cleaner sentences avoiding noisy in the source sentences.

Although we accept human judgement as a gold standard, giving us more reliable signal than automatic metrics, we should mention that human annotations are noisy (Wei and Jia, 2021) and their performance is affected by quality of other evaluated systems (Mathur et al., 2020). Moreover, reference-based human judgements are biased by the quality of references.

The error analysis of Croatian translations was carried out by one evaluator. Also, the selected sample is different than the one used for direct assessment.

10 Ethical consideration

Several of the domains contained texts that included personal data, for example the conversational data (See Section 2.5 for more details). Entities were replaced by anonymisation tags (e.g. #NAME#, #EMAIL#) to preserve the anonymity of the users behind the content.

The sentences in Ukrainian datasets (as described in Section 2.4) were collected with users' opt-in consent and any personal data related to people other than well-known people was pseudonymized (using random first names and surnames). Sentences where such pseudonymization would not be enough to preserve reasonable anonymity of the users (e.g. describing events uniquely identifying the persons involved) were not included in the test set.

As described in Section 2.2 and in the linguistic brief (Appendix Section C), inappropriate, controversial and/or explicit content was filtered out prior to translation, particularly keeping in mind the translators and not exposing them to such content or obliging them to translate it. A few sentences containing explicit content managed to escape the filter, and we removed these sentences from the test sets without translation.

Human evaluation using Appraise for collecting human judgements was fully anonymous. Automatically generated accounts associated with annotation tasks with single-sign-on URLs were distributed randomly among pools of annotators and did not allow for storing personal information. For language pairs for which we used calibration HITs, we received lists of tasks completed by an individual anonymous annotator.

Acknowledgments

This task would not have been possible without the sponsorship of monolingual data, test sets translation and evaluation from our partners. Namely Microsoft, Charles University, Toloka, NTT Resonant, LinguaCustodia, Webinterpret, Google, CyberAgent, and Phrase. This work was supported by the European Commission via its H2020 Program (project WELCOME, contract no. 870930) and by 20-16819X (LUSyD). We greatly appreciate the help of Jaroslava Hlaváčová, Lucie Poláková, Pavel Pecina, and Mariia Anisimova with preparation of the Ukrainian↔Czech testset. Additionally, we would like to thank Loïc Barrault, Markus Freitag, Jesús Gonzáles Rubio, Marcin Junczys-Dowmunt, Raheel Qader, Matiss Rikters and many others.

Rachel Bawden's participation was funded by her chair position in the PRAIRIE institute funded by the French national agency ANR as part of the "Investissements d'avenir" programme under the reference ANR-19-P3IA-0001.

Maja Popović's participation was funded by the ADAPT SFI Centre for Digital Media Technology, funded by Science Foundation Ireland through the SFI Research Centres Programme and co-funded under the European Regional Development Fund (ERDF) through Grant 13/RC/2106.

Michal Novák's and Martin Popel's participation was funded by LM2018101 (LINDAT/CLARIAH-CZ) of the Ministry of Education, Youth, and Sports of the Czech Republic.

Yvette Graham's participation was supported by the ADAPT Centre for Digital Content Technology (www.adaptcentre.ie) at Trinity College Dublin funded under the SFI Research Centres Programme (Grant 13/RC/2106) co-funded under the European Regional Development Fund.

Table 20: Statistics for parallel training set provided for General/News Translation Task. All numbers are obtained after running MosesDecoder's `tokenizer.perl`. *Tokens* are the total number of words, whereas *Types* are total number of distinct case-insensitive words. Suffixes, k, M, and B, are short for thousands, millions, and billions, respectively.

B Differences in Human Scores

Tables 23–27 show differences in average standardized human scores for all pairs of competing to-English systems for each language pair. The numbers in each of the tables' cells indicate the difference in average standardized human scores for the system in that column and the system in that row.

Because there were so many systems and data conditions the significance of each pairwise comparison needs to be quantified. We applied Wilcoxon rank-sum test to measure the likelihood that such differences could occur simply by chance. In the following tables $\star$ indicates statistical significance at $p < 0.05$, † indicates statistical significance at $p < 0.01$, and ‡ indicates statistical significance at $p < 0.001$, according to Wilcoxon rank-sum test.

Each table contains final rows showing the average score achieved by that system and the rank range according to Wilcoxon rank-sum test ($p < 0.05$). Gray lines separate clusters based on non-overlapping rank ranges.

Table 27: Head to head comparison for Ukrainian→English systems

C Preprocessing cleanup brief for linguists

In this task, we wish to check the data to remove all inappropriate content, remove repetitive content, or correct minor problems with the text.

The data is automatically broken down into individual sentences, which may be wrong sentence splitting. Each document is separated by empty lines. Keep the document-separators intact, split long documents into several by adding empty lines if necessary based on the context (some documents may be merged). In general, documents should be under 30 sentences long.

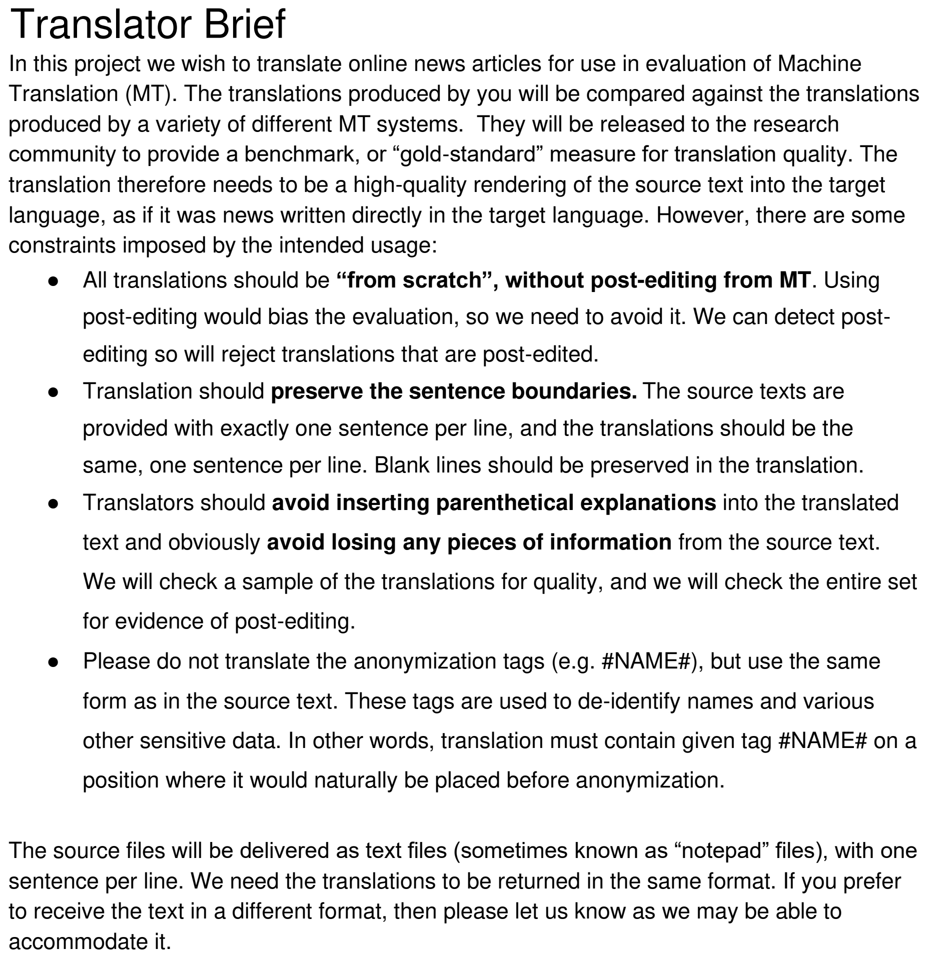
In the first step, check if a document shouldn't be removed (delete sentences from document) based on the following conditions, be on the save side, rather remove documents where you are uncertain. The conditions for removal of documents are as follows:

- Remove inappropriate content (such as sexually explicit, vulgar, or otherwise inappropriate)
- Remove controversial content (propagandist, controversial political topics, etc.)
- Remove content that is too noisy or doesn't resemble natural text (such as documents badly formatted, hard to understand, containing unusual language, lists or other structured data generated automatically)
- Remove repeated/similar content already part of previous documents

For documents that are not removed, do minor corrections (do not try reformulating the content). The main goal is to make sure each line contains a single sentence (or is empty line which represent document boundaries). The result should be documents that are fluent when reading. Here is a non-complete list of phenomena to pay attention to:

- Each line must be a single sentence, remove anything that dangles around or doesn't fit the context. Also reconnect sentences that have been accidentally split (for example trailing words or punctuation should be appended to the previous line).
- You may do small corrections to make the text cleaner (adding punctuation, correcting small typos, etc.). If text would need more correction, remove whole document. Also, do not polish everything.
- Sentences containing a short phrase or single words that are not necessary for the context (like "Description:" or emoticons like ":)") can be removed.

D Translator Brief for General MT



Translator Brief

In this project we wish to translate online news articles for use in evaluation of Machine Translation (MT). The translations produced by you will be compared against the translations produced by a variety of different MT systems. They will be released to the research community to provide a benchmark, or “gold-standard” measure for translation quality. The translation therefore needs to be a high-quality rendering of the source text into the target language, as if it was news written directly in the target language. However, there are some constraints imposed by the intended usage:

- All translations should be **“from scratch”, without post-editing from MT**. Using post-editing would bias the evaluation, so we need to avoid it. We can detect post-editing so will reject translations that are post-edited.
- Translation should **preserve the sentence boundaries.** The source texts are provided with exactly one sentence per line, and the translations should be the same, one sentence per line. Blank lines should be preserved in the translation.
- Translators should **avoid inserting parenthetical explanations** into the translated text and obviously **avoid losing any pieces of information** from the source text. We will check a sample of the translations for quality, and we will check the entire set for evidence of post-editing.
- Please do not translate the anonymization tags (e.g. #NAME#), but use the same form as in the source text. These tags are used to de-identify names and various other sensitive data. In other words, translation must contain given tag #NAME# on a position where it would naturally be placed before anonymization.

The source files will be delivered as text files (sometimes known as “notepad” files), with one sentence per line. We need the translations to be returned in the same format. If you prefer to receive the text in a different format, then please let us know as we may be able to accommodate it.

E Additional statistics of the test sets

Table 28 shows the type-token ratios for the source and target side of each of the test sets, shown for each available domain. As mentioned previously, texts are tokenised using the language-specific Spacy models (Honnibal and Montani, 2017) where available. For Czech, Livonian and Yakut, for which Spacy models are not available, we took as a rough approximation models for Croatian, Finnish and Russian respectively. The type-token ratio is calculated as the number of unique tokens divided by the total number of tokens. The absolute value depends not only on the lexical diversity of the text but also on the morphological complexity of the language in question.

Table 28: Type-token ratio for individual source languages used in the general translation test sets.

F News Task System Submission Summaries

F.1 AISP-SJTU (Liu et al., 2022)

This paper describes AISP-SJTU's participation in WMT 2022 shared general mt task on English->Chinese, Chinese->English, English->Japanese and Japanese->English with constrained training data. Our systems are based on the Transformer architecture with several novel and effective variants, including network depth and internal structure. In our experiments, we employ data filtering, large-scale back-translation, knowledge distillation, forward-translation, iterative in-domain knowledge finetune and model ensemble.

F.2 AIST (no associated paper)

The model was trained similarly to Optimus (Li et al., 2020) with the difference of using BERT (Devlin et al., 2019) for both encoding and decoding instead of BERT for encoding and GPT-2 for decoding as in Optimus, therefore enabling non-autoregressive sequence-to-sequence modeling. We used the pre-trained "bert-base-cased" configuration for English and the "bert-base-japanese" from CL Tohoku for Japanese.

F.3 ALMAnaCH-Inria (Alabi et al., 2022)

ALMAnaCH-Inria's primary submissions are multilingual transformer models between English, Russian, Ukrainian and Russian. The models exploit a dedicated Latin-script transcription convention designed to represent the Slavic languages in a way that maximises character- and word-level correspondences between them as well as with English. For directions where the target language is not English, this involves a final translation step into the original script. Our hypothesis was that bringing the languages closer together could boost vocabulary sharing and have a positive impact on machine translation results. Initial results indicate that the transcription strategy was not successful, resulting in lower results than baselines. We nevertheless submit these models as our primary systems.

F.4 AMU (Nowakowski et al., 2022)

AMU submission is a weighted ensemble of 4 models based on the transformer-big architecture. Models use source factors to utilize the information about named entities present in the input. Each of the models in the ensemble was trained using only the data provided by the shared task organizers. A noisy back-translation technique was used to augment the training corpora. One of the models in the ensemble is a document-level model, trained on parallel and synthetic longer sequences. During the sentence-level decoding process, the ensemble generated the n-best list (n=200). The n-best list was merged with the n-best list (n=50) generated by a single document-level model which translated multiple sentences at a time. Finally, existing quality estimation models and minimum Bayes risk decoding were used to rerank the n-best list so that the best hypothesis is chosen according to the COMET evaluation metric.

F.5 ARC-NKUA (Roussis and Papavassiliou, 2022)

The ARC-NKUA submission to the WMT22 General Machine Translation shared task concerns the unconstrained tracks of the English-Ukrainian and Ukrainian-English translation directions. The 2 Neural Machine Translation systems are based on Transformer models and our primary submissions were determined through experimentation with (a) checkpoint averaging, (b) ensemble decoding, (c) continued training with a subset of the training data, (d) data augmentation with back-translated monolingual data, and (e) post-processing of the translation outputs. We used various techniques to clean and filter the data provided by the organizers, as well as the additional parallel and monolingual data which we acquired from various sources.

F.6 CUNI-Bergamot (Jon et al., 2022)

CUNI-Bergamot submission is based on block-backtranslation method and MBR decoding using neural metrics. Block-BT is a method which switches between blocks of authentic parallel and backtranslated data during training based on a predefined pattern. The paper compares various parameters of the block-BT method: block size, checkpoint averaging methods, using only BT or also forward translation. The authors also show that MBR decoding can profit from more diverse checkpoints created by this method, as opposed to traditional mixed data training.

F.7 CUNI-DocTransformer (Jon et al., 2022)

Exactly the same as submitted in WMT20 (Popel, 2020), document-level Transformer trained with Block Backtranslation.

F.8 CUNI-Transformer (Jon et al., 2022)

The English↔Czech sentence-level models are exactly the same as submitted in WMT20 (Popel, 2020). The Ukrainian↔Czech models are very similar, also trained with Block Backtranslation. The Czech→Ukrainian system uses in addition special preprocessing (romanization of the Ukrainian side and a novel vocabulary-based inline casing on both sides).

F.9 CharlesTranslator (Popel et al., 2022)

Charles Translator for Ukraine is a free Czech-Ukrainian online translation service available for the public at `https://translator.cuni.cz` and as an Android app. It was developed at Charles University in March 2022 to help refugees from Ukraine by narrowing the communication gap between them and other people in the Czech Republic. It is based on Transformer and Block Backtranslation (Popel et al., 2020a).

F.10 DLUT (no associated paper)

We participate in the WMT 2022 general translation task in 2 language pairs and four language directions, English-Chinese and English-Japanese. Our submission use standard Transformer bilingual models.

We mainly improve performance by data filtering, large-scale data generation (i.e., back-translation, forward-translation, knowledge distillation, R2L training), domain finetuning, model ensemble and post-editing.

F.11 GTCOM (Zong and Bei, 2022)

This submission is based on Transformer architecture and involves data augmentation techniques.

F.12 HuaweiTSC (Wei et al., 2022)

This paper describes the submission of huawei translation services center (HW-TSC) to WMT22 general MT translation task.

F.13 JDExploreAcademy (Zan et al., 2022)

We push the limit of our previous work – bidirectional training (Ding et al., 2021) for machine translation by scaling up two main factors, i.e. language pairs and model sizes, namely the Vega-MT system. As for language pairs, we scale the "bidirectional" up to the "multidirectional" settings, covering all competitive high-resource languages, including en-de, en-cs, en-ru, en-zh, and en-ja, to exploit the common knowledge across languages, and transfer them to the downstream bilingual tasks. As for model size, we scale the transformer-big up to the extremely large model that owns nearly 4.7 Billion parameters, to fully enhance the model capacity for our Vega-MT. Also, we adopt the widely-used data augmentation strategies, e.g. back translation, knowledge distillation, cycle translation, and bidirectional self-training to comprehensively exploit the bilingual and monolingual data. To adapt our Vega-MT to the general domain test set, the noisy channel reranking and generalization tuning are employed.

F.14 KYB (Kalkar et al., 2022)

KYB team participated in the WMT22 general machine translation task on English-to-Japanese and Japanese-to-English directions. Our submissions are based on the transformer model with base setting. We employed several techniques to improve system's performance, such as data cleaning and selection, model ensembling/averaging, beam search, fine-tuning, and post-processing.

F.15 LT22 (Malli and Tambouratzis, 2022)

Our submission consists of translations produced from a series of NMT models of the following two language pairs: german-to-english and german-to-french. All the models are trained using only the parallel training data specified by WMT22. The models follow the transformer architecture employing eight attention heads and six layers in both the encoder and decoder. It is also worth mentioning that, in order to limit the computational resources that we would use during the training process, we decided to train the majority of models by limiting the training to 21 epochs. Moreover, the translations submitted at WMT22 have been produced using the test data released by the WMT22. The aim of our experiments has been to evaluate methods for cleaning-up a parallel corpus to determine if this will lead to a translation model producing more accurate translations. For each language pair, the base NMT models have been trained from raw parallel training corpora, while the additional NMT models have been trained with corpora subjected to a special cleaning process with the following tools: Bifixer and Bicleaner. It should be mentioned that the Bicleaner repository doesn't provide pre-trained classifiers for the above language pairs, consequently we trained probabilistic dictionaries in order to produce new models. The fundamental differences between these NMT models produced are mainly related to the quality and the quantity of the training data, while there are very few differences in the training parameters. To complete this work, we used the following three tools:(i) MARIAN NMT (Version: v1.11.5), which was used for the training of the NMT models and (ii) Bifixer and (iii) Bicleaner, which were used in order to correct and clean the parallel training data. Concerning the Bifixer and Bicleaner tools, we followed all the steps as described meticulously in the relevant article.

F.16 Lan-Bridge (Han et al., 2022)

Team Lan-Bridge's submission are transformer base models. For non-Chinese language pairs, we trained some multilingual models. For Chinese-English and English-Chinese, we train seperated models for each direction.

F.17 LanguageX (Zeng, 2022)

LanguageX submission is an ensemble model equipped with our recent technique of fast domain adaptation and data selection.

F.18 Liv4ever (Rikters et al., 2022)

The submitted translations were generated by an ensemble of three different iterations of multi-lingual transformer models trained on Latvian, Estonian, English and Livonian data from the constrained track. All parallel data were filtered (?) before training. After initial training the models were further improved by performing iterative back-translation of batches of 200,000 sentences from each language to the other languages (Livonian monolingual data was upscaled) for four iterations. The ensemble was composed of the single best checkpoint from the last three iterations of the back-translation process.

F.19 NAIST-NICT-TIT (Deguchi et al., 2022)

This paper describes the NAIST-NICT-TIT submission to the WMT22 general machine translation task. We participated in this task in the English-Japanese language pair. Our system is built on an ensemble of Transformer big models, k-nearest-neighbor machine translation (kNN-MT) (Khandelwal et al., 2021), and reranking.

Our base translation system is a combination of kNN-MT and an ensemble of four Transformer big models. Each of the Transformer model instances is trained using a different random seed, and we reuse one of the models for kNN-MT. A notable point of our system is that we construct the datastore for kNN-MT from back-translated monolingual data. We find that using the back-translated data improves translation performance when compared to using a parallel training corpus for the datastore.

We designed a reranking system to select a sentence from among the n-best sentences generated by the base translation system. For each translation hypothesis, the reranker computes a weighted sum of multiple model scores. It then selects the hypothesis with the highest score. We used k-best batch MIRA (Cherry and Foster) to select the weights for the model scores that maximize the BLEU score of the development set. We use context-aware model scores to improve the document-level consistency of the translation.

F.20 NT5 (Morishita et al., 2022)

The NT5 team submission is standard ensemble Transformer models equipped with several extensions, including our recent techniques, followed by a reranking module based on source-to-target, target-to-source, and masked language models. We also applied data augmentation and selection techniques to training data of the Transformer models.

F.21 NiuTrans (Shan et al., 2022)

This paper describes NiuTrans neural machine translation systems of the WMT22 General MT task with constrained data sets. We participated in Chinese to English, English to Croatian, and Livonian-English total of three tasks. We mainly utilized iterative back-translation, iterative knowledge distillation, and iterative fine-tuning. We also use various Transformer variants to improve the model's performance further, e.g., ODE-Transformer, UMST. Moreover, we tried some multi-domain methods, such as multi-domain model structure and multi-domain data clustering method, to adapt to this year's multi-domain test set. We also tried some methods to build a machine translation system using pre-trained language models.

F.22 OpenNMT (no associated paper)

In this paper, we first benchmark the mainstream translators on the English-to-German task by making sure we take into account: - The changes that occurred in the WMT test sets starting 2019 - The post-processing differences between systems - The recent research in automatic metrics beyond BLEU Over the past 3 years, WMT has shown that both OnlineW and FacebookAI have a clear lead in the human evaluations. When looking at various metrics, we make the assumptions that one reason comes from the very good fluency which exposes a low perplexity when measuring with a GPT-2 language model.

We will therefore try 3 types of experiments: 1) filter various datasets with a GPT-2 model to retain only sentences under a given threshold. 2) Use a noisy channel decoding reranking method (used by FacebookAI) and maybe by OnlineW since their API is way slower then G/M/A. 3) Use a GPT-2 large model distillation during NMT training.

Given the training time of the last experiment we were not able to submit this system, however we will continue and report results in the paper.

F.23 PROMT (Molchanov et al., 2022)

The PROMT systems are trained with the MarianNMT toolkit. All systems use the transformer-big configuration. We use BPE for text encoding, the vocabulary sizes vary from 24k to 32k for different language pairs. All systems are unconstrained. We use all data provided by the WMT organizers, all publicly available data and some private data.

F.24 SRPOL (Dobrowolski et al., 2022)

We present the work of Samsung R&D Institute Poland in WMT 2022 General MT solution for medium to low resource languages: Russian and Croatian. Our approach combines iterative back-translation with noise and iterative distillation. We investigated different monolingual resources and compared their effects on the final translation. We used available BERT-like models to classify texts and to distinguish text domains. We attempted to predict ensemble weight vectors based on BERT-like domain classification for individual sentences. The final models achieved quality comparable to the best online translators using only limited resources during training.

F.25 TAL-SJTU (He et al., 2022)

TAL-SJTU submission is based on M2M100 (Fan et al., 2021a) with novel techniques that adapt it to the target language pair: (1) We propose a cross-model word embedding alignment method that transfers a pre-trained word embedding to M2M100, enabling it to support Livonian. (2) We also utilize Estonian and Latvian languages as auxiliary languages for training and pivot languages for data augmentation. (3) Finally, the best result was achieved after fine-tuning the model using the validation set and online back-translation. In model evaluation: (1) We find that previous work (Rikters et al., 2022) underestimated the translation performance of Livonian due to inconsistency in Unicode normalization, which may cause a discrepancy of up to 19 BLEU score. (2) In addition to the standard validation set, we also employ round-trip BLEU to evaluate the models, which we find a more appropriate way for this task.

F.26 TartuNLP (Tars et al., 2022)

TartuNLP's submission is a model based on Transformers. Our main approach was utilizing large pre-trained multilingual neural machine translation models, specifically the M2M-100 model (Fan et al., 2021b). In our systems we used the 1.2 billion parameter model. We fine-tuned the pre-trained model (more specifically we performed cross-lingual transfer learning) to our data, which consisted of WMT22 liv-en, en-liv data and other data from the Finno-Ugric language family for support. The main pipeline was the following: fine-tuning with original parallel data, then two iterations of back-translation and finally fine-tuning on original parallel data again.

F.27 eTranslation (Oravecz et al., 2022)

eTranslations's Fr-De system is an ensemble of 4 big transformers, trained from all available parallel data and with additional tagged, back-translated data generated from a 30M subset of various German monolingual corpora. The monolingual and original parallel data is cleaned up and filtered with heuristic rules. In the model trainings, the original parallel data is upsampled to a 1:1 ratio. Each transformer model is then fine tuned for 3 epochs on the original parallel data. The models use a 32k SentencePiece vocabulary. The SentencePiece module as built in the Marian toolkit is used for end-to-end text processing, without the standard pre- and postprocessing steps of truecasing, or (de)tokenization.

The En-Uk system is an ensemble of 4 multilingual (En -> Uk, Ru) big transformers, trained from all available parallel data. Each transformer model is then fine tuned only on the En-Uk data for about 50 epochs and the best checkpoint is used in the ensemble. Vocabulary and pre/postprocessing settings are the same as the Fr-De system. The En-Ru system is built with the same setup as the En-Uk, except it is an ensemble of 3 models.

F.28 manifold (Jin et al., 2022)

Manifold's English-Chinese System at WMT22 is an ensemble of 4 models, each trained by one of four different configurations and fine-tuned by applying scheduled-sampling. The four configurations are DeepBig (Xenc), DeepLarger (Xenc), DeepBigTalkingHeads (Xenc) and DeepBig (LaBSE). DeepBig is an extension to TransformerBig, the only difference is the former has 24 encoder layers. DeepLarger has 20 encoder layers and its FFN dimension is 8192. *TalkingHead applies talking-heads trick. For Xenc configs, we selected monolingual and parallel data that is similar to the past newstest datasets using Xenc, and for LaBSE, we cleaned the officially provided parallel data using LaBSE pretrained model.

F.29 shopline-pl

The model we submitted is based on the query results of the transformer and its variants, which includes the integration effect of different models and incorporates the reserved word mechanism.

G Automatic scores

This section contains automatic metric scores. While human judgement is the official ranking of systems and their performance, we share automatic scores to show expected system performance for various testsets.

We use COMET (Rei et al., 2020) as the primary metric and ChrF (Popović, 2015) as the secondary metric, following recommendation by (Kocmi et al., 2021). We present BLEU (Papineni et al., 2002) scores as it is still widely used metric. The COMET scores are calculated with the default model `wmt20-comet-da`. The ChrF and BLEU scores are calculated using SacreBLEU with signature (Post, 2018) is `chrF2|nrefs:all|case:mixed|eff:yes|nc:6|nw:0|space:no|version:2.0.0`. Scores are multiplied by 100.

The different suffix represents the name of reference used for calculation (A, B, C, stud), references has been translated by different translators but with the same sponsor. A notable difference is Czech-English, where we are missing reference "A" for it's low quality, which was partly corrected and placed under "C". The second exception is Croatian reference "stud" which was created by students in contrast to "A" prepared by professionals. Lastly, testsets liv-en and ru-sah are reverse testsets to their opposite counterparts (i. e. "en" and "sah" are original sources)

Abstract

This paper presents the results of the WMT22 Metrics Shared Task. Participants submitting automatic MT evaluation metrics were asked to score the outputs of the translation systems competing in the WMT22 News Translation Task on four different domains: news, social, e-commerce, and chat. All metrics were evaluated on how well they correlate with human ratings at the system and segment level. Similar to last year, we acquired our own human ratings based on expert-based human evaluation via Multidimensional Quality Metrics (MQM). This setup had several advantages, among other things: (i) expert-based evaluation is more reliable, (ii) we extended the pool of translations by 5 additional translations based on MBR decoding or rescoring which are challenging for current metrics.

In addition, we initiated a challenge set subtask, where participants had to create contrastive test suites for evaluating metrics' ability to capture and penalise specific types of translation errors.

Finally, we present an extensive analysis on how well metrics perform on three language pairs: English→German, English→Russian and Chinese→English. The results demonstrate the superiority of neural-based learned metrics and demonstrate again that overlap metrics like Bleu, spBleu or chrF correlate poorly with human ratings. The results also reveal that neural-based metrics are significant better than non-neural metrics across different domains and challenges.

1 Introduction

The metrics shared task[1] has been a key component of WMT since 2008, serving as a way to validate the use of automatic MT evaluation metrics and drive the development of new metrics. We evaluate reference-based automatic metrics that score MT output by comparing the translations with a reference translation generated by human translators, who are instructed to translate "from scratch" without post-editing from MT. In addition, we also invited submissions of reference-free metrics (quality estimation metrics or QE metrics) that compare MT outputs directly with the source segments. All metrics are evaluated based on their agreement with human rating when scoring MT systems and human translations at the system or sentence level. The final ranking of this year's submitted primary metrics is shown in Table 1. We provide details in the remainder of the paper.

Metric	avg rank
MetricX XXL	1.20

Reuse*	6.69

Table 1: Official ranking of all primary submissions of the WMT22 Metric Task. The final score is the weighted average ranking over 201 different scenarios. Metrics with * are reference-free metrics.

We implemented several changes to the methodology that was followed in previous years' editions:

- **Expert-based human evaluation**: Like last year, we collected our own human ratings for select language pairs (en→de, en→ru, zh→en) from professional translators via MQM (Lommel et al.,

[1] https://wmt-metrics-task.github.io/

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 46 - 68
December 7-8, 2022 ©2022 Association for Computational Linguistics

2014). Freitag et al. (2021a) showed that expert-based MQM evaluations produce more reliable[2] scores when compared to the DA-based human ratings acquired by the WMT Translation task. This step was necessary as Freitag et al. (2021a) showed that the DA-based ground-truth is already of lower quality than some of our submissions (Section 3).

- **Additional Training Data**: We encouraged the participants to make use of existing MQM annotations for newstest2020 (Freitag et al., 2021a)[3], and the MQM annotations from the WMT21 Metrics Task (Freitag et al., 2021b) to improve and/or test their metrics.

- **Additional MT systems**: The primary use case for automatic metrics is guiding research to translations that are better than what we can generate right now. To address this scenario, we not only want to evaluate metrics on MT output that we are currently capable of generating, but also on translations that are better than the current WMT submissions. For that we need to add alternative translations that cover a wider space of possible translations. To address this, we added MT systems that were generated with MBR decoding or reranking (Section 2.2).

- **Challenge sets subtask**: In the main metrics task, the metrics are evaluated on MT systems translating test sets drawn from large sources of continuous text. In an effort to have a more fine-grained analysis on the strengths and weaknesses of the metrics, we introduced the concept of challenge sets. A challenge set consists of contrasting MT outputs, which have been deliberately devised or selected to include correct and incorrect translations of particular phenomena, along with their respective reference translation. The evaluation of every metric in this setup depends on its ability to rank the correct translations higher than their corresponding incorrect ones. Whereas a first version of challenge sets appeared in last year's metrics shared task (Freitag et al., 2021b), this year they appear for the first time as a subtask in a decentralized manner. Inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017), participants (the *Breakers*) had to submit their own test suites to test the robustness of MT metrics to particular phenomena that they choose. Our first edition of this subtask (Section 8) received four challenge set submissions covering a wide range of phenomena and languages.

- **Meta Evaluation**: A main aim of the metrics task is to rank the overall performance of various metrics. This requires some way of aggregating scores across different settings (language pair, domain, granularity etc.), in order to provide a balanced picture. Correlations with human scores have different ranges in different settings, so averaging them is not a good solution. Last year, we adopted a proposal by Kocmi et al. (2021) that involves taking the microaverage of a metric's accuracy in making pairwise system-ranking decisions across different settings. This is easy to interpret and reflects a common use-case for metrics, but because we have only three language pairs, and thus relatively few pairwise comparisons, it tends to place many metrics into large significance clusters (eg, 8 metrics in the top cluster last year, including CHRF but excluding COMET). In an effort to better discriminate, and to represent a broader set of use-cases, this year we computed the average rank of each metric across a large set of tasks (Section 5). This statistic has a clear interpretation, is justified by social choice theory (Colombo et al., 2022), and makes it easy to zoom into different subsets of tasks to provide finer-grained characterizations. To reflect the importance of the accuracy metric from last year, we define it as a single highly-important task (out of 201 tasks in total), with an overall weight of 25%.

- **MTME**: Similar to last year, all results in this paper are calculated with MTME[4]. We want to encourage every metric developer to use this tool to calculate scores for consistency and comparability going forward.

Our main findings are:

- Out of 13 reference-based metrics **BLEU is ranked last**, followed by F200SPBLEU and CHRF.

[2] DA is unreliable for high-quality MT output; ranks human translations lower than MT; correlates poorly with metrics. Expert-based MQM ranks human translations higher than MT and correlates generally much better with automatic metrics.

[3] https://github.com/google/wmt-mqm-human-evaluation

[4] https://github.com/google-research/mt-metrics-eval

- **Neural fine-tuned metrics are not only better, but also robust to different domains**. Furthermore, based on the results from the four submitted challenge sets, neural fine-tuned metrics exhibit superior performance when compared to lexical and embedding similarity metrics.
- Top performing metrics from previous years are still top-performers, being only outperformed by model ensembles or metrics based on considerably larger neural models.
- For the first time since 2008, there was no new purely lexical metric submission, which indicates that metric developers are moving away from lexical metrics.

The rest of the paper is organized as follows: Section 2 describes the additional MT systems. Section 3 presents an overview of the conducted expert-based human evaluation. Section 4 describes the metrics evaluated this year (baselines and participants). Section 5 describes the conducted meta-evaluation. Section 6 reports our main results. Section 7 summarizes our results for additional WMT22 Translation task language-pairs based on their Direct Assessment human evaluation. Section 8 presents a description of the submitted challenge sets along with their findings. Finally, Section 9 presents our most relevant conclusions.

2 Translation Systems

Similar to the previous years' editions, the source, reference texts, and MT system outputs for the metrics task are mainly derived from the WMT22 general MT Task. In addition to the MT system outputs from the WMT evaluation campaign, we added translations from six additional MT systems which we deemed interesting for evaluation.

2.1 WMT Test Sets

The general MT 2022 test set contains around 2000 segments for each translation direction. This year, the test sets cover 4 domains: news, social, conversational, and e-commerce. There are around 500 sentences for each domain resulting in reasonably balanced test sets. English sources are identical for both into-German and into-Chinese translation directions. The reference translations provided for the test sets are translated by professional translators. We have two reference translations for English→German and Chinese→English sponsored by Microsoft and one reference translation for English→Russian sponsored by Google. For more details regarding the news test sets, we refer the reader to the WMT22 General MT task findings paper (Kocmi et al., 2022a).

2.2 Additional MT Output

Similar to last year, we want to expand the pool of translations beyond the WMT submissions, which usually are quite similar to each other. We added translations based on M2M100 and translations generated with MBR decoding.

M2M100 1.2B As the field moves forward to large multilingual pre-trained models, we are interested in comparing such general-purpose large multilingual MT systems against direct submissions to the general MT task. Models such as MBART50 (Tang et al., 2021) and M2M100 (Fan et al., 2021) are publicly available, easy to use and have recently been used as baselines and/or as a backbone for new research. We tested both models on the newstest2021 and we decided to include M2M100 1.2B as an additional MT output as it yielded better automatic scores.

MBR Outputs Minimum Bayes Risk (MBR) decoding has recently gained attention in MT as a decision rule, with the potential to overcome some of the biases of MAP decoding in NMT (Eikema and Aziz, 2020; Müller and Sennrich, 2021; Eikema and Aziz, 2021; Freitag et al., 2022; Fernandes et al., 2022). MBR decoding centrally relies on a reference-based utility metric: its goal is to identify a hypothesis with a high estimated utility (expectation under model distribution) with the hope that a high estimated utility translates into a high actual utility (with respect to a human reference). MBR decoding is particularly interesting for reference-based metrics as it stress tests the metric, using it as a utility function.

This year, we added three different MBR runs using three different utility functions (BLEU, BLEURT-20, and COMET-20) as additional translations. Freitag et al. (2022) demonstrated that the translations generated with a neural-based utility (BLEURT-20, and COMET-20) generate translations that are not only better when compared to MAP decoding, but the resulting translations are also significantly different from both the beam search decoding and the MBR decoding output using BLEU as a utility function. To make it even more interesting for the metric task, for these MBR translation models we used a transformer-big baseline trained only on WMT22 bilingual training data. By not using the strongest NMT system, we hope to see interesting new errors in the translation output. To generate the candidate list for MBR decoding, we sampled 256 times from the model using unbiased ancestral sampling.

Reranking Outputs Complementary to MBR outputs, we were also interested in comparing and evaluating the quality produced by reranking approaches based on QE. Our hope is that QE based reranking would lead to translations that are lexically different than traditional beam search output and thus lead to more diverse translations for the same source sentences. For English→German and English→Russian we used the Fairseq WMT19 systems[5] (Ng et al., 2019) with Nucleus Sampling (Holtzman et al., 2019) to generate 200 candidate translations, from which we choose the best translation according to the Tune Reranker proposed in Fernandes et al. (2022). For Chinese→English we used the same process but replacing the NMT model with MBART50 (many-to-one) and using only 50 samples.

3 MQM Human Evaluation

Automatic metrics are usually evaluated by measuring correlations with human ratings. The quality of the underlying human ratings is critical and recent findings (Freitag et al., 2021a) have shown that crowd-sourced human ratings are not reliable for high quality MT output. Furthermore, an evaluation schema based on MQM (Lommel et al., 2014), which requires explicit error annotation, is preferable to an evaluation schema that only asks raters for a single scalar value per translation. Similar to last year, we decided to not use the human ratings from the WMT General MT task, and conducted our own MQM-based human evaluation on a subset of submissions and a subset of language pairs that are most interesting for evaluating current metrics. This not only had the advantage of more reliable ratings for a subset of language pairs, but also gave us the opportunity to add our own translations that might be challenging for current metrics and are not part of an WMT submission.

MQM is a general framework that provides a hierarchy of translation errors which can be tailored to specific applications. Google and Unbabel sponsored the human evaluation for this year's metrics task for a subset of language pairs using either professional translators (English→German, Chinese→English) or trusted and trained raters (English→Russian). The error annotation typology and guidelines used by Google's and Unbabel's annotators differ slightly and are described in the following two sections.

3.1 English→German and Chinese→English

Annotations for English→German and Chinese→English were sponsored and executed by Google, using 11 professional translators (7 for English→German, 4 for Chinese→English) having access to the full document context. Each segment gets annotated by a single rater. Instead of assigning a scalar value to each translation, annotators were instructed to label error spans within each segment in a document, paying particular attention to document context. Each error was highlighted in the text, and labeled with an error category and a severity. To temper the effect of long segments, we imposed a maximum of five errors per segment, instructing raters to choose the five most severe errors for segments containing more errors. Segments that are too badly garbled to permit reliable identification of individual errors are assigned a special *Non-translation* error. Error severities are assigned independent of category, and consist of *Major*, *Minor*, and *Neutral* levels, corresponding respectively to actual translation or grammatical errors, smaller imperfections and purely subjective opinions about the translation. Since we are ultimately interested in scoring segments, we adopt the weighting scheme shown in Table 2, in which segment-level scores can range from 0 (perfect) to 25 (worst). The final segment-level score is an average over scores from all annotators. For more details, exact annotator instructions and a list of error categories, we refer the reader to Freitag et al. (2021a) as the exact same setup was used for the WMT21 metrics task.

Severity	Category	Weight
Major	Non-translation all others	25 5
Minor	Fluency/Punctuation all others	0.1 1
Neutral	all	0

Table 2: Google's MQM error weighting.

[5] https://github.com/facebookresearch/fairseq/tree/main/examples/wmt19

3.2 English→Russian

The annotations for English→Russian were provided by Unbabel who utilized four professional, native language annotators with ample translation experience. Annotation was conducted using Unbabel's own proprietary variant of the MQM framework (Lommel et al., 2014) which is fully compliant with MQM 2.0, being the most recent iteration of the framework[6]. Annotation was split along the four domain boundaries with each of the annotators evaluating all of the systems for a single content type. Similarly to Google, the annotators were given the full document context (up to ten segments) and were instructed to identify (by highlighting) and classify errors in accordance with the MQM typology. Annotators were also asked to classify error severity; in addition to *Minor* and *Major* error severities used by Google, Unbabel also uses a *Critical* error severity. However, in the interest of maintaining consistency in evaluation, we calculated the MQM score in a manner compliant with the Google methodology outlined above. Specifically all annotated *Critical* errors were counted as *Major* and punctuation errors were weighted using the weighting scheme in Table 2.

3.3 Human Evaluation Results

As discussed in Section 1, we decided to run our own human evaluation in order to generate our golden-truth ratings and come to stronger conclusions about the quality of each automatic metric across all domains. However, this also meant that we were only able to evaluate a subset of the test sets. In Table 3, you can see the number of segments for each language pair and test set that we used for human evaluation. We followed a simple and consistent approach to downsample the data: we kept the first 10 sentences of each document. By doing this, we did not need to discard any documents and only needed to crop longer documents. An exception is Chinese→English where we evaluated the full test set.

language	news	social	ecomm.	conv.
en→de	300/511	340/512	230/530	445/484
en→ru	300/511	340/512	230/530	445/484
zh→en	505/505	503/503	518/518	349/349

Table 3: Numbers of MQM-annotated segments per domain.

The results of the MQM human evaluation can be seen in Table 4. Most of the reference translations are ranked first, except for refB for English→German. Not ranking the human evaluation on top of the MT output is usually a signal for a corrupt human evaluation. We double checked the annotation for refB and can confirm that the reference translation indeed contained some errors.

4 Baselines and Primary Submissions

We computed scores for several baseline metrics in order to compare submissions against previous well-studied metrics. We will start by describing those baselines and then we will describe the submissions from participating teams. An overview of the evaluated metrics can be seen in Table 5.

4.1 Baselines

SacreBLEU baselines We use the following metrics from the SacreBLEU (Post, 2018) as baselines:

- **BLEU (Papineni et al., 2002)** is based on the precision of n-grams between the MT output and its reference weighted by a brevity penalty. Using SacreBLEU we obtained sentence-BLEU values using the `sentence_bleu` Python function and for corpus-level BLEU we used `corpus_bleu` (both with default arguments[7]).

- **F101SPBLEU (Goyal et al., 2022)** and **F200SPBLEU (NLLB Team et al., 2022)** are BLEU scores computed with subword tokenization done by standardized Sentencepiece Models (Kudo and Richardson, 2018). We used the command line SacreBLEU to compute the sentence level F101SPBLEU[8] and F200SPBLEU[9] and we average those scores to obtain a corpus-level score.

- **CHRF (Popović, 2015)** uses character n-grams instead of word n-grams to compare the MT output with the reference. For CHRF we used the SacreBLEU `sentence_chrf` function (with default arguments[10]) for segment-level scores and we average those scores to obtain a corpus-level score.

Table 4: MQM human evaluations for generaltest2022. Lower average error counts represent higher MT quality.

BERTScore (Zhang et al., 2020) leverages contextual embeddings from pre-trained transformers to create soft-alignments between words in candidate and reference sentences using cosine similarity. Based on the alignment matrix, BERTScore returns a precision, recall and F1 score. We used F1 without TF-IDF weighting.

YiSi-1 (Lo, 2019) is a MT evaluation metric that measures the semantic similarity between a machine translation and human references by aggregating the IDF-weighted lexical semantic similarities based on the contextual embeddings extracted from pre-trained language models (e.g. RoBERTa, CamemBERT, XLM-RoBERTa, etc.).

Bleurt (Sellam et al., 2020) is a learned metric that is fine-tuned to produce a DA for a given translation by encoding it jointly with its reference. We used the Bleurt20 checkpoint (Pu et al., 2021) which was trained on top of RemBERT using DA from previous shared tasks ranging 2015 to 2019 and additional synthetic data created from Wikipedia articles.

Comet (Rei et al., 2020) is a learnt metric that is fine-tuned to produce a z-standardized DA for a given translation by comparing its representation to source and reference embeddings. We used the default model `wmt20-comet-da` provided in version 1.1.2 which is trained on top of XLM-R large using data from from previous shared tasks ranging 2017 to 2019.

Comet-QE (Rei et al., 2021) is a reference-free learnt metric similar to Comet. We used the `wmt21-comet-qe-mqm`) model which was a top-performing metric from last year's shared task. This metric is first trained on z-standardized DA from 2017 to 2020 and then fine-tuned on z-standardized MQM from (Freitag et al., 2021a).

Table 5: Baseline metrics and primary submissions for the metrics task. We categorize metrics into 3 major classes: lexical, embedding similarity and fine-tuned metrics. Regarding fine-tuned metrics we have metrics that use human quality scores such as DA or MQM and metrics that use synthetic labels for fine-tuning (3rd column).

4.2 Metric Submissions

The rest of this section summarizes participating metrics. The ★ symbol indicates that the metric is the primary submission of the research group.

Comet-22★ (Rei et al., 2022) is an ensemble of two models; 1) Comet estimator model trained with Direct Assessments and 2) a newly proposed multitask model trained to predict sentence-level MQM scores along with Ok/Bad word-level tags derived from annotation spans.

CometKiwi★ ensembles 2 QE models similarly to COMET-22; 1) classic Predictor-Estimator QE model trained on DAs ranging 2017 to 2019 and then fine-tuned on DAs from MLQE-PE (the official DA from the QE shared task) and 2) the same multitask model used in the COMET-22 submission but without access to a reference translation.

MS-Comet-22★ and MS-Comet-QE-22★ (Kocmi et al., 2022b) are built on top of Comet by Microsoft Research using proprietary data. This metric is trained on a several times larger set of human judgements compared to Comet-baseline, covering 113 languages and 15 domains. Furthermore, the authors propose filtering of human judgement with potentially low quality to further improve the model.

MS-Comet-22 evaluated source, MT hypothesis and human reference from the input, while MS-Comet-QE-22 calculated scores in quality estimation fashion with only source segment and MT hypothesis.

EE-BERTScore★ (Liu et al., 2022) stands for Entropy Enhanced BERTScore and aims at achieving a more balanced system-level rating by assigning weights to segment-level scores produced by BERTScore. The weights are determined by the difficulty of a segment determined by the entropy between the hypothesis-reference pair.

KG-BERTScore (Liu et al., 2022) is a reference-free machine translation (MT) evaluation metric, which incorporates multilingual knowledge graph into BERTScore by linearly combining the results of BERTScore and bilingual named entity matching.

Cross-QE (Liu et al., 2022) is a reference-free metric with a similar architecture to Comet-QE.

HWTSC-Teacher-Sim★ (Liu et al., 2022) is a reference-free metric by fine-tuning the multilingual Sentence BERT model paraphrase-multilingual-mpnet-base-v2

HWTSC-TLM (Liu et al., 2022) is a reference-free metric which only uses a target-side language model to score the system translations as input.

Matese★ (Perrella et al., 2022) and Matese-QE★ leverage transformer-based multilingual encoders to identify error spans in translations, and classify their severity between *Minor* and *Major*. The quality score returned for a translation is computed following the MQM error weighting used by Google (see Section 3.1).

Mee (Mukherjee et al., 2020) is an automatic evaluation metric that leverages the similarity between embeddings of words in candidate translation and the corresponding reference. Unigrams are matched based on their surface forms, root forms and meanings while semantic evaluation is achieved by using pretrained fasttext embeddings. MEE computes evaluation score using three modules namely exact match, root match and synonym match. In each module, fmean-score is calculated giving more weight to recall. Final score is the average of the three individual modules.

Mee2 and Mee4★ (Mukherjee and Shrivastava, 2022b) are improved versions of Mee focusing on computing contextual and syntactic equivalences along with lexical, morphological and semantic similarity. The intent is to capture fluency and context of the MT outputs along with their adequacy. Fluency is captured using syntactic similarity and context is captured using sentence similarity leveraging sentence embeddings. The final score is the weighted combination of three similarity scores: a) syntactic similarity achieved by modified Bleu score; b) lexical, morphological and semantic similarity: measured by explicit unigram matching; c) contextual similarity: sentence similarity scores from Language-Agnostic BERT model.

Reuse★ (Mukherjee and Shrivastava, 2022a) is a bilingual, unsupervised reference-free metric. It estimates the translation quality at chunk-level and sentence-level. Source and target sentence chunks are retrieved by using a multi-lingual chunker. Chunk-level similarity is computed by leveraging BERT contextual word embeddings and sentence similarity scores are calculated by leveraging sentence embeddings of Language-Agnostic BERT models. The final quality estimation score is obtained by mean pooling the chunk-level and sentence-level similarity scores.

MetricX XL and MetricX XXL★ are massive multi-task metrics, which fine-tune large language model checkpoints such as mT5 on a variety of human feedback data such as DA, MQM, QE, NLI and Summarization Eval. The resulting primary submission uses the MQM score outputted by a fine-tuned 30B mT5.

UniTE★ (Wan et al., 2022a,b) is a learnt metric that can possess the ability of evaluating translation outputs following all three evaluation scenarios, i.e., source-only, reference-only, and source-reference-combined. Following their previous work, the authors improve their models by pre-training on pseudo-labeled data examples, and applying data cropping and a ranking-based score normalization during fine-tuning. The resulting submission is an ensemble of two models trained with different backbone models (XLM-R and InfoXLM).

SEScore★ (Xu et al., 2022) is an unsupervised reference-based evaluation metric, which takes model output and reference to produce a quality score. SEScore is trained from a pre-trained language model (Ex. Roberta) on synthetic triples generated from raw text. The synthetic triples consist of (raw text, synthetic error text, pseudo score), corresponding to (reference, model output, human rating). The data used for training the metric is constructed by synthesising candidate sentences y' to mimic plausible errors by transforming raw input sentences multiple times. At each step, a random span of text is selected and new content is inserted, deleted or replaced. All these errors are non-overlapping. The authors name this data construction process "stratified error synthesis", which randomly samples a set of potential errors and stochastically applies them on a given sentence. The score assigned to the perturbed sentences is a raw count of the severities applied by each transformation. In the end, SEScore is a regression quality prediction model trained on synthetic triples. Since this process can be applied to raw data and the resulting model can be developed for any text generation domain.

5 Meta Evaluation

Our main goal in evaluating metrics is to establish a ranking that reflects a metric's accuracy across a broad range of settings and applications. Combining results across different settings is challenging because correlations with human gold scores have different ranges and may be subject to differing degrees of noise. There are also many ways of measuring correlation, with different strengths and weaknesses, and it is often not clear which is best in a given setting.

This year, our overall ranking is just each metric's average rank across a large number of "tasks". Unlike raw correlation scores, ranks are comparable across tasks. The resulting global ranking approximates the "Kemeny consensus" – the ranking with lowest aggregate Kendall distance to the per-task rankings – which in turn satisfies several criteria from social choice theory (Colombo et al., 2022). Our version has the following features:

- We use a large number of tasks which may contain overlapping information. For instance, on each dataset, we compute both Pearson and Kendall-Tau correlation, and treat these as separate tasks. This makes the overall ranking robust to quirks in particular correlations.
- To guard against inadvertent bias toward settings that have more tasks than others, we use a task weighting that reflects the relative importance of various attributes (language pair, domain, etc.).
- Within each task, we establish a ranking that includes ties to reflect statistical significance. This naturally up-weights tasks that are more discriminative. For instance, a task that yields the ranking 1, 1, 1, 1 will not affect the overall ranking at all, while a ranking of 1, 2, 3, 4 is a maximal vote.
- In order to indicate metric proximity, we report raw averages over (weighted) per-task ranks rather than the resulting ranking as advocated by Colombo et al. (2022). For instance, average ranks of 1.1, 1.2, 2.1, 3.9 indicate that the top two metrics perform similarly and the last metric is considerably worse; these details is lost in the global ranking 1, 2, 3, 4.
- We also report rankings on selected subsets of tasks to characterize metric behavior on attributes such as language or domain.

5.1 Tasks

Tasks are identified by unique value assignments for each of the following attributes: language, domain, level, include-human, averaging method, and correlation. These are as follows:

Language (4 values)

Language pairs include those for which we have MQM ratings – English→German, English→Russian, and Chinese→English – plus *All*, which indicates all pairs pooled together.

Domain (5 values)

We computed correlations on domain-specific portions of each test-set as well as on each test-set as a whole. All language pairs have the same set of domains: *conversation*, *e-commerce*, *news*, and *social*. We use *mixed* to refer to all domains together, *i.e.*, the whole test set.

Level (2 values)

For each domain (including *mixed*), we computed correlations at the *system* level and the *segment* level. Human scores for each domain are averages over the corresponding segments. For metric submissions that did not include domain-level scores, we computed similar averages.

Include-human (2 values)

We computed separate correlations over sets of outputs that exclude human references (include-human=*false*) and that include all available references (include-human=*true*) except the standard reference, which is never scored by metrics. The first scenario reflects the standard use-case for metrics; the second captures a future scenario in which MT output quality approaches human quality. Since English→Russian has only a single reference, it participates only in the first condition. For the other two language pairs we use the reference that was judged best by the MQM raters. Table 6 summarizes the use of reference translations for different language pairs.

language	best ref	scored ref
en→de	A	B
en→ru	A	{}
zh→en	A	B

Table 6: Use of reference translations.

language	domain	level	+human	averaging	correlation	tasks	weight
all (1/4)	mixed (1/1)	sys (1/1)	no (1/1)	none (1/1)	acc (1/1)	1	1/4
en-ru (1/4)	* (1/5)	sys (1/2)	no (1/1)	none (1/1)	P,K (1/2)	10	1/80
		seg (1/2)	no (1/1)	* (1/3)	P,K (1/2)	30	1/240
en-de,zh-en (1/4)	* (1/5)	sys (1/2)	* (1/2)	none (1/1)	P,K (1/2)	40	1/160
		seg (1/2)	* (1/2)	* (1/3)	P,K (1/2)	120	1/480
						201	

Table 7: Task weighting. Column entries are sets of values for the attribute in the heading, with * designating all possible values. Numbers in brackets show the weight assigned to each value in the set. Each line corresponds to a set of tasks that have the same weight: the product of all the per-attribute weights shown in brackets. *P* and *K* refer to Pearson and Kendall correlation, respectively.

Averaging (3 values)

At the segment level, metric and human scores are naturally represented as system × segment matrices. However, correlations operate over pairs of vectors rather than pairs of matrices. There are three ways to resolve the problem: flatten the matrices into single vectors, compute average correlations over matching pairs of row vectors, or compute average correlations over matching pairs of column vectors. We designate these as *none*, *system*, and *segment* averaging, respectively. They measure a metric's ability to rate an arbitrarily-chosen (system, segment) pair, an arbitrary segment for a fixed system, and different system outputs for the same segment. Last year we used only the first alternative; this year include all three. System-level correlations do not require averaging, since their inputs are vectors in the first place.

Correlation (3 values)

We computed three correlations: system-level pairwise ranking *accuracy* (as proposed by Kocmi et al., 2021), *Pearson* and *Kendall*. Accuracy was used only for a single task in which all language pairs were pooled (language=*All*), while Pearson and Kendall were used for all other tasks. Pearson correlation tests linear fit with MQM scores, a stringent but reasonable criterion since we expect these scores to conform to a linear scale (for example, a translation with two minor errors is twice as bad as one with only a single error). Pearson has well-known drawbacks (Mathur et al., 2020), notably sensitivity to outliers, which we minimized by choosing only relatively high-performing systems. Like accuracy, Kendall is based on pairwise score comparisons, and thus reflects a common ranking use-case. It is susceptible to noise in gold pairwise rankings, for which a common strategy is to discard pairs judged not to be significantly different. We did not take this into account, relying instead on our significance tests for metric (rather than system) rankings.

5.2 Task Weighting

As explained in the previous section, attributes are not independent. For instance, there are three averaging methods for segment-level tasks, but only one for system-level tasks. If all tasks were weighted equally, this would have the undesirable consequence of making segment-level correlations count for 3× as much as system-level correlations when determining the overall ranking.

To avoid this, we used a hierarchical weighting scheme. We first ordered the attributes as listed in the previous section, then distributed weights evenly among all permissible values at each step of the hierarchy. The results are shown in Table 7. There are a total of 201 tasks, of which the accuracy task for all language pairs receives a weight of 1/4, with the remaining mass of 3/4 distributed among tasks whose individual weights vary between 1/80 and 1/420.

In Figures 1 through 4, we show analyses of how metric performance varies along different dimensions (attributes) such as language, domain, etc.. To do this, we partition tasks according to the values of the selected attribute, re-normalizing their global weights so they sum to 1 for each partition. We then compute weighted average ranks for each partition separately, in the same fashion as the overall ranking.

5.3 Per-task Ranking

For each task, we compare all pairs of metrics, and determine whether the difference in their correlation scores is significant according to the PERM-

BOTH hypothesis test of Deutsch et al. (2021), using 1000 re-sampling runs, and setting $p = 0.05$. For the averaging methods, sampling is performed separately for each row or column vector prior to averaging.

We then assign ranks as follows. Starting with the highest-scoring metric, we move down the list of metrics in descending order by score, and assign rank 1 to all metrics until we encounter the first metric that is significantly different from any that have been visited so far. That metric is assigned rank 2, and the process is repeated. This continues until all metrics have been assigned a rank.

6 Main Results

As we have seen in Section 5, the main results are defined across different settings including system-level and segment-level tasks. Nonetheless, since the main use case of automatic metrics is to rank systems, system-level accuracy has a 1/4 weight on the final score with the remaining 3/4 distributed over 200 different settings.

Table 1 shows the official ranking of all primary submissions over the 201 different settings. A key observation is that neural metrics perform significantly better than lexical metrics. Of the 20 evaluated metrics, BLEU and SPBLEU are ranked 19th and 17th respectively. On the other hand, fine-tuned neural baseline metrics such as COMET-20 and BLEURT-20 are still ranked above several of the new primary submissions. They are outperformed only by submissions based on models that are considerably larger[11]. Figure 1 shows the ranking split by the different language pairs. The trend is very similar for all language pairs. While METRICX XXL performs best for En→De and En→Ru, COMET-22 performs best for Zh→En.

One open question about neural metrics has been their ability to generalise to new domains, since most training and testing data from previous years were based on News data. In Figure 2 we present the performance of each metric across four domains: news, social, conversational, and e-commerce. Similar to last year, we observe that the neural metrics perform better than lexical overlap metrics across all four domains.

Figure 3 shows the average rankings when grouped separately by system-level and segment-level tasks. Many metrics fall into the same significance cluster when evaluated on the system-level as we only have a very limited number of MT systems. Nevertheless, we observe that the metric rankings are largely stable across both granularities and that METRICX XXL and COMET-22 perform best on both the segment-level and system-level tasks. The differences are more prevalent in the segment-level task, though.

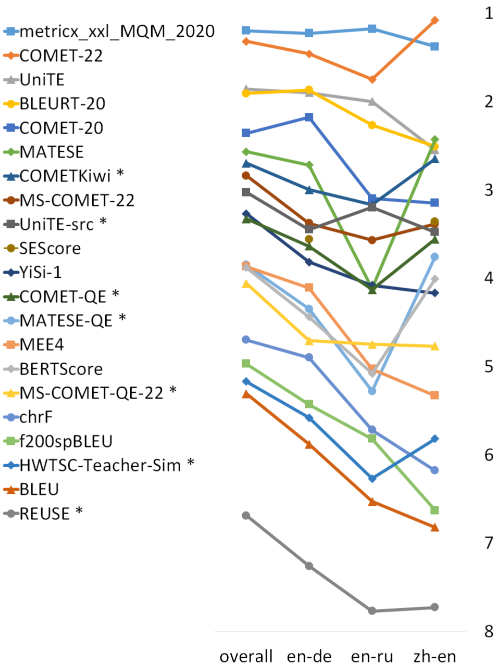

Figure 1: Weighted ranking of metrics' correlation with human grouped by translation directions.

In Figure 4, we compare the rankings when including human translations as MT systems (with human) or just considering MT submission (without human). Overall, the majority of metrics show

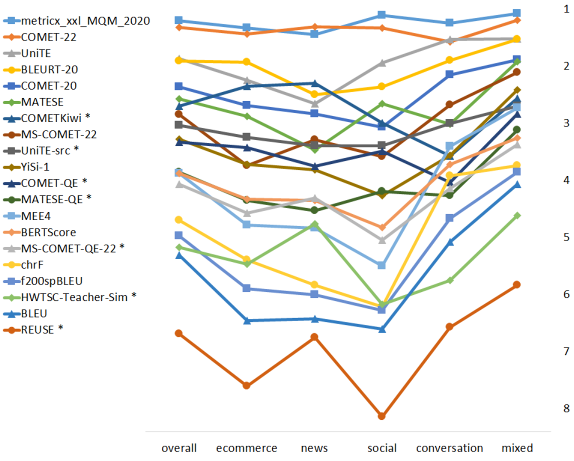

Figure 2: Weighted ranking of metrics' correlation with human grouped by domains.

[11] Both UNITE and COMET-22 are ensembles of two models trained on XLM-R variants while METRICX XXL uses mT5 XXL as a backbone

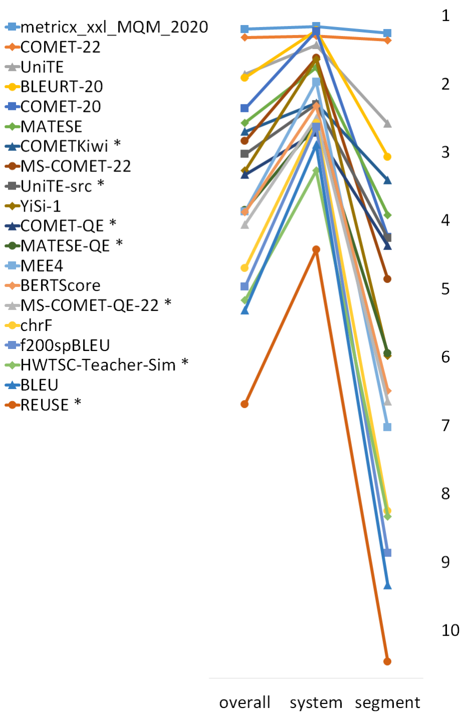

Figure 3: Weighted ranking of metrics' correlation with human grouped by granularity levels.

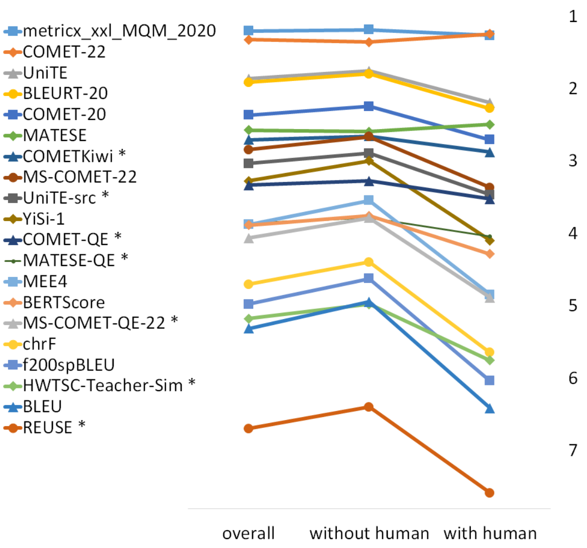

Figure 4: Weighted ranking of metrics' correlation with human grouped by candidate pools (with or without human translations).

lower correlation when we include human translations, except Comet-22 and Matese.

7 Direct Assessment Human Evaluation

In addition to our MQM annotations and as a contrastive evaluation to cover more language pairs, we look into the performance of metrics when compared to the human evaluation campaign conducted by the General MT shared task (Kocmi et al., 2022a), who ran human evaluation for all 21 translation directions and WMT22 submissions. Last year, we decided to exclude the human ratings by the WMT main task as they were of lower quality than the best automatic metrics. However, the GeneralMT task improved their evaluation methodology in particular for all from-English and non-English translation directions and implemented the Scalar Quality Metric (SQM) which has been shown to have high correlation with MQM on at least the system-level (Freitag et al., 2021a). The GeneralMT task used two different human evaluation methodologies depending on the language pair: reference-based Direct Assessment (Ref. DA) (Graham et al., 2013) and SQM style source-based DA (DA+SQM) (Kocmi et al., 2022a).

Ref. DA has been used for all into-English translation directions and asks human raters to judge each system translation against human reference translation on a 0–100 scale. This technique does not use bilingual speakers and is evaluated by non-professional crowd workers. In order to increase quality of assessment, there are several quality control items. Out of all collected human annotations, 63% have been removed due to failing quality control.

DA+SQM asks bilingual raters to annotate system translations against original sources on a 0–100 labeled scale. The scale is marked with seven points representing expected quality. In this setting, Kocmi et al. (2022a) evaluated all from-English and non-English translation directions. They used mainly professional raters.

We present system-level accuracy results in Table 8. The ranking generated based on accuracy scores when taking the DA+SQM annotation as ground truths is comparable to the primary results in Table 1, ranking MetricX XXL as the best performing metric followed by UniTe and COMET-22. Similarly, it ranks n-gram matching metrics (Bleu, chrF, f101spBleu) among worst performing metrics. This confirms the main findings from MQM evaluation.

On the other hand, accuracy scores taking ref. DA as the ground truth, result in a very different ranking of the metrics. It ranks n-gram matching metrics as the top performing metrics. This suggest that the technique does not evaluate systems well

Number of languages	13	6
Number of system pairs	564	329
Human judgement style	DA+SQM	ref. DA
MetricX XXL	**0.862** (1)	0.620 (11)
UniTE	0.849 (2)	0.623 (10)
Comet-22	0.842 (3)	0.626 (9)
CometKiwi*	0.835 (4)	0.617 (12)
MS-Comet-22	0.833 (5)	0.626 (9)
Bleurt-20	0.830 (6)	0.650 (5)
Comet-20	0.826 (7)	0.635 (8)
MS-Comet-qe-22*	0.824 (8)	0.641 (7)
Comet-QE*	0.821 (9)	0.605 (13)
UniTE-src*	0.800 (10)	0.623 (10)
YiSi-1	0.785 (11)	0.660 (3)
BERTScore	0.764 (12)	0.666 (2)
chrF	0.762 (13)	0.666 (2)
EE_BERTScore	0.750 (14)	0.647 (6)
f101spBleu	0.748 (15)	**0.669 (1)**
HWTSC-Teacher-Sim*	0.720 (16)	0.568 (15)
Bleu	0.707 (17)	0.653 (4)
Reuse*	0.344 (18)	0.584 (14)

Table 8: System-level pairwise accuracy for WMT style human evaluation. Numbers in brackets show rank of metrics given human judgement style. The highest score is present bolded.

and instead human crowd workers are incentivized to quickly compare the surface forms of translation against reference without understanding. We would advise metric developers and researchers running human evaluations not to use reference-based DA, especially when evaluated with non-professional crowd workers.

8 Challenge Sets Subtask

The challenge sets subtask is inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017) which aimed at testing the generalizability of NLP systems beyond the distributions of their training data. With that said, our goal is to encourage researchers to build a set of test sets that measure metrics' ability to detect different targeted phenomena that might not be well represented in traditional test sets used to evaluate metrics.

This subtask is made of three consecutive phases; 1) the *Breaking Round*, 2) the *Scoring Round* and 3) the *Analysis Round*:

1. In the *Breaking Round*, the challenge set participants (*Breakers*) submit their challenge sets composed of contrastive examples for different phenomena with source sentences (s), incorrect translations ($\hat{t}$), correct translations (t) and references (r).

2. In the *Scoring Round* the metrics participants from the main task (the *Builders*) are asked to score all translations with their metrics without knowing which ones are correct or incorrect. Also, in this phase the organisers score all data with the baseline metrics.

3. Finally, after gathering all metric scores, the data is returned to the *Breakers* for the *Analysis round*, where they look at which metrics are able to correctly rank the correct translations above the incorrect ones for the different phenomena being tested.

We had a total of 4 submissions to this shared task, covering a wide range of phenomena and 146 different language pairs. Table 9 provides an overview of the submitted challenge sets. A short description of every submission follows:

ACES The ACES (Translation Accuracy Challenge Sets; Amrhein et al., 2022) results from a collaboration between the University of Zurich with the University of Edinburgh. This challenge set, highly inspired by the MQM framework, consists of 36,499 examples, covering 146 language pairs and 68 phenomena, ranging from simple perturbations at the word/character level to more complex errors based on discourse and real-world knowledge. The data was created artificially for some error types and manually for others.

Their analysis aimed to reveal the extent to which metrics take into account the source sentence context and the surface-level overlap with the reference, and if they profit by using multilingual embeddings. Finally, they recommend that one considers a) **combining metrics with different strengths** and b) explicitly **modelling additional language-specific information** beyond what is available via multilingual embeddings.

SMAUG The challenge set based on Sentence-level Multilingual data Augmentation (SMAUG; Alves et al., 2022), submitted by Unbabel and IST evaluates the robustness of MT metrics to 5 different types of translation errors; Named entity errors, numerical errors, meaning errors, insertion of content and content missing. These errors are created by perturbing reference translations and then curated by the authors. The challenge set covers 3

challenge set	method	lang. pairs	pheno-mena	items	citation	availability (https://github.com/)
ACES	automatic	146	68	36,499	Amrhein et al. (2022)	EdinburghNLP/ACES
DFKI-CS	semi-autom.	2	107	19,347	Avramidis and Macketanz (2022)	DFKI-NLP/mt-testsuite
HwTsc-CS	semi-autom.	1	5	721	Chen et al. (2022)	HwTsc/Challenge-Set-for-MT-Metrics
SMAUG	automatic	3	5	632	Alves et al. (2022)	Unbabel/smaug

Table 9: Overview of the participations at the challenge sets task

language pairs and contains close to 50 high-quality examples for each phenomenon.

In this challenge set the authors show that there has been a promising progress in terms of detecting these critical errors when compared to last year's metric submissions. Nevertheless, errors related to **named entities and numbers were found to pose a challenge for several tested metrics**. Also, due to a high variance in the observed results across all the error types it becomes **hard to predict performance of current methods with respect to untested translation errors**.

HWTSC Challenge Set The challenge set submitted by Huawei Translation Services Center (Chen et al., 2022) aims at examining metrics ability to handle synonyms and to discern critical errors in translations. This challenge set is composed of 721 zh-en examples for 5 different error types; Named entity errors, numerical errors, time & date errors, wrong unit conversions and Affirmation/Negation errors. The underlying data is either WMT 21 or Flores 101 which covers two distinct domains, News and Wikipedia respectively. To create alternative translations the authors used in-house translators (performing post-edit) and to create the adversarial translations they used LIST (Alzantot et al., 2018).

The authors of this challenge set conclude that although embedding-based metrics perform relatively well on discerning sentence-level negation/affirmation errors, they **perform poorly on relating synonyms**. Additionally they find that the generalizability of some metrics is compromised, as they are **susceptible to different text styles**.

DFKI Challenge Set The submission by DFKI (Avramidis and Macketanz, 2022) employs a linguistically motivated challenge set that includes about 20,000 items extracted from 145 MT systems for two language directions (German⇔English). It is based on a test suite (Macketanz et al., 2022) that covers more than 100 linguistically-motivated phenomena organized in 14 categories.

The best performing metrics are YiSi-1, BERTScore and COMET-22 for German-English, and UniTE, UniTE-ref, MetricX-xl-DA-2019 and MetricX-xxl-DA-2019 for English-German. Metrics in both directions are performing worst when it comes to **named-entities & terminology** and particularly **measuring units**. Particularly in German-English they are weak at detecting issues at **punctuation, polar questions, relative clauses, dates** and **idioms**. In English-German, they perform worst at **present progressive of transitive verbs, future II progressive of intransitive verbs, simple present perfect of ditransitive verbs** and **focus particles**.

9 Conclusion

This paper summarizes the results of the WMT22 shared task on automated machine translation evaluation, the Metrics Shared Task. We presented an extensive analysis on how well metrics perform on our three main language pairs: English→German, English→Russian and Chinese→English. The results, based on 201 different tasks, demonstrated the superiority of neural-based learned metrics over overlap-based metrics like Bleu, spBleu or chrF. These results are confirmed with DA+SQM human judgement. Although this was already the case in the previous years' Metric Shared Tasks, we further strengthened the case for neural-based fine-tuned metrics by demonstrating their superiority across four different domains. In addition, we initiated a challenge set subtask, where participants had to create contrastive test suites for evaluating metrics' ability to capture and penalise specific types of translation errors.

10 Ethical Considerations

MQM annotations and additional reference translations in this paper are done by professional translators. They are all paid at professional rates.

Organizers from the National Research Council

Canada and Unbabel have submitted to this task the frozen stable versions of their metrics (YiSi and COMET) dated before this year's shared task and publicly available. Newer versions of COMET were developed without using any of the test set, test suite or challenge sets.

11 Acknowledgments

Results for this shared task would not be possible without tight collaboration with the organizers of the General MT Task. We are grateful to Google and Unbabel for sponsoring and overseeing the human evaluation.

Table 10: Pearson correlation of all metrics with system-level MQM scores for the three main language pairs. Rows are sorted by the system-level pairwise accuracy across the three language pairs. Primary submissions are bolded, and baselines are underlined. Reference-free metrics are indicated using an asterisk.

A Language-Specific Results Tables

Language-specific results are given in Table 10 and Table 11. Each page contains results for scores over all domains over a single granularity (system or segment).

For all tables, the correlations are calculated on metric scores comparing MT system translations with Reference A, and any additional human reference translations are not included.

For segment level correlation, we report results on the "none" averaging method, where we flatten the matrices into single vectors before computing the Kendall Tau correlation.

B Correlations with WMT Human Evaluation

Correlations with WMT Direct Assessment Human scores are given in the following tables, with results for language pairs evaluated using reference-based Direct Assessment (Ref. DA) (Graham et al., 2013), followed by results for language pairs evaluated using SQM style source-based DA (DA+SQM) (Kocmi et al., 2022a). Since most language pairs contained only a single reference, we used reference A for all pairs, and report results only for scoring MT output (omitting additional scored references for language pairs where these were available). System-level correlations use Pearson and segment-level scores use Kendall. For simplicity, both statistics are computed over raw rater scores, with no traditional difference-25

Table 11: Kendall Tau correlation of all metrics with segment-level MQM scores for the three main language pairs. Rows are sorted by the system-level pairwise accuracy across the three language pairs. Primary submissions are bolded, and baselines are underlined. Reference-free metrics are indicated using an asterisk.

filtering.[12]

[12] The traditional recipe made little difference in overall correlation patterns.

Table 12: System-level Pearson correlation with crowdsourced Ref. DA scores. Rows are sorted by the system-level pairwise accuracy across all language pairs. Primary submissions are bolded, and baselines are underlined. Reference-free metrics are indicated using an asterisk.

System-level Metric accuracy and correlations with REFDA scores contradict the main results. We strongly recommend against using Ref. DA scores to evaluate MT metrics.

Abstract

We report the results of the WMT 2022 shared task on Quality Estimation, in which the challenge is to predict the quality of the output of neural machine translation systems at the word and sentence levels, without access to reference translations. This edition introduces a few novel aspects and extensions that aim to enable more fine-grained, and explainable quality estimation approaches. We introduce an updated quality annotation scheme using Multidimensional Quality Metrics to obtain sentence- and word-level quality scores for three language pairs. We also extend the Direct Assessments and post-edit data (MLQE-PE) to new language pairs: we present a novel and large dataset on English-Marathi, as well as a zero-shot test-set on English-Yoruba. Further, we include an explainability sub-task for all language pairs and present a new format of a critical error detection task for two new language pairs. Participants from 11 different teams submitted altogether 991 systems to different task variants and language pairs.

1 Introduction

The 11th edition of the shared task on Quality Estimation (QE) builds on its previous editions and findings to further benchmark methods for estimating the quality of neural machine translation (MT) output at run-time, without the use of reference translations. It includes (sub)tasks that consider quality of machine translations at the word and sentence levels.

Over the past years, the QE field has been moving towards trainable, large, multilingual models that have been shown to achieve high performance, especially at sentence-level (Specia et al., 2021). In this edition, we further expand the provided resources, introducing new low-resource language pairs: a large dataset of English-Marathi, suitable for training, development and testing and a smaller test-set on English-Yoruba for zero-shot approaches. These, as well as previously published datasets for QE, rely mainly on Direct Assessments (DA)[1] and post-edited translations, which provide estimates of quality either by using the human quality score(s) for each segment or by estimating the distance of a translation from a human-provided correction. As these annotations can sometimes obscure the exact location and/or significance of a translation error, we wanted to investigate the feasibility and efficiency of using a more fine-grained annotation schema to obtain quality estimations at word- and sentence- level, namely Multidimensional Quality Metrics (MQM) (Lommel et al., 2014). MQM annotations have shown to be more trustworthy for the metrics task (Freitag et al., 2021a,b), motivating us to evaluate their suitability for the QE task. We make available new development and test data on three language pairs using MQM annotations.

The aforementioned boost in performance of QE systems frequently comes at the cost of efficiency and interpretability, since they heavily rely on large models with many parameters. As a result, the predicted quality estimates are hard to interpret. At the same time, such high-performance, "black-box" models are frequently susceptible to systematic errors, such as negation omission (Kanojia et al., 2021) and mistranslated entities (Amrhein and Sennrich, 2022). Both phenomena are major concerns for MT quality estimation since they can undermine users' trust in new technologies and hamper the adoption of such models on a wide scale. To motivate approaches that address these cases we include an explainability subtask following its first edition at Eval4NLP 2021 (Fomicheva et al., 2021). In this subtask we ask participants to predict

[1] We note that the procedure followed for our data diverges from that proposed by Graham et al. (2016) in three ways: (a) we employ fewer but professional translators to score each sentence, (b) scoring is done against the source segment (bilingual annotation) and not the reference, and (c) we provide translators with guidelines on the meaning of ranges of scores.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 69 - 99

the erroneous words as rationale extraction for a sentence-level quality estimate, without any word-level supervision. By framing error identification as rationale extraction for sentence-level quality estimation systems, this subtask offers an opportunity to study whether such systems behave in the same way as humans would do. We also reshape the critical error detection task of last year and we build a new corpus to test the ability of QE systems to detect critical errors that simulate hallucinated content with additions, deletions, named entities, polarity changes and numbers. The corpus is created using SMAUG (Alves et al., 2022) and we allow participation in constrained and unconstrained settings. For the constrained setting, participants have to build QE systems without having access to data from SMAUG, whereas participants from the unconstrained task can train their systems using additional data from SMAUG.

In addition to advancing the state-of-the-art at all prediction levels, our main goals are:

- To extend the languages covered in our datasets;
- To further motivate fine-grained quality annotation, informed at word and sentence level using MQM;
- To encourage language-independent and even unsupervised approaches especially for zero-shot prediction;
- To study and promote explainable approaches for MT evaluation; and
- To revisit critical error detection.

We thus have three tasks:

Task 1 The core QE task, consisting of separate sentence-level and word-level subtasks. For the sentence-level sub-tasks, the goal is to predict a quality score for each segment in the test set, which can be a variant of DA (§2.1.1) or MQM (§2.1.1). For the word-level subtasks, participants have to predict translation errors at word-level, via binary quality tags (see §2.1.2).

Task 2 Explainable QE task, aiming to obtain word-level rationales for sentence-level quality scores (§2.2).

Task 3 The critical Error Detection task, aiming to predict sentence-level binary scores indicating whether or not a translation contains a critical error (§2.3).

The tasks make use of large datasets annotated by professional translators with either 0-100 DA scoring, post-editing or MQM annotations. We update the training and development datasets of previous editions and provide new test sets for Tasks 1 and 2. Additionally, we provide a novel setup for Task 3, with novel train, development and test data. The datasets and models released are publicly available[2]. Participants are also allowed to explore any additional data and resources deemed relevant, across tasks.

The shared task uses CodaLab as submission platform, where participants (Section 4) could submit up to 2 submissions a day for each task and language pair (LP), up to a total of 10 submissions. Results for all tasks evaluated according to standard metrics are given in Section 5. Baseline systems were trained by the task organisers and entered in the platform to provide a basis for comparison (Section 3). A discussion on the main goals and findings from this year's task is presented in Section 6.

2 Quality Estimation tasks

In what follows, we briefly describe each subtask, including the datasets provided for them.

2.1 Task 1: Predicting translation quality

Being able to automatically predict the quality of translations on sentence- or word-level without access to human-references is the core goal of the QE shared task. In this edition, we explored some new approaches towards quality annotations for sentence- and word-level, and redefined the word-level quality labelling scheme, in an attempt to allow participants to employ multi-task approaches and exploit fine-grained quality annotations. Hence, the data was produced in two ways:

1. DA & Post-edit approach: The quality of each source-translation pair is annotated by at least 3 independent expert annotators, using DA on a scale 0-100. The translation is also post-edited to obtain the closest possible, fully correct translation of the source. Using the post-edited data, we generate Human-mediated

[2] https://github.com/WMT-QE-Task/wmt-qe-2022-data

Translation Edit Rate (HTER) (Snover et al., 2006) scores, which are obtained by calculating the minimum edit distance between the machine translation and its manually post-edited version. By additionally considering the alignment between the source and post-edited sentence, we can propagate the errors to the source sentence and annotate the segments that were potentially mistranslated and/or not translated at all. The HTER scores were made available to participants as additional data, but are not used as prediction targets.

2. MQM approach: Each source-translation pair is evaluated by at least 1 expert annotator, and errors identified in text are highlighted and classified in terms of severity (minor, major, critical) and type (omission, style, mistranslation, etc).

The DA and MQM data was further processed to a) obtain normalised quality scores that have the same direction between high and low quality and b) obtain word-level binary quality labels. We provide more details on the required pre-processing in §2.1.1 and §2.1.2.

DA & Post-edit data: For all language pairs the data provided is selected from publicly available resources. Specifically for training we used the following language pairs from the MLQE-PE dataset (Fomicheva et al., 2022): English-German (En-De), English-Chinese (En-Zh), Russian-English (Ru-En), Romanian-English (Ro-En), Nepalese-English (Ne-En), Esthonian-English (Et-En) and Sinhala-English (Si-En), which are all sampled from Wikipedia, except for the Ru-En pair, which also contains sentences from Reddit. Additionally, the language-pairs used for development and testing also originate from Wikipedia: English-Czech (En-Cs), English-Japanese (En-Ja), Khmer-English (Km-En) and Pashto-English (Ps-En).

Finally, the new English-Marathi (En-Mr) data that is made available for train, development and testing this year is sampled from a combination of sources. More specifically the source side segments of the English-Marathi data contain segments from three different domains – healthcare, cultural, and general/news. The general domain and cultural domain data were obtained from the English (source side) segments in the IITB English-Hindi Parallel Corpus (Kunchukuttan et al., 2018). However, the healthcare domain data was obtained from publicly available NHS monolingual corpus[3].

All of the data was translated using large transformer-based NMT models, with established high performance for the languages in question. Specifically, for the language pairs in the training data (En-De, En-Zh, Et-En, Ne-En, Ru-En, Ro-En, Si-En), all source sentences were translated by a *fairseq* Transformer (Ott et al., 2019) bilingual model. The exception is the English-Marathi which was translated by the multilingual IndicTrans (En-X) Transformer-based NMT model, which was trained on the Samanantar parallel corpus (Ramesh et al., 2022).

For the languages provided in the development and test set, namely: En-Cz, En-Ja, Km-En and Ps-En we maintain the same we use the MBART50 (Tang et al., 2020),[4] to translate the source sentence of the other languages pairs, since it has been found to perform well, especially for low-resource languages (Tang et al., 2020). The En-Mr portion of the development and test data is translated similarly to the training data for this language pair.

Zero-shot language pair: This year we introduced a "surprise" language-pair, English-Yoruba (En-Yo), which represents a low-resource language pair. The Yoruba language is the third most spoken language in Africa, and it is native to southwestern Nigeria and the Republic of Benin (Eberhard et al., 2020). We extracted 1010 sentences in English from Wikipedia across 7 topics and translated them to Yoruba using Google Translate. Using adjusted guidelines from Fomicheva et al. (2021), we trained annotators to indicate sentence-level DA scores and to highlight erroneous words as word-level explanations for the DA scores.[5] On the 1010 sentences, they obtained agreements of 0.487 Pearson on sentence-level and 0.380 kappa on word-level. Note that in order to further encourage multilingual and unsupervised approaches, the setup for this zero-shot approach was slightly different to the previous edition, since we did not reveal the language pair before the release of the test data, and the zero-shot pair was included only in the multilingual sub-tasks for quality estimation

[3] The NHS corpus source sentences were crawled from the health directory of NHS available here: https://www.nhs.uk/conditions/

[4] https://github.com/pytorch/fairseq/tree/master/examples/multilingual

[5] Annotators were graduate students and native speakers of Yoruba and fluent in English.

(as opposed to a standalone subtask for this language pair only).

MQM data: As training data, we used annotations released for the Metrics shared task namely, the concatenation of the annotations released from Freitag et al. (2021a) with the annotations from last year Metrics task (Freitag et al., 2021b). Together, these annotations, cover 3 high-resource language pairs, namely: Chinese-English (Zh-En), English-German (En-De) and English-Russian (En-Ru), and span across two domains (News and Ted Talks). In contrast to DA, instead of one translation for each source, we have multiple translations coming from system participation's in the 2020 and 2021 News translation tasks (Barrault et al., 2020; Akhbardeh et al., 2021). For development set however, we follow an approach that is similar to the one use for the DA data: we translated the Newstest 2019 using a single NMT system, namely MBART50. Subsequently, for each language pair we asked an expert translator to provide MQM annotations. The test set was created similarly to the development, but instead of using Newstest 2019 we used the Newstest 2022 (the News data from this year's General MT shared task).

Overall, the released data for Task 1covers a total of 9 language pairs for training, 4 language pairs for development and 6 language pairs for testing including 1 zero-shot language pair. Statistics and details for each language pair are provided in Table 1.

2.1.1 Sentence-level quality prediction

There were two competition instances for the sentence-level sub-task. The first one focuses on DA- and the second one on MQM-derived annotations, both including a separate multilingual track. In the future, we aim to consolidate the competition instances into a single one for sentence-level, using our findings from this edition to align the annotation schemes in a better manner. We provide below the details for each annotation scheme and a comprehensive table with statistics for all annotations (Table 1).

DA annotations: For DA annotations, we followed the annotation and scoring conventions of previous editions. We provided MLQE-PE data (Fomicheva et al., 2022) used in previous years for training, which includes seven language pairs with $\approx$ 8,000 segments each. We also provided 26,000 segments of En-Mr which were annotated using the same annotation conventions. All translations were manually annotated for perceived quality, with a quality label ranging from 0 to 100, following the FLORES guidelines (Guzmán et al., 2019). According to the guidelines given to annotators, the 0-10 range represents an incorrect translation; 11-29, a translation with few correct keywords, but the overall meaning is different from the source; 30-50, a translation with major mistakes; 51-69, a translation which is understandable and conveys the overall meaning of the source but contains typos or grammatical errors; 70-90, a translation that closely preserves the semantics of the source sentence; and 91-100, a perfect translation. For each segment, there were at least three scores from independent raters (four in the case of En-Mr). DA scores were standardised using the z-score by rater, and the z-scores were provided as training targets. Participating systems are required to score sentences according to z-standardised DA scores.

MQM annotations: As we have seen (§2.1), for the MQM annotations, we built on the available Google MQM annotations (Freitag et al., 2021a) that contain annotated data for the En-De and Zh-En data of WMT 2020 News Translation Systems (Barrault et al., 2020) as well as En-De, Zh-En and En-Ru annotations from WMT Metrics 2021 (Freitag et al., 2021b). These annotations, provided as training data, amount to more than 30,000 segments in total (see Table 1 for details per language pair). In addition, we provide newly annotated development and test sets for all three language pairs (En-De, En-Ru, Zh-En), amounting to approximately 1,000 segments per language pair.

Originally, MQM annotated segments include annotated erroneous text-spans on the translation side that are assigned two types of labels: (a) an error severity label {`minor`, `major`, `critical`} and (b) an error category label such as {`grammar`, `style/awkward`, `omission`, `mistranslation`}, `...`}. Each error severity is associated with a specific weight; hence a sentence score can be calculated for each segment based on these error weights. We demonstrate an example of MQM annotations and scores in Figure 1.

MQM scores according to Google weight scheme have the opposite direction of the DA scores since larger MQM scores denote worse translation quality, i.e., a larger number of errors or more severe errors. To address this inconsistency, we

Figure 1: Example of MQM annotations on the target (translation) side, on a English–German (En-De) sentence pair.

invert the MQM scores and standardise per annotator. For training data we had access to multiple annotations per segment and calculated an average score after standardisation, keeping also the original MQM scores per annotator, to allow the participants to take full advantage of the different annotations (Basile et al., 2021). For the same reasons, we opted not to aggregate the annotated text-spans.

Regarding evaluation, systems in this task (both for DA and MQM) are **evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient** ρ **as the primary metric**. This is what was used for ranking system submissions. Pearson's correlation coefficient, r, Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) were also computed as secondary metrics but not used for the final ranking between systems.

2.1.2 Word-level quality prediction

This sub-task focuses on detecting word-level errors in the MT output. The goal is to automatically predict the quality of each token using a binary decision, i.e., using OK as a label for tokens translated correctly and BAD otherwise. We deviate from the annotation pattern of previous years in that, we do not consider annotations of the gaps between tokens or source-side annotations. Instead, to account for omission errors, we consider the following convention: the token on the right side of the omitted text in the translation is annotated as "BAD". An additional `<EOS>` token is appended at the end of every translation segment to account for omissions at the end of each sentence. This allows the provision of a unified framework for both the post-edit originated annotations and the MQM annotations.

We thus use the same source-translation pairs used for the sentence-level tasks and obtain the binary tags as follows:

- For post-edited data, we use TER (Snover et al., 2006) to obtain alignments between translation and post-edit and annotate the misaligned tokens as BAD.

- For MQM data, the tokens that fall within the text-spans annotated as errors (or any severity or category) are annotated as BAD. If the whitespace between two words is annotated as an error, then this is considered an omission, and the next token is annotated as BAD.

Participants were encouraged to submit for each language pair and also for the **multilingual variants** of each sub-task. For the DA-based sentence-level competition, as well as the word-level sub-task, there was an additional multilingual variant that included the zero-shot language pair (En-Yo). The latter aimed at fostering work on language-independent models, as well as models that are truly multilingual.

For word-level task, **submissions are ranked using the Matthews correlation coefficient (MCC) as the primary metric**, while F1-scores are provided as complementary information.

2.2 Task 2: Explainable Quality Estimation

Following the success of the shared task on Explainable Quality Estimation organized by the Eval4NLP workshop in 2021 (Fomicheva et al., 2021), in this sub-task we aim to address translation error identification as rationale extraction from sentence-level quality estimation systems. If a QE system reasonably estimates the quality of a translated sentence, an explanation extracted from the system should indicate word-level translation errors in the input (if any) as reasons for imperfect sentence-level scores. Particularly, for each input pair of source and target sentences, participating teams are asked to provide (*i*) a sentence-level score estimating the translation quality and (*ii*) a list of continuous word-level scores where the tokens with the highest scores are expected to correspond to translation errors considered relevant by human annotators.

In this explainable QE task, we use all the nine language pairs and their word-level test sets from Task 1 (see §2.1.2) with En-Yo being a separate language pair (rather than blending it in the multilingual test set). Therefore, the participants are allowed to use the sentence-level scores from the datasets in Task 1 to train their sentence-level models in Task 2. However, as Task 2 aims to promote the research on the explainability of QE systems, we encourage the participants to use or develop explanation methods to identify contributions of words or tokens in the input. Unlike Task 1, **the participants of Task 2 are not allowed to supervise their models with any token-level or word-level labels or signals (whether they are from natural or synthetic data) in order to directly predict word-level errors.** Consequently, we do not require the participants to convert their word-level scores into predicted binary labels (OK/BAD) since this process usually requires a word-level QE dataset to search for an optimum score threshold.

Concerning the evaluation of this task, we focus on assessing the quality of explanations (i.e., the submitted word-level scores), not the sentence-level predictions. Specifically, we measure how well the word-level scores provided by the participants correspond with human word-level error annotations, which are binary ground truth labels. Unlike the Eval4NLP 2021 shared task, which ranked participating systems by a combination of three metrics (Fomicheva et al., 2021), **we use *Recall at Top-K*, also known as *R-precision* in information retrieval literature (Manning et al., 2008, chapter 8), as the primary metric this year** due to two reasons. First, it is preferable to have a single main metric to avoid confusion and also some potential side effects that combining the three metrics might produce. Second, Recall at Top-K seemed to help discriminate best between the participating submissions in the Eval4NLP shared task. Assume that, for a given pair of source and target sentences, there are K words annotated as translation errors by humans. Recall at Top-K equals $\frac{r}{K}$ when there are r out of the K error words appearing in the list of top-K words ranked by the submitted word-level scores descendingly. In addition, AUC (an area under the receiver operating characteristic curve) and AP (average precision) are used as secondary metrics. Considering the word level, AUC summarises the curve between true positive rate and false positive rate, while AP summarises the curve between precision and recall. For both of the secondary metrics, higher values are the better. Although we report metrics for sentence-level predictions, including Pearson's correlation and Spearman's correlation, as additional information, we do not use them for ranking the participants or determining the winner in this explainability task.

2.3 Task 3: Critical Error Detection

In this sub-task, we reshape the binary classification task introduced in last year's edition (Specia et al., 2021) to predict whether the translated sentence contains (at least) one critical error.

Following Specia et al. (2021), we consider that a translation contains a critical error if it deviates from the meaning of the source sentence in such a way that it is misleading and may lead to several implications. As noted by Specia et al. (2021), deviations in meaning can happen in three ways: mistranslation errors have critical content translated incorrectly into a different meaning; hallucination errors introduce critical content in the translation that is not in the source; and deletion errors remove critical content that is in the source from the translation.

In this task, we focus on five critical error categories:

- Additions: The content of the translation is only partially supported by the source.
- Deletions: Part of the source sentence is ignored by the MT engine.
- Named Entities: A named entity (people, organization, location, etc.) is mistranslated into another incorrect named entity.
- Meaning: The translated sentence either introduces or removes a negation and the sentence meaning is completely reversed.
- Numbers: The MT system translates a number/date/time or unit incorrectly.

For this task, we introduce a new dataset obtained by perturbing a corpus of News articles with SMAUG (Alves et al., 2022) and using humans to validate perturbation on the test set. The original data for this task is composed of the News articles from OPUS News-Commentary (Tiedemann, 2012) for the language pairs English-German and Portuguese-English.

For the English-German language pairs, there are no Deviation in Meaning errors, as the perturbation is only available for into English language pairs. The new dataset is purposefully unbalanced, as these phenomena are rare, containing approximately 5% of translations with critical errors. Table 1 presents the number of records for each language pair.

Since the dataset for this task is artificially generated, the participants were encouraged to submit systems that did not rely on the provided training data. As such, submissions were split into two groups: *unconstrained* and *constrained*. In the first group, the participants have access to the training data. In the second, the systems should only be trained on quality scores such as DA, HTER and MQM annotations. With this setting, we aim to evaluate whether systems can identify critical errors while maintaining correlations with human judgements.

In the evaluation of this task, the participants were not required to submit any classification threshold for their systems. For the *unconstrained* setting, the systems are specifically trained to detect errors and should output high scores for translations containing these errors. As such, for each language-pair, we considered as positive predictions the K records with highest scores, where K is the number of positive records for that language-pair in the test set. Regarding the *constrained* setting, these systems are only trained on quality scores and are expected to assign lower scores to translations with critical errors. Therefore, we considered the K records with lowest scores as positive predictions. From here, we measured the MCC, *Recall* and *Precision* for each submission.

3 Baseline systems

Task 1: Quality Estimation baseline systems: For Task 1, both for word and sentence-level, we used a multilingual transformer-based Predictor-Estimator approach (Kim et al., 2017), which is described in detail in Fomicheva et al. (2022). For the implementation and training we use the OpenKiwi (Kepler et al., 2019) framework. We trained the baseline model using a multilingual and multitask setting and training jointly on the sentence-level scores and word-level tags. For the word-level loss, $\mathcal{L}_{\text{word}}$, the weight of BAD tags is multiplied by a factor of $\lambda_{BAD} = 3.0$, but the sentence- and word-level loss have equal weight in the overall joint loss estimation: $\mathcal{L} = \mathcal{L}_{\text{word}} + \mathcal{L}_{\text{sent}}$. We trained different baselines for the DA/post-edit originated language pairs and the MQM originated language-pairs.

For the DA/post-edit baseline, the model was trained using the DA scores as sentence targets and the OK/BAD tags as word targets. For training we used the concatenated data for all language pairs available under training data and used the concatenation of the additional language pairs that were made available in the development set as validation. We trained two baselines with this setup, using different encoders for the encoding (predictor) part of the architecture: (a) XLM-R transformer with the `xlm-roberta-large` model and (b) RemBERT model which has been pre-trained on additional languages that include Yoruba and can hence account for the zero-shot language.

For the MQM baseline, the model was trained using the normalised and inverted MQM scores as sentence targets and the OK/BAD tags as word targets. The baseline model was trained using the concatenated training data for all three language pairs and used the concatenated development data for the same pairs as the validation set. The XLM-R transformer with the `xlm-roberta-large` model was used as an encoder.

Task 2: Explainability baseline systems: We provide two baseline systems for Task 2. One is a random baseline where we sampled scores uniformly at random from a continuous [0..1) range for each target token and for a sentence-level score. The other one is a combination of a supervised quality annotation model, OpenKiwi (Kepler et al., 2019) and LIME (Ribeiro et al., 2016) where OpenKiwi is used to predict sentence-level quality scores while LIME is used to compute, for every token in the target sentence, its importance for the sentence-level quality score returned by OpenKiwi. For the OpenKiwi implementation we used a similar setup described for the baselines of Task 1, but we trained the OpenKiwi model using only sentence-level supervision, to align with the task requirements. We trained two multilingual instances, one on DA- and one on MQM-derived data, using XLM-R large encoder in both cases.

LIME is a model-agnostic post-hoc explanation method which trains a linear model to estimate the behavior of a target model (i.e., OpenKiwi in our case) around an input example to be explained so the weights of the linear model correspond to the importance of individual input tokens. Because higher sentence-level scores in our gold standard mean better translation quality, we invert token-level scores generated by LIME so that higher values correspond to errors as required by the task description.

Task 3: Critical Error Detection baseline systems: For task 3, we consider a baseline system for each setting.

In the *constrained* setting, we considered COMET-QE (Rei et al., 2021)[6], which was a top-performing QE-as-a-Metric system in last years Metrics shared task (Freitag et al., 2021b).

Regarding the *unconstrained* setting, we fine-tune an `xlm-roberta-large` model using the COMET framework (Rei et al., 2020). Both the source and translation are jointly encoded into a vector representation which is the input of a final estimator that predicts the probability of the translation containing a critical error. Here, the estimator weights are randomly initialised. We fine-tune the model on the provided training data for a maximum of 5 epochs. At the end of each epoch, we perform a validation step by measuring the MCC on the validation set considering a classification threshold of 0.5. We select the model with the highest MCC on the validation data.

4 Participants

Alibaba-Translate (T1-DA): For the DA subtask, the team participated in all language pairs except the zero-shot LP. The implemented system (Wang et al., 2021), uses glass-box QE features to estimate the uncertainty of machine translation segments and incorporates the features into the transfer learning from the large-scale pre-trained model, XLM-R. The participants used exclusively the DA data provided for this edition of the QE shared task. Of the provided data, the 7 language pairs except for English-Marathi, were combined to train a multilingual model. For English-Marathi, a separate bilingual model was trained. For the final submission the participants ensembled multiple checkpoints.

(T1-MQM): The submission for sentence-level MQM task is based on a multilingual unified framework for translation evaluation. The applied framework UniTE (Wan et al., 2022) considers three input formats – source-only (QE or reference-free metric), reference-only and source-reference-combined. The participants used synthetic datasets with pseudo labels during continuous pre-training phase, and fine-tuned with DA and MQM training

[6] More precisely we used the `wmt21-comet-qe-mqm` model

datasets from the year 2017 to 2021. To obtain the final model predictions they use the source-only evaluation. For multilingual phase, they ensembled predictions using two different backbones – one using XLM-R encoder and the other using InfoXLM. For the ensembling, they picked the best 2 checkpoints on the development dataset.

BJTU-Toshiba (T1-MQM): BJTU-Toshiba participation focused on ensembling different models and using external data. They ensemble multiple pre-trained models, both monolingual and bilingual. The monolingual models are trained only on the text of the target language. Specifically, they use monolingual BERT, Roberta, and Electra-discriminator as the monolingual extractor, and XLM-R as the bilingual extractor. They also use in-domain parallel data to fine-tune and adapt the pre-trained models to the target language and domain. The in-domain data is selected by a BERT-classifier from the parallel data provided by the news translation task, and for each direction, they end up using roughly 1 million sentence pairs for fine-tuning. They explore two styles of fine-tuning, namely Translation Language Model and Replaced Token Detection. For Replaced Token Detection, they use the first 1/3 layers of the model as generator, and after the training they drop the generator and only use the discriminator as the feature extractor.

HW-TSC (T1): HW-TSC's submission follows Predictor-Estimator framework with a pre-trained XLM-R Predictor, a feed-forward Estimator for sentence-level QE subtask and a binary classifier Estimator for word-level QE subtask. Specially, the Predictor is a cross-lingual language model that receives source and target tokens concatenated and returns representations that attend to both languages. WMT 2022's news translation task training data is been used to train the Predictor using a cross-lingual masked language model objective. All of the WMT QE 2022 DA and MQM training data are used to train two different multilingual QE models, one for sentence-level and another one for word-level.

(T2:) The language encoder trained for Task 1 is being used to get source and target token embeddings. After computing cosine similarity between target and source token embeddings, the max cosine similarity of each target token to all the source tokens is selected as quality score. Intuitively, a low score means the target token is more likely to be an error (lack of good alignment), so every target word quality score is multiplied by a negative value.

HyperMT - aiXplain (T1-all): The system is trained with AutoML functionalities in FLAML framework using lightgbm estimator. It utilizes COMET-QE score as feature along-side with many other linguistic features extracted with Stanza from source texts and their translations: the number of tokens, characters, and the average word length of sentences; the frequency of Part-of-Speech and Named Entity Recognition labels, and the frequency of morphological features. The differences in values of linguistic features between source texts and translations are also included as features. This allows the system to work in multilingual settings as well.

IST-Unbabel (T1-all): IST-Unbabel team proposed an extension of COMET, dubbed COMET-Kiwi, which includes a word-level layer and can be trained on both sentence-level scores and word-level labels in a multi-tasking fashion. Their final submission for task 1 is a weighted ensemble between models trained using InfoXLM (Chi et al., 2021) and RemBERT (Chung et al., 2021). All these models are pretrained on the data from the metrics shared tasks and, for word-level, they pretrained on both QT21 and APE-Quest datasets.

(T2) For the second task they use the COMET-Kiwi framework as the backbone of a sentence-level QE model and added layer and headwise parameters to the QE model: for each layer and for each head, they train individual parameters to construct a sparse distribution over the layers/heads to better leverage these representations. They leveraged different encoders – InfoXLM and RemBERT – and used them individually as the backbone of our QE sentence-level models. The models used to extract explanations were multilingual ones trained for DA and MQM separately. The explainability weights were obtained from the attention weights scaled by the norm of the gradient of the value vectors (Chrysostomou and Aletras, 2022). No word supervision was used and all explanations were extracted relying solely on models that produced the sentence-level scores. The final submissions are ensembles of explanations from different attention layers/heads according to the validation data. For the zero-shot language pair (En-Yo), they created an ensemble with the attention layers/heads that were among the top-performing ensembles for other language pairs.

(T3) For task 3 a single model from task 1 using InfoXLM encoder and trained on DA annotations was submitted.

KU X Upstage (T3): KU X Upstage employs an XLM-R large model without leveraging any additional parallel corpus. Instead, they attempt to maximise its capability by adopting prompt-based fine-tuning, which reformulates the Critical Error Detection task as a masked language modelling objective (a pre-training strategy of this model) before training. They generate hard prompts suitable for QE task through prompt engineering, and templates consist largely of three types according to the information utilised: naive template, template with a contrastive demo, and template with Google Translate. The final score is obtained by extracting the probability of a word mapped to BAD among verbalizers. They gain an additional performance boost from the template ensemble by adding the values from multiple templates.

NJUNLP (T1-all): NJUNLP submission makes use of pseudo data and multi-task learning. Inspired by DirectQE (Cui et al., 2021), they experiment with several novel methods to generate pseudo data for all three subtasks (MQM, DA, and PE) using the conditional masked language model and the NMT model to generate high quality synthetic data and pseudo labels. The proposed methods control the decoding process to generate more fluent pseudo translations close to the actual distribution of the gold data. They pre-train the XLM-R large model with the generated pseudo data and then fine-tune this model with the real QE task data, using multi-task learning in both stages. They jointly learn sentence-level scores (with regression and rank tasks) and word-level tags (with a sequence tagging task). For the final submissions they ensemble sentence-level results by averaging all valid output scores and ensemble word-level results using a voting mechanism. For the pseudo label generation they use publicly available parallel data, specifically: the data provided by the WMT translation task for En-De (9M), En-Ru (3M), and Zh-En (3M) language pairs. The 660K parallel sentences from OPUS[7] for the Km-En language pair. They also use 3.6M parallel data from the target translation model[8] for the En-Mr language pair, as well as WMT2017, WMT2019, and WMT2020 En-De PE data for the En-De language pair.

Papago (T1-full): Papago submitted a multilingual and multi-task model, trained to predict jointly both sentence and word level. The system's architecture consists of Pretrained Language Model with task independent layers optimized for both sentence and word level quality prediction. They propose an auxiliary loss function to the final objective function to further improve performance. They also augment training data by either generating (i.e. pseudo data) or collecting open source data that is deemed to be relevant to QE task. Finally, they train and select the checkpoints for the final submission with cross-validation for better generalization and ensemble multiple models for their final submission.

UCBerkeley-UMD (T1:DA): UCBerkeley-UMD used a large-scale multilingual model to back translate from Czech to English. They compared the quality of the Czech translation by examining the translation from Czech back to English with the original source text in English. This is motivated by literature that humans tend to perform quality checks on translations when they do not understand the target language.

UT-QE (T2): The UT-QE team used XLMR-Score (Azadi et al., 2022) as an unsupervised sentence-level metric, which is computed as BERTScore but in a cross-lingual manner while using the XLM-R model. The matched

tokens distances in this metric were used as token-level scores. In order to alleviate the mismatching issues, they also try to fine-tune the XLM-R model on word alignments from parallel corpora to make it represent the aligned words in different languages closer to each other, and use the fine-tuned model instead of XLM-R for scoring sentences and tokens.

Welocalize-ARC/NKUA (T1-DA): Welocalize-ARC/NKUA's submission for the Task 1 follows the Predictor-Estimator framework (Kim et al., 2017) with a regression head on top to estimate the z-standardised DA. More specifically, they use a pre-trained Transformer for feature extraction and then concatenate the extracted features with additional glass-box features. The glass-box features are also produced using pre-trained models and by applying multiple techniques to estimate different types of uncertainty for each translated sentence. The final features are then used as input for the QE regression model, which is a simple sequential Neural Network with a linear output layer. Finally, the performance of the model is optimised by employing Monte Carlo Dropout during both training and inference. Regarding the data, they use only the provided datasets (the MLQE-PE train/dev sets along with the additional dataset for Marathi language) as well as some of the provided additional training resources of the Metrics shared task.

Table 2 lists all participating teams submitting systems to any of the tasks, and Table 3 report the number of successful submissions to each of the sub-tasks and language pairs. Each team was allowed up to ten submissions for each task variant and language pair (with a limit of two submissions per day). In the descriptions below, participation in specific tasks is denoted by a task identifier (T1 = Task 1, T2 = Task 2, T3 = Task 3).

5 Results

In this section, we present and discuss the results of our shared task. Please note that for all the three subtasks we used statistical significance testing with $p = 0.05$.

5.1 Task 1

As we have seen in Task 1 description (§2.1.1), submissions are evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient ρ along with the following secondary metrics: Pearson's correlation coefficient, r, Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE). Nonetheless, **the final ranking between systems is calculated using the primary metric only (Spearman's ρ).** Also, statistical significance was computed using William's test.[9]

For the Task 1 word-level task, the submissions are ranked using the Matthews correlation coeffi-

Table 3: Number of submissions to each sub-task and language-pair at the WMT22 Quality Estimation shared task.

cient (MCC). F1-scores are provided as complementary information only and statistical significance was computed using randomisation tests (Yeh, 2000) with Bonferroni correction (Abdi, 2007) for each language pair.

The majority of participants implemented multilingual models and the top performing systems adopted a multi-tasking approach, learning the sentence- and word-level targets jointly (IST-Unbabel, Papago, NJUNLP). It is important to note that all participants relied on large pre-trained encoders (XLM-R, RemBERT, BERT, ELECTRA), which seems to be the norm for high-performance in quality estimation, but can constitute a limitation for performance in truly multi-lingual scenarios where the target languages are not seen during pre-training. Additionally, many final submissions consisted of ensembles combining different large pretrained models increasing even further the total number of model parameters.

Another trend that seems to carry on from previous editions of the task is the incorporation of additional features in QE models (glass-box features were incorporated in Alibaba's DA systems while linguistic features were incorporated in aiXplain QE system), however in this edition such approaches were outperformed by models that put more emphasis on pre-training, using auxiliary tasks and external data.

For the sentence-level sub-tasks, participants managed to achieve high correlations for the majority of language pairs, especially for the DA originated data, with the exception of En-Ja. The results show an improvement compared to the last edition, although it is hard to draw a direct comparison due to changes in the available train/development data. However, it is interesting to note that performance for En-Mr, for which we provided considerable more data than for the other language pairs is still in the same range as results for the other language pairs. It would thus be interesting to investigate further which properties render a language pair harder to evaluate.

For the MQM data the overall correlations achieved were lower in comparison to the DA ones although still meaningful. Note that compared to the DA data, the MQM language pairs were high-resource ones, which could also influence performance. Additionally, small discrepancies between the annotation guidelines in the train set and the dev/test sets could have further complicated the task. We intend to further investigate the MQM potential in future editions, with the addition of new language pairs and more annotated data.

For the word-level subtask, IST-Unbabel, NJUNLP and Papago tied at the top for most language pairs, and we can observe that correlations are moderate across language pairs (both DA and MQM originated ones). It is important to note that no team seems to have submitted predictions using a word-level only supervision; instead all the participants of this task used a multi-task approach, learning jointly word and sentence level scores.

Table 5: Spearman correlation with **MQM** for the submissions to WMT22 Quality Estimation **Task 1**. For each language pair, results marked in bold correspond to the winning submissions, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey; ‡ indicates Codalab username of participants from whom we have not received further information.

Best performers The scores in Tables 4 - 6 show the participant scores for the main metric, ordered by the best performance in the multilingual subtasks. IST-Unbabel is the clear winner for the multilingual subtasks, but for the individual language pairs results vary and multiple participants are tied at the top. All top-performing approaches (IST-Unbabel, Papago, NJUNLP and Alibaba) share some common characteristics: (1) they constitute multilingual and multi-task approaches; (2) they use external data during pre-training, either adapted from other tasks (such as the Metrics task (Freitag et al., 2022)) or generated artificially (pseudo data); and (3) they use ensembling for the final submission.

5.2 Task 2

Three teams participated in Task 2, IST-Unbabel, HW-TSC and UT-QE. IST-Unbabel participated in all 9 language pairs, HW-TSC in all languages pairs except English-Yoruba, and UT-QE only in Khmer-English and Pashto-English. As shown in Table 7, IST-Unbabel wins 7 of 9 LPs according to the metric Recall at Top-K, HW-TSC the remaining 2. With Bonferroni correction, IST-Unbabel wins 4 LPs, HW-TSC wins 2, and both are indistinguishable on the remaining 3 LPs. Average precision (AP) yields identical results as Recall at Top-K in terms of ranking of the teams. There is one difference according to the metric AUC in terms of winners: HW-TSC wins English-Japanese. Finally, all participating teams beat both baselines in all cases.

For sentence-level performance (see Appendix D), IST-Unbabel wins all LPs according to Pearson's correlation and all LPs according to Spearman's correlation except for Khmer-English, which HW-TSC wins. Not all teams beat all baselines in terms of sentence-level performance.

The winning teams obtain the lowest sentence-level correlations for English-Chinese, English-Japanese and English-Yoruba and the highest correlations for Khmer-English and English-German. This may be related to the quality of annotations and the quality of MT systems involved. For word-level explainability scores, the lowest Recall at Top-K scores are obtained for English-Yoruba and English-Marathi, whereas the highest scores are obtained for Pashto-English and Khmer-English. The fact that the winning systems obtain low sentence and word-level scores for English-Yoruba and high scores for Khmer-English may indicate that the

Baseline systems are highlighted in grey.

tasks are correlated (as one may intuitively expect): a QE system that yields better sentence-level scores also highlights word-level errors more correctly.

5.3 Task 3

In this task, we divide participants into *unconstrained* and *constrained* settings, and address each group in separate. As in the last year, this task attracted few participants, which we attribute to the recentness of the task.

In the *unconstrained* setting, there are two participants: KU X Upstage and HyperMT - aiXplain. The first achieved very high values for the measured metrics, and is the best performer for this setting for both language pairs. The second obtained lower values, falling below the baseline on both language pairs.

In the *constrained* setting, a single submission was received: IST-Unbabel. Their system outperformed the baseline on both language pairs.

6 Discussion

In what follows, we discuss the main findings of this year's shared task based on the goals we had previously identified for it.

General progress Participating systems achieved very promising results for most languages, including the newly introduced language-pairs as well as the new annotation style (MQM). The **best performing submissions showed moderate to strong correlation for sentence-level DA and MQM prediction tasks.** While it is hard to draw direct comparisons with the previous editions, the overall correlation scores obtained are similar or improved for the common language-pairs. In combination with the outcomes of previous editions, it seems that multi-lingual and multi-task systems that are able to take advantage of multiple resources, are showing better and more robust results. However, the **word-level quality prediction is still a challenging task and there is ample room for improvement**. Along the same lines, further **exploring explainability tasks, that support the sentence level predictions with word level scores seems a promising path to motivate finer-grained approaches to word-level** quality annotations.

DA vs MQM annotations To further understand the observed discrepancies between top performances in the DA and MQM sub-tasks for sentence-level quality estimation, we analyse the distributions of predicted scores vs gold scores for each language pair, as presented in Figure 2.

We can see in the scatter plots that there are multiple test-segments which are annotated as perfect translations (maximum possible normalised MQM score), which fail to be classified accordingly as indicated by the top parts of the MQM scatter plots in Figure 2. Overall, even with DA annotations we can see that **language pairs with more balanced distribution between high and low quality segments (Km-En, Ps-En) are those for which QE systems obtain better correlations**, compare to more skewed language pairs (En-Mr, En-Ja).

Additionally, we can see that the **MQM scores are significantly skewed towards higher scores**, with long-tails of few very low quality instances. This provides motivation to revisit the quantification of MQM annotations to generate sentence level scores and further experiments into consolidating MQM annotations from different annotators. Furthermore, perhaps providing access to finer-grained MQM annotations (using the category or severity labels as targets) could aid in obtaining more meaningful outcomes. In future editions we intend to further expand the coverage of languages for MQM annotations that will allow us to draw further conclusions and push the state-of-the-art further in this track.

Zero shot predictions We found that **even without development data or prior knowledge about the language pair, the systems that submitted predictions for En-Yo still achieved meaningful correlations**. For the quality assessment and explainability tasks, the achieved correlations are lower compared to the "seen" language pairs, but still comparable. We can also observe the scatter plot distributions that show the correlation obtained by the top performing system that is comparable with the other DA distributions.

However, we noticed that the **availability of the zero-shot languages in the frequently used pretrained encoders posed an additional challenge** for the participants as the performance on En-Yo seemed dependent on whether the pretrained language model had seen Yoruba text during pretraining. In future editions, we hope that mixing different zero-shot languages will further motivate unsupervised approaches.

Explainable quality estimation The performance of the baselines in Task 2 suggests that applying a model-agnostic explanation method (i.e., LIME) to a relatively good sentence-level QE system (i.e., OpenKiwi) straightforwardly may not result in plausible explanations. In particular, the OpenKiwi+LIME baseline got higher Recall at Top-K than the random baseline for only 5 LPs. Using randomisation tests with Bonferroni correction, we found that the OpenKiwi+LIME baseline can significantly outperform the random baseline for only 2 LPs (En-Cs and En-Ja). Despite its higher Pearson's correlation at the sentence level, OpenKiwi+LIME yielded random-like (or even worse) explanations for MQM language pairs. This also calls for a stronger baseline for the future edition of the QE shared task. Additional signals/heuristics might be added to the future shared task's baselines such as sparsity of the rationales (as used by IST-Unbabel) and alignments between source and target sentences (as used by HW-TSC and UT-QE).

Critical error detection. By comparing the performance of the submitted systems, in particular the baselines, we see that the difficulty of the *constrained* setting is much higher. We attribute this discrepancy to the fact that the artificially generated data follows a specific set of patterns, which can be captured by current methods when given enough examples. The HyperMT - aiXplain submission seems to be an exception. However, although this system is *unconstrained*, it is composed of fine-tuned decision trees where the base features are *constrained*. We consider that these features are unable to provide sufficient information for the decision trees to be able to identify critical errors, even when fine-tuned on the provided training data.

Due to the scarcity of annotated data containing critical errors, we argue that the *constrained* setting presents a much more realist challenge, where systems are trained for correlating with human judgements but are tested for robustness to critical errors.

For a future edition of this task, we envision a design that simultaneously considers both correlations with human judgements and robustness to critical errors when evaluating a QE system. This can be combined with Task 1, where besides the current evaluation method, participants would also receive a robustness score for their systems, mea-

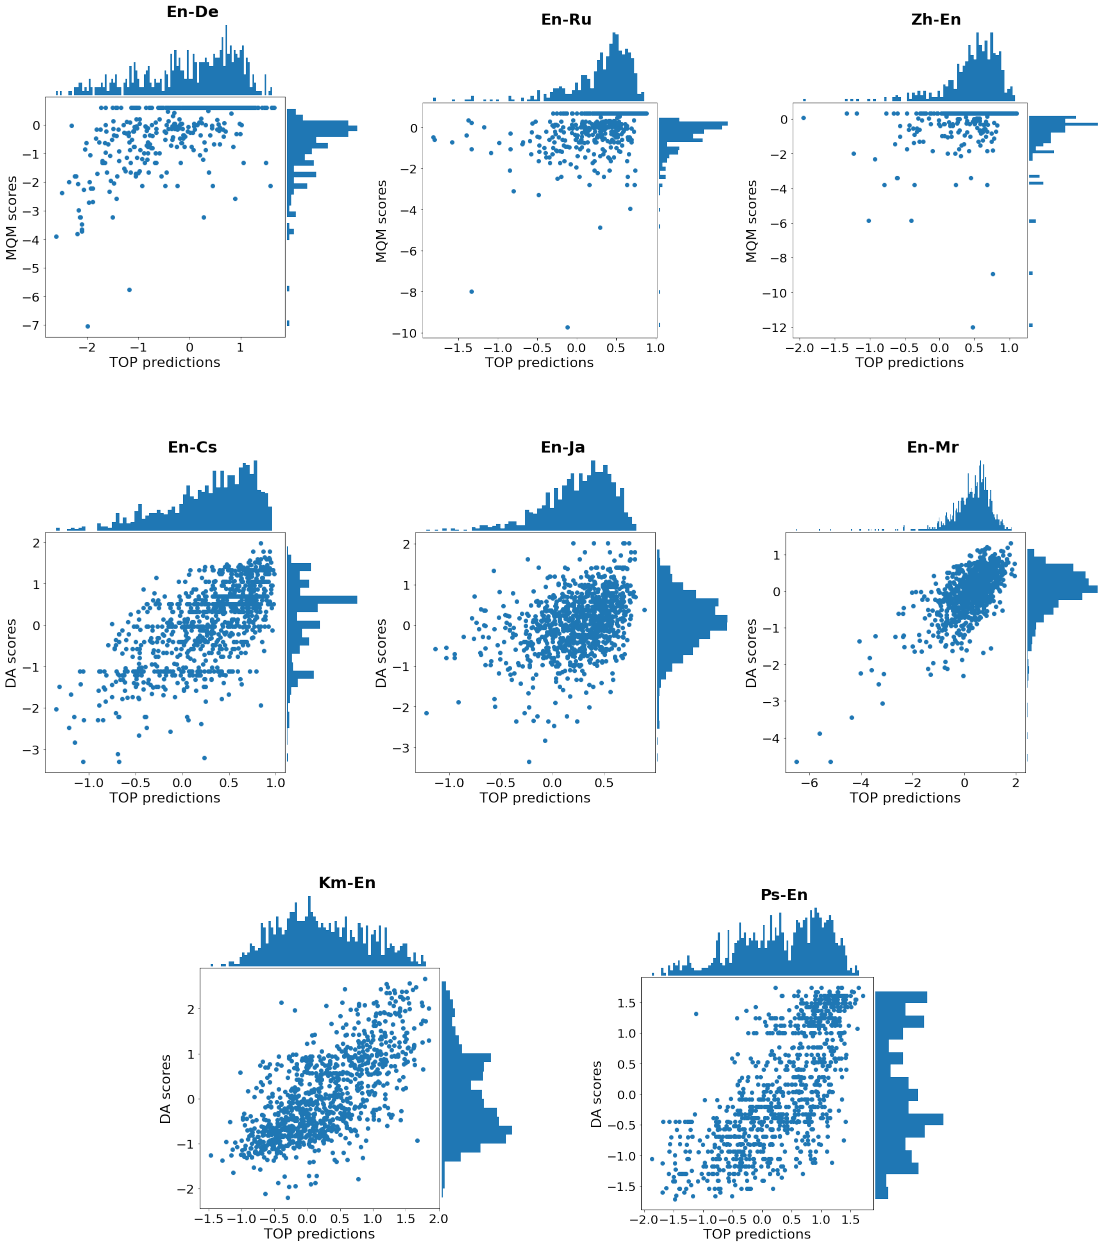

Figure 2: Scatter plots for the predictions against true DA/MQM scores for the top-performing system for each language pair. The histograms show the corresponding marginal distributions of predicted and true scores.

sured on a test set with critical errors. We hope that this configuration would both attract more participants to this task (as it would not required training a specific system for critical error detection) and further motivate the treatment of critical errors in the development of QE systems.

7 Conclusions

This year's edition of the QE Shared Task introduced a number of new elements: new low-resource language pairs (Marathi and Yoruba), new annotation conventions for sentence and word level quality (MQM), new test sets, and new versions of explainability and critical error detection subtasks. The tasks attracted a steady number of participating teams and we believe the overall results are a great reflection of the state-of-the-art in QE.

We have made the gold labels and all submissions to all tasks available for those interested in further analysing the results, while newly interested participants can still access the competition instances on codalab and directly compare their performance to other models. We aspire for the future editions to continue the efforts set in this and previous years and expand the resources and coverage of QE, while further exploring recent and more challenging subtasks such as fine-grained QE, explainable QE and critical error detection.

{Kenneth.Heafield,b.zhang,graeme.nail,jelmer.vanderlinde,n.bogoych}@ed.ac.uk

Abstract

The machine translation efficiency task challenges participants to make their systems faster and smaller with minimal impact on translation quality. How much quality to sacrifice for efficiency depends upon the application, so participants were encouraged to make multiple submissions covering the space of trade-offs. In total, there were 76 submissions from 5 teams. The task covers GPU, single-core CPU, and multi-core CPU hardware tracks as well as batched throughput or single-sentence latency conditions. Submissions showed hundreds of millions of words can be translated for a dollar, average latency is 3.5–25 ms, and models fit in 7.5–900 MB.

1 Introduction

The efficiency task complements the collocated news task by challenging participants to make their machine translation systems computationally efficient. This is the fifth edition of the task, expanding upon previous editions (Heafield et al., 2021, 2020; Hayashi et al., 2019; Birch et al., 2018).

Participants built English→German machine translation systems following a constrained data condition. The data condition follows the constrained **2021** Workshop on Machine Translation news translation task. This year, to reduce the barrier to entry, organisers provided an ensemble of teacher systems, as well as cleaned data and distilled output from the teacher ensemble. Participants were required to use the provided teacher systems, but were free to distil additional data from the constrained condition. The SentencePiece vocabulary used by the teachers was also made available.

For translation quality measurement, we use the news-focused WMT22 dataset, and the systems are ranked according to the COMET (Rei et al., 2020) automatic metric. We also evaluate systems on BLEU and chrF for additional reference.

	Throughput		**Latency**	
	CPU-ALL	GPU	CPU-1	GPU
CUNI	1	1	1	1
ECNU	1	1	1	1
Edinburgh	15	11	15	11
HuaweiTSC	5		5	
RoyalFlush				6

Table 1: Number of systems submitted by each participant for the different hardware and batching conditions. CPU-ALL refers to the 36-core hardware setting.

Submissions are made as Docker containers so we can consistently measure their performance in terms of quality, speed, memory usage, and disk space. We run the containers in three different hardware environments: one GPU, one CPU core, and multiple CPU cores. Systems were tested for throughput by providing 1 million sentences upfront to allow batching and parallelization. We also tested for latency with a program that drip-feeds one input sentence, waits for the translation, and then provides the next input sentence. There were four conditions in total: GPU throughput, GPU Latency, 1 CPU Core Latency, and 36 CPU cores throughput. We did not measure latency in a multi-core CPU setting because the test hardware has 36 cores and overhead for 36 threads is larger than the cost of arithmetic for the small tensors in optimized models. We also did not measure throughput on a single CPU core as we found that setting to be a somewhat unrealistic real world scenario.

Participants were free to choose which conditions to participate in. The condition was passed to the Docker container as command line arguments. Table 1 shows the five participants and the number of systems they submitted to each of the conditions.

Machine translation is used in a range of settings where users might choose different trade-offs between quality and efficiency. For example, a high-frequency trading system might prefer the lowest latency at the expense of quality given that the out-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 100 - 108
December 7-8, 2022 ©2022 Association for Computational Linguistics

put will only be read by a machine. Conversely, in a post-editing scenario the personnel costs outweigh many computational costs. Therefore there is not a single best system, but a range of options that trade between quality and efficiency.

We emphasize the Pareto frontier: the fastest systems at each level of quality, or the smallest systems at each level of quality. To explore the Pareto frontier, participants were encouraged to make multiple submissions covering the range of trade-offs. In total, 76 combinations of models, hardware, and batching were benchmarked.

2 Hardware

We chose modern hardware to encourage exploiting new hardware features. The GPU is an NVidia A100 from the Oracle Cloud `BM.GPU4.8` instance. The instance has eight GPUs and we limited Docker to using only one GPU. The GPU machine has an AMD EPYC 7542 CPU with all cores allowed.

The CPU-only condition used a dual-socket Intel Xeon Gold 6354 from Oracle Cloud `BM.Optimized3.36` with a total of 36 cores. For the single-core CPU track, we reserved the entire machine then ran Docker with `-cpuset-cpus=0`. In the 36-core CPU track, participants were free to configure their own CPU sets and affinities.

The Oracle Cloud machines are bare metal servers, meaning there was no shared tenancy, no virtualization, and the test machines were otherwise quiescent.

3 Input Text

To amortize loading time, avoid starving highly parallel submissions, and reduce the ability to cheat, we benchmark systems on 1 million sentences of input. The test set is hidden inside these 1 million sentences, shuffled with filler sentences. Many filler sentences are drawn from parallel corpora to check that systems are in fact translating all sentences, though we do not consider scores on noisy corpora reliable enough to report. The composition of this set changes each year and is decided after the submission deadline.

The filler data was gathered from parallel corpora and gender bias challenge sets: WMT news test sets from 2008 through 2022 (Akhbardeh et al., 2021), the additional test inputs in WMT 2021, Khresmoi summary test v2 (Dušek et al., 2017), IWSLT 2019 (Jan et al., 2019), SimpleGen (Renduchintala et al., 2021), WinoMT (Stanovsky et al., 2019), TED 2020 (Reimers and Gurevych, 2020), and Tilde RAPID 2019 (Rozis and Skadiņš, 2017). We limit sentence lengths to 150 space-separated tokens. Because WMT 2020 includes excessively long segments that are actually concatenated sentences, we also added sentence split versions of WMT 2020 and WMT 2021, though the difference on WMT 2021 was minor. Source sentences were concatenated, deduplicated, and shuffled. The Tilde RAPID corpus was clipped to make a total of 1 million deduplicated lines. Counts are shown in Table 2.

Corpus	**Sentences**
WMT 08–19	32,477
WMT 20 under 150 tokens	1,416
WMT 20 sentence split	2,048
WMT 21 sentence split	1,096
WMT 21 inc. additional tests	14,938
WMT 22	2,037
Khresmoi Summary Test v2	1,000
IWSLT 2019	2,278
SimpleGen	2,664
WinoMT	3,888
TED 2020 v1	293,562
Tilde RAPID 2019	663,922
Total	1,021,326
Deduplicated	1,000,000

Table 2: Summary of corpora used for the input text.

Input text and tools to extract test sets from system outputs are available at `https://data.statmt.org/wmt22/efficiency-task/wmt22-testdata.tar.xz`.

The input file is 1,000,000 lines, consisting of 19,926,744 space-separated words, or 124,186,772 bytes of English text in UTF-8. This is a mean of 19.9 words per sentence and is comparable to the previous year (Heafield et al., 2021). Teams were responsible for their own tokenization and detokenization; for this they were permitted to use the SentencePiece vocabulary provided with the teacher system, or to implement an alternative. We provided raw UTF-8 English input text with one sentence per line.

4 Metrics

4.1 Resources

Time was measured with wall (real) time reported by `time` and CPU time reported by the kernel for the process group. We do not measure loading time because it is small compared to translating 1 million sentences, some tools load lazily, and it is easily gamed by padding loading time.

Peak RAM consumption was measured using `memory.max_usage` in bytes from the kernel for the CPU and by polling `nvidia-smi` for the GPU. Swap was disabled.

Participants were instructed to separate their Docker images into model and code files so that models could be measured separately from the relatively noisy size of code and libraries. A model was defined as "everything derived from data: all model parameters, vocabulary files, BPE configuration if applicable, quantization parameters or lookup tables where applicable, and hyperparameters like embedding sizes." Code could include "simple rule-based tokenizer scripts and hard-coded model structure that could plausibly be used for another language pair." They were also permitted to use standard compression tools such as `xz` to compress models; decompression time was excluded in results. We report size of the model directory captured before the model ran. We also measured the total size of the Docker image (after compressing with `xz`).

4.2 Quality

Translation quality is measured on the WMT 2022 news test set. The automatic metrics are COMET (Rei et al., 2020) from `unbabel-comet` version `1.1.3` with the pretrained model `wmt20-comet-da`, BLEU from sacrebleu (Post, 2018) `nrefs:1|case:mixed|eff:no|tok:13a |smooth:exp|version:2.3.1`, and chrF also from sacrebleu.

5 Results

The results of the task evaluation for the latency scenario are presented in Table 3, and those for throughput are presented in Table 4. Results are separated by the different hardware conditions and within each hardware setting the results are ordered by their COMET score, which is shown to have closer correspondence to human evaluation as compared to BLEU and ChrF (Freitag et al., 2021).

Figure 1 shows the trade-off between quality and speed of batched translation submissions separated by hardware environment. Each plot shows the Pareto frontier as a black staircase to highlight the best combinations of quality and speed. While GPU systems (Figure 1a) achieve higher throughput compared to CPU systems (Figure 1b), this ignores pricing differences between these compute options. In Figure 2, we combine GPU and 36 Core CPU speed by using Oracle Cloud pricing. Despite the less expensive per-hour pricing of CPU, GPU is cheaper for throughput-oriented tasks that allow batching.

The all-hardware latency Pareto frontier is shown in Figure 3. This year all participants submitted systems to the latency task. This year, for the first time, the semi-autoregressive GPU system by RoyalFlush dominates the lower quality settings of the latency Pareto frontier, with Edinburgh GPU systems having won on some higher quality systems.

Model sizes at rest on disk appear in Figures 4a. Participants were allowed to compress their models using their own tools and standard tools like `xz`. The Pareto frontier consists of almost entirely Edinburgh submissions, with HuaweiTSC producing several systems on the lower quality settings, due to their 4-bit compression models. Docker image sizes, which include model and software, appear in Figure 4b, where the Pareto frontier is dominated by Edinburgh submissions. Conversely, some others opted to optimize other metrics and included large Linux installations. We compressed all docker images with `xz` before measuring.

Memory (RAM) consumption appears in Figure 5. GPU memory consumption reflects batch size and some participants set a large batch size to maximize speed. Optimizing speed for multi-socket CPU machines implies having a copy of the model in RAM close to each socket, so memory consumption is larger beyond simply having temporary space for more batches. Finally, participants may have sorted the entire 118 MB input file in RAM to form batches of equal length sentences. RoyalFlush is the clear winner on the GPU latency RAM consumption, and HuaweiTSC is the winner of CPU latency RAM consumption.

6 Conclusion

Using the highest quality system in this evaluation, translating 124,186,772 characters took 283

seconds on an A100 GPU that costs $3.05/hr in a cloud. That is $0.002/million characters. By comparison, Google Translate's cost is $20/million characters.[1]

In terms of translation throughput cost per $ spent, the GPU submissions are better value for money, provided that enough sentences can be fed to the GPU continuously.

The GPU latency track had been intended to attract non-autoregressive machine translation submissions in their ideal condition with a large GPU and no batch to parallelize. For the first time this year, we had a mix of autoregressive, semi-autoregressive and non-autoregressive systems:

- CUNI submitted a fully non-autoregressive system based on connectionist-temporal-classification (CTC) networks (Helcl et al., 2022).

- Edinburgh submitted bidirectional decoder based semi-autoregressive system (Zhang et al., 2020). This system generates two tokens at an autoregressive step at a time from both sides of the sentences.

- RoyalFlush submitted a semi-autoregressive system based on their novel hybrid regressive translation framework (HRT). They first perform a coarse-grained autoregressive pass that generates some words in the target sentence, with gaps of up to several words in between. Afterwards a second, non-autoregressive pass fills in all the missing words.

The RoyalFlush system proves extremely well suited to the GPU latency task, dominating the pareto frontier in the lower quality setting, even outperforming CPU systems, which have traditionally won this task.

Finally, we note that in semi-autoregressive models and non-autoregressive models, a small drop in BLEU results in a large drop in COMET compared to an autoregressive system, as evidenced by all teams who submitted any form of non-autoregressive MT to the task. This corroborates the findings of (Helcl et al., 2022) where the large discrepancies between BLEU and COMET were noted. We urge participants in future editions of the task to examine manually the output of their non-autoregressive systems.

7 Future tasks

This year's shared task had an increased number of participants, likely due to the organisers providing the distilled data and therefore substantially decreasing the computational cost to participants. We intend to keep this format of the task for future years, in the hopes of attracting even more participants.

German is a high-resource language, which raises the computational cost of participation. We would be interested in also potentially including a medium resource language for distillation so that we can see if the methods that work on high-resource languages generalize well to lower-resource languages, or languages with more morphological complexity.

Last year (Heafield et al., 2021) the organisers suggested that an efficient training shared task would be an interesting natural extension to the efficient translation shared task, however it has proven difficult to set up in practice: we are conscious that the validity of such a task can be easily undermined by participants finding a favorable random seed that fits the training data, or more egregiously by including evaluation data in their training data. We are looking for potential solutions to these problems and we are open to suggestions for next year's edition of the task.

Abstract

We present the results from the 8^{th} round of the WMT shared task on MT Automatic Post-Editing, which consists in automatically correcting the output of a "black-box" machine translation system by learning from human corrections. This year, the task focused on a new language pair (English→Marathi) and on data coming from multiple domains (healthcare, tourism, and general/news). Although according to several indicators this round was of medium-high difficulty compared to the past, the best submission from the three participating teams managed to significantly improve (with an error reduction of 3.49 TER points) the original translations produced by a generic neural MT system.

1 Introduction

This paper presents the results of the 8^{th} round of the WMT task on MT Automatic Post-Editing (APE). The task consists in automatically correcting the output of a "black-box" machine translation system by learning from human-revised machine-translated output supplied as training material. The overall task formulation (see Section 2) remained the same as in all previous rounds, where the challenge consisted in fixing the errors present in English documents automatically translated by state-of-the-art, not domain-adapted neural MT (NMT) systems unknown to participants. However, two main factors of novelty characterized the APE 2022 evaluation setting:

- **Language Pair:** This year, we focus on English→Marathi. Marathi is an Indo-Aryan language predominantly spoken by Marathi people in the Indian state of Maharashtra (see Section 3).
- **Data Domain:** Instead of covering one single domain as in previous rounds (either news, medical, or information technology of Wikipedia documents), training/dev/test data were selected from a mix of domains, namely: healthcare, tourism, and general/news.

This year, we had three teams submitting a total of five systems for final evaluation (see Section 5). While the difficulty (Section 4) of this round falls in a medium-high range attested by relatively high baseline results on the test data (20.28 TER / 67.55 BLEU), final results indicate the overall good quality of the submitted runs. Two teams were indeed able to significantly improve over the baseline in terms of the official automatic evaluation metrics (Section 6). In particular, according to the primary metric (*i.e.,* the TER score computed between automatic and human post-edits), the top-ranked system (16.79 TER / 72.92 BLEU) achieved an error reduction of 3.49 TER points. Also, this year, the standard automatic evaluation was complemented by a human evaluation based on direct assessment. However, some problems in the procedure[1] were later discovered, which make it unreliable to draw insights except for the confirmation that two of the three submitted systems were able to improve over the baseline significantly. Specifically, both of them achieved a mean direct assessment score that drastically reduces the gap between the baseline and human post-editing quality. However, due to the mentioned problems in the human evaluation procedure, further details about it will not be included in the discussion below.

Although the different language/domain testing conditions prevent from drawing precise conclusions about the progress of APE technology with respect to last year, the overall positive results confirm its viability for downstream improvements of "black-box" MT systems whose inner workings are not accessible.

[1] Basically, due to an error in assigning the direct assessment tasks, the scores collected can be used to compare systems to the baseline but cannot be used to compare them to each other.

2 Task Description

MT Automatic Post-Editing (APE) is the task of automatically correcting errors in a machine-translated text. As pointed out by (Chatterjee et al., 2015), from the application point of view, the task is motivated by its possible uses to:

- Improve MT output by exploiting information unavailable to the decoder, or by performing deeper text analysis that is too expensive at the decoding stage;
- Cope with systematic errors of an MT system whose decoding process is not accessible;
- Provide professional translators with improved MT output quality to reduce (human) post-editing effort;
- Adapt the output of a general-purpose MT system to the lexicon/style requested in a specific application domain.

This 8^{th} round of the WMT APE shared task kept the same overall evaluation setting of the previous seven rounds. Specifically, the participating systems had to automatically correct the output of an unknown "black-box" MT system (a generic NMT system not adapted to the target domain) by learning from training data containing human revisions of translations produced by the same system. The selected language pair and the data domain, however, were totally new to the task. Different from previous rounds covering more language pairs (or directions), this year focused only on English-Marathi, presenting participants with the traditional source language and, for the third time in a row, an Eastern language as the target. Moreover, while the training, development and test data released in previous rounds were always drawn from a single domain, this year, they covered three domains: healthcare, tourism, and general/news.

3 Data, Metrics, Baseline

3.1 Data

In this round of the APE task, we introduce a new language pair - English-Marathi. Marathi is one of the most spoken Indian languages, with approximately 83 million native speakers and 16 million speakers as a second/third language[2]. Marathi is a known agglutinative language and presents various challenges to machine translation when compared to its other Indian counterparts (Khatri et al., 2021; Banerjee et al., 2021). Moreover, the English-Marathi language pair is considered a low-resource language pair compared to English-Hindi/Bengali/Malayalam (Ramesh et al., 2022) despite having more native speakers around the world. An automatic post-editing approach which helps correct the issues posed by NMT systems is crucial for a low-resource language such as Marathi.

As in all previous rounds, participants were provided with **training** and **development** data consisting of (*source*, *target*, *human post-edit*) triplets. This year, the two sets respectively comprise 18,000 and 1,000 instances, in which:

- The source (SRC) is an English sentence;
- The target (TGT) is a Marathi translation of the source produced by a generic, black-box NMT system unknown to participants. This multilingual NMT system (Ramesh et al., 2022) is based on the Transformer architecture (Vaswani et al., 2017) and is trained on a total of 49 million sentence pairs where the En-Mr parallel corpus is 4.5 million sentence pairs. This parallel data is generic and covers many domains, including the three domains covered by the evaluation setting of this year: healthcare, tourism/culture and general/news.
- The human post-edit (PE) is a manually-revised version of the target, which was produced by native Marathi speakers.

Also this year, a corpus of artificially-generated data has been released as additional training material. It consists of 2 million triplets derived from the *Anuvaad* en-mr parallel corpus[3]. The *Anuvaad* parallel corpus consists of data for 12 language pairs en-X, where X is 12 Indian languages, including Marathi. The English-Marathi data consists of 2.5 million parallel sentences. Specifically, the *source*, *target*, *post-edit* instances of this synthetic corpus are respectively obtained by combining: *i)* the original English source sentence from the *Anuvaad* corpus, *ii)* its automatic translation in Marathi[4], *iii)* the original Marathi target sentence from the *Anuvaad* corpus.

[2] Ethnologue-2022 - Ethnologue has been an active research project since 1951 which maintains online archives of recognized languages list, and their statistics.

[3] https://github.com/project-anuvaad/anuvaad-parallel-corpus

[4] from IndicTrans En-X Model (Ramesh et al., 2022)

Test data consisted of 1,000 (*source*, *target*) pairs, similar in nature to the corresponding elements in the train/dev sets (*i.e.,* same domains, same NMT system). The human post-edits of the target elements were left apart to measure APE systems' performance both with automatic metrics (TER, BLEU) and via manual assessments.

3.2 Metrics

In line with the previous rounds, also this year the plan was to evaluate the participating systems both by means of automatic metrics and, manually, via source-based direct human assessment (Graham et al., 2013). However, as discussed in Section 1, some issues in the manual evaluation procedure were later discovered. For this reason, the discussion of the evaluation results in Section 6 will only concentrate on the automatic metrics. Automatic evaluation was carried out after tokenizing the data using sacremoses[5] and then computing the distance between the automatic post-edits produced by each system for the target elements of the test set, and the human corrections of the same test items. Case-sensitive TER (Snover et al., 2006) and BLEU (Papineni et al., 2002) were respectively used as primary and secondary evaluation metrics. The official systems' ranking is hence based on the average TER calculated on the test set by using the TERcom[6] software: lower average TER scores correspond to higher ranks. BLEU was computed using the multi-bleu.perl package[7] available in MOSES. Automatic evaluation results are presented in Section 6.1.

3.3 Baseline

Also this year, the official baseline results were the TER and BLEU scores calculated by comparing the raw MT output with human post-edits. This corresponds to the score achieved by a "*do-nothing*" APE system that leaves all the test targets unmodified. For each submitted run, the statistical significance of performance differences with respect to the baseline was calculated with the bootstrap test (Koehn, 2004).

4 Complexity Indicators

To get an idea of the difficulty of the task, in previous rounds, we focused on three aspects of the released data, which provided us with information about the possibility of learning useful correction patterns during training and successfully applying them at test time. These are: *i)* repetition rate, *ii)* MT quality, and *iii)* TER distribution in the test set. For the sake of comparison across the eight rounds of the APE task (2015–2022), Table 1 reports, for each dataset, information about the first two aspects. The third one, instead, will be discussed by referring to Figure 1.

4.1 Repetition Rate

The repetition rate (RR), measures the repetitiveness inside a text by looking at the rate of non-singleton n-gram types (n=1...4) and combining them using the geometric mean. Larger values indicate a higher text repetitiveness that may suggest a higher chance of learning from the training set correction patterns that are also applicable to the test set. However, over the years, the influence of repetition rate in the data on system performance was found to be marginal.[8]

Looking at the data released this year, the very low RR values (*i.e.,* 1.46, 0.89, and 0.72 respectively for the SRC, TGT and PE elements) seem to confirm that repetition rate is a scarcely reliable complexity indicator. On one side, these values are close to those observed in rounds were the top-ranked submissions achieved both very large (2020) and very small (2021) gains over the baseline. On the other side, the best result for this year is close to the best results obtained, in previous rounds, on data featuring considerably higher repetition rates (2016, 2017). This suggests that other complexity factors may provide more reliable insights about the difficulty of the task, possibly with an additive effect, still to be fully understood, given by repetition rate.

4.2 MT Quality

Another possible complexity indicator is MT quality, that is the initial quality of the machine-translated (TGT) texts to be corrected. We measure it by computing, the TER (↓) and BLEU (↑) scores (Basel. TER/BLEU rows in Table 1) using the human post-edits as reference. In principle, higher quality of the original translations leaves the APE systems with smaller room for improvement since they have, at the same time, less to learn during

[6] http://www.cs.umd.edu/~snover/tercom/

[7] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

[8] The analyses carried out over the years produced mixed outcomes, with impressive final results obtained in spite of low repetition rates (Chatterjee et al., 2020) and vice-versa (Chatterjee et al., 2018, 2019; Akhbardeh et al., 2021).

Table 1: Basic information about the APE shared task data released since 2015: languages, domain, type of MT technology, repetition rate and initial translation quality (TER/BLEU of TGT). The last column (δ TER) indicates, for each evaluation round, the difference in TER between the baseline (*i.e.,* the "*do-nothing*" system) and the top-ranked submission.

training and less to correct at the test stage. On one side, training on good (or near-perfect) automatic translations can drastically reduce the number of learned correction patterns. On the other side, testing on similarly good translations can *i)* drastically reduce the number of corrections required and the applicability of the learned patterns, and *ii)* increase the chance of introducing errors, especially when post-editing near-perfect TGTs. The findings of all previous rounds of the task support this observation, which is corroborated by the high correlation (>0.83) between the initial MT quality ("Basel. TER" in Table 1) and the TER difference between the baseline and the top-ranked submission ("δ TER" in Table 1).

As discussed in Section 6, this year seems to confirm the trends observed in the past, albeit with a less evident match. The quality of the initial translations (20.28 TER / 67.55 BLEU) places this round among those of medium-high difficulty (20.0<TER<25.0) for which, except in one case (2015[9]), the performance gains obtained by the top-ranked submissions fall in the range -3.2<δ TER<-6.2. The δ TER of this year (-3.49) also falls in this range, confirming the correlation between the quality of the initial translations and the actual potential of APE.

4.3 TER Distribution

A third complexity indicator is the TER distribution (computed against human references) for the translations present in the test sets. Although TER distribution and MT quality can be seen as two sides of the same coin, it's worth remarking that, even at the same level of overall quality, more/less peaked distributions can result in very different testing conditions. Indeed, as shown by previous analyses, harder rounds of the task were typically characterized by TER distributions particularly skewed towards low values (*i.e.,* a larger percentage of test items having a TER between 0 and 10). On one side, the higher the proportion of (near-)perfect test instances requiring few edits or no corrections at all, the higher the probability that APE systems will perform unnecessary corrections penalized by automatic evaluation metrics. On the other side, less skewed distributions can be expected to be easier to handle as they give automatic systems larger room for improvement (*i.e.,* more test items requiring - at least minimal - revision). In the lack of more focused analyses on this aspect, we can hypothesize that in ideal conditions from the APE standpoint,

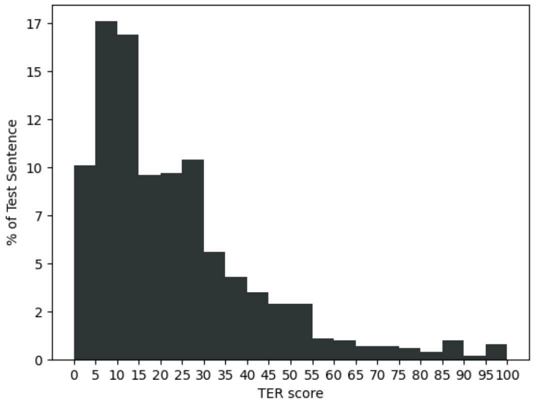

Figure 1: TER distribution in the APE 2022 English-Marathi test set.

[9] The 2015 round is the one in which the APE task was launched. It is somehow an exception being one of the two cases in which none of the participants managed to beat the *do-nothing* baseline (the other one was the 2019 sub-task on English-Russian, also exceptional in the choice of the target language).

ID	Participating team
IITB	Computation for Indian Language Technology - IIT Bombay, India (Deoghare and Bhattacharyya, 2022)
IIIT-Lucknow	IDIAP Research Institute, Switzerland
LUL	Samsung Research and Communication University of China, China (Xiaoying et al., 2022)

Table 2: Participants in the WMT22 Automatic Post-Editing task.

the peak of the distribution would be observed for "post-editable" translations containing enough errors that leave some margin for focused corrections but not too many errors to be so unintelligible to require a whole re-translation from scratch.[10]

Also, with respect to this complexity indicator, the APE 2022 test set can be considered of medium-high difficulty compared to the past rounds. As shown in Figure 1, the TER distribution is quite skewed towards lower values (about 45% of the samples fall in the 15<TER<45 interval) but only 10% of the items can be considered as perfect or near-perfect translations (*i.e.,* 0<TER<5). These values are lower compared to those observed in the test data of harder rounds and higher compared to those observed in the test data of easier rounds.[11] All in all, the improvements over the baseline observed this year for two of the three participating systems (respectively -3.49 and -1.22 TER for the top-ranked and the second-best one) seem to confirm the correlation between TER distribution and task difficulty. However, weighing and understanding the actual contribution of TER distribution and MT quality, together with the possible additive effect of RR, remains a topic for more focused future research.

5 Submissions

As shown in Table 2, this year we received submissions from three teams. Two of them (IIIT-Lucknow and LUL) submitted two runs, while the third one (IITB) participated with only one submission. The main characteristics of two of the three participating systems are summarized below.[12]

Samsung Research and Communication University of China (LUL). This team participated with a Transformer-based system built using fairseq (Ott et al., 2019). Their submissions are characterized by two main aspects: data augmentation and the use of a mixture of experts' approach (Jacobs et al., 1991). Data augmentation is pursued by generating synthetic triplets by means of both an in-house MT system and an external system (Google Translate). The former is used to translate text drawn from several resources, while the latter is used to back-translate the post-edits in the APE training set. The resulting material is combined in different ways so as to obtain different data sets for model fine-tuning. The mixture of experts' approach exploits three domain-specific adapters (Bapna and Firat, 2019; Pham et al., 2020), which are added to the decoder of the base APE model. At inference time, a classifier (added after the encoder) is used to decide which adapter has to be activated.

Computation for Indian Language Technology - IIT Bombay (IITB). This team participated with a Transformer-based system. It exploits a multi-source approach similar to the one in (Chatterjee et al., 2017), with two separate encoders to generate representations for SRC, MT and one decoder. The model is trained with a curriculum learning strategy similar to the one applied by the 2021 winning system (Oh et al., 2021). This is done by first incrementally using out-/in-domain synthetic data (*i.e.,* those released to participants and additional

[10] For instance, based on the empirical findings reported in (Turchi et al., 2013), TER=0.4 is the threshold that, for human post-editors, separates the "post-editable" translations from those that require complete rewriting from scratch.

[11] Although the final results are not comparable due to the different evaluation settings (*i.e.,* different target languages and data domains), the findings from the last two rounds of the APE task provide good examples. In the 2021 round (English-German), where the top submission achieved a small TER reduction compared to the baseline (-0.77), more than 35% of the test instances featured a TER between 0 and 5 and almost 50% of them had 0<TER<10. In contrast, in the 2020 round (English-Chinese) where the top submission achieved the largest baseline improvement ever observed (-12.13), less than 1% of the test samples had 0<TER<5 and ∼89% of them had 40<TER<85.

[12] The IIIT-Lucknow did not produce a system description paper and is left out of our analysis.

ones generated via MT) and then by fine-tuning the model on the real APE data. To ensure the quality of the training material, the LaBSE technique (Language-agnostic BERT sentence embedding) by Feng et al. (2022) is used to filter out low-quality synthetic triplets. To reduce over-correction, a sentence-level quality estimation system trained on the WMT-22 QE English-Marathi sub-task is used to select the final output between an original translation and the corresponding (corrected) version generated by the APE model.

6 Results

6.1 Automatic Evaluation

Participants' results are shown in Table 3. The submitted runs are ranked based on the average TER (case-sensitive) computed using human post-edits of the MT segments as a reference, which is the APE task's primary evaluation metric. We also report the BLEU score, computed using the same references, which represents our secondary evaluation metric.

As it can be seen from the table, the two rankings are coherent: the top submission (16.79 TER, 72.92 BLEU) is the same, and the top three systems outperform by a large margin ($\sim$1 TER and $\sim$2 BLEU scores) the *do nothing* baseline, both in term of BLEU and TER score. These systems are statistically better than the baseline. This is indeed an interesting result showing the effectiveness of the APE systems and confirming their capability of profitably leveraging additional and external resources compared to the MT system.

Looking at relationships between the primary and contrastive submissions (IIT and LUL), the contrastive system shows slightly better performance of the primary submission in one case (LUL). This highlights the difficulty to select the best configuration during system development and indirectly confirms the difficulty to handle APE data characterized by high MT quality, and TER distribution skewed towards perfect/near-perfect translations.

6.2 Systems' Behaviour

Modified, improved and deteriorated sentences. To better understand the behaviour of each APE system, we now turn an eye toward the changes made by each system to the test instances. To this aim, Table 4 shows, for each submitted run, the number of modified, improved and deteriorated sentences, as well as the overall system's precision (*i.e.,* the proportion of improved sentences out of the total number of modified instances for which improvement/deterioration is observed). It's worth noting that, as in the previous rounds, the number of sentences modified by each system is higher than the sum of the improved and the deteriorated ones. This difference is represented by modified sentences for which the corrections do not yield any TER variations. This grey area, for which quality improvement/degradation can not be automatically assessed, would contribute to motivating the integration of human assessments, as done previously.

As it can be seen from the table and similarly to last year's edition, the top systems have been quite conservative in applying their edits by modifying a limited percentage of sentences ($\sim$50% on average, 45.2 for the top submission). Considering the TER distribution where a large number of samples lay in the 15<TER<45 interval, there is the possibility of substantially changing the MT outputs to achieve better performance. This limited number of edits is unexpected and similar to more difficult test sets with more skewed TER distributions toward near-perfect translations. However, systems' final scores are inversely proportional to their aggressiveness showing that limiting the APE edits and carefully selecting them is the right strategy toward significant improvements in quality.

Precision-wise, this year's systems reached 63.9 (in 2021 it was 51.12 and 58.0 in 2020) on average with the best run peaking at 69.49 (vs 53.96 in 2021 and 69.0 in 2020). It is important to note that the average value is significantly affected by the low-performing systems having a precision close to 0. Looking at the percentage of improved (55.6 on average, 63.49 for the top submission) and deteriorated (31.2 on average, 27.87 for the winning system) sentences, the results confirm the capability of the top systems to minimize the wrong changes. Compared to the last editions, the percentage of the improved sentences is among the largest ones achieved by the all-time submitted APE systems.

Edit operations. Similar to previous rounds, we analysed systems' behaviour also in terms of the distribution of edit operations (insertions, deletions, substitutions and shifts) done by each system. This fine-grained analysis of how systems corrected the test set instances is obtained by computing the TER between the original MT output and the output of each primary submission taken as a reference. Sim-

Table 4: Number (raw and proportion) of test sentences modified, improved and deteriorated by each run submitted to the APE 2022 English-Marathi sub-task. The "Prec." column shows systems' precision as the ratio between the number of improved sentences and the number of modified instances for which improvement/deterioration is observed (*i.e.,* Improved + Deteriorated).

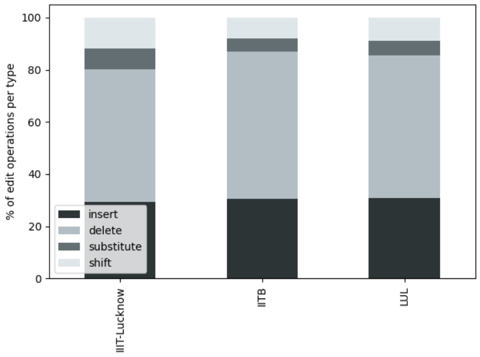

Figure 2: Distribution of edit operations (insertions, deletions, substitutions and shifts) performed by the three primary submissions to the WMT22 APE English-Marathi shared task.

ilar to last year, differences in systems' behaviour are minimal. All of them are characterised by a large number of deletions (∼55.0% on average), followed by insertions (∼30%), shifts (∼10%) and substitutions (∼6%). The system that seems to have a slightly different distribution is IIT-Lucknow resulting in more shifts and substitutions, but these differences are barely visible. Although this year's test set turned out to be simpler than last year (less shewed TER distribution and higher TER), the edit operations are very similar to last year's with a small difference in the number of deletions (65% last year, 55% this year) and insertions (19.2% vs 30%). These variations may depend on the new data, target language and MT system. More thorough future investigations would be needed to find clear explanations for these observations.

7 Conclusion

The 8^{th} round of the shared task on Automatic Post-Editing at WMT was characterized by two main factors of novelty: the language pair (English-Marathi) and the domain of the released data (a mix covering healthcare, tourism, and general/news). Apart from this, the overall setting was the same as in previous recent rounds, in which participating systems had to automatically correct the output of a generic neural MT system, being evaluated with the TER (primary) and BLEU (secondary) automatic metrics. In continuity with the past, also human evaluation via source-based direct assessment was carried out, but it is not discussed in this report due to its unreliable outcomes. In terms of the three complexity indicators discussed in Section 4 (repetition rate, original MT quality and TER distribution), the difficulty of this round falls in a medium-high range. This is reflected by the performance of the systems submitted by the three participating teams: two of them were indeed able to improve over the *do-nothing* baseline with (statistically significant) error reductions up to -3.49 TER points (+5.37 BLEU). Although these results are not comparable with those from previous years due to the different language/domain testing conditions, the observed improvements in the new language direction confirm the viability of APE for downstream improvements of "black-box" MT systems whose inner workings are not accessible.

Acknowledgments

We would like to thank the translation agencies Techliebe, Shri Samarth Krupa Language Solutions, Zibanka, and Desicrew, who helped post-edit the dataset for the English-Marathi language pair.

Embarrassingly Easy Document-Level MT Metrics: How to Convert Any Pretrained Metric Into a Document-Level Metric

Abstract

We present a very simple method for extending pretrained machine translation metrics to incorporate document-level context. We apply our method to four popular metrics: BERTScore, Prism, COMET, and the reference-free metric COMET-QE. We evaluate our document-level metrics on the MQM annotations from the WMT 2021 metrics shared task and find that the document-level metrics outperform their sentence-level counterparts in about 85% of the tested conditions, when excluding results on low-quality human references. Additionally, we show that our document-level extension of COMET-QE dramatically improves accuracy on discourse phenomena tasks, supporting our hypothesis that our document-level metrics are resolving ambiguities in the reference sentence by using additional context.

1 Introduction

Automatic evaluation is crucial to the machine translation (MT) community for tracking progress, evaluating new ideas and making modeling choices. While human evaluation is the gold standard for MT evaluation, it is very expensive, and thus most research groups must rely on automatic metrics. Current State-of-the-art (SOTA) metrics are *pretrained* (Kocmi et al., 2021; Freitag et al., 2021b), leveraging existing language models (LMs) or sequence-to-sequence models to judge how well a hypothesis (i.e. MT system output) conveys the same meaning as a human reference translation.

Sentences are often ambiguous, and many recent works have demonstrated that incorporating inter-sentential (i.e. document-level) context is beneficial in both MT (Lopes et al., 2020; Fernandes et al., 2021) and human evaluation of MT (Läubli et al., 2018; Toral, 2020; Freitag et al., 2021a).

A human reference translation is (at least ideally) created taking the entire source document into account. However, just as source sentences are often ambiguous, we hypothesize that human reference sentences also contain ambiguities. Thus, when a system output deviates from the human reference, we may need to look at additional context to determine if those deviations are acceptable, in the context of the full document translation.

In this study, we present a simple procedure for extending pretrained MT metrics to the document level. Prior work has used pretrained models models like BERT (Devlin et al., 2019) to embed a single human reference sentence and hypothesis (e.g. an MT output) sentence. We instead argue that a *better* representation of the reference or hypothesis sentence can be obtained by providing several sentences of context to the pretrained model, allowing the pretrained model to *use surrounding context when embedding each sentence of interest*. Once the embeddings of the reference or hypothesis sentence have been computed (taking into account surrounding sentence context), the metric is computed in the same manner as the sentence-level metric.[1,2]

We apply this method to extend four popular pretrained metrics to the document level:[3]

- BERTScore (Zhang et al., 2020), a text generation metric that uses the alignments from token embeddings of a pretrained BERT model to score the similarity of a hypothesis and reference.
- Prism (Thompson and Post, 2020a), a text generation metric which utilizes a sequence-to-sequence paraphrase model to score how well a hypothesis paraphrases the reference.
- COMET (Rei et al., 2020), an MT metric which fine-tunes a multilingual LM, namely

[*] Work conducted during an internship at Amazon.

[1] In the case of Prism (Thompson and Post, 2020a), we modify this logic slightly to retain only the probabilities of the sentence of interest (see § 3.2).

[2] In the case of COMET/COMET-QE (Rei et al., 2020), which incorporates the source sentence, we provide additional source context in the same manner (see § 3.3 and § 3.4).

[3] We release our code at `https://github.com/amazon-research/doc-mt-metrics`.

XLM-R (Conneau et al., 2020), to predict translation quality given a hypothesis, source, and reference.

- COMET-QE (Rei et al., 2020), the reference-free (i.e. "quality estimation as a metric") version of COMET.

To test the effectiveness of our document-level metrics, we measure system-level correlation with human judgments. We select the so-called "platinum" Multidimensional Quality Metrics (MQM) judgments collected for the WMT 2021 metrics task (Freitag et al., 2021b). We believe MQM judgments are the best available to test document-level MT metrics as these judgments are made by expert translators that have access to—and are strongly advised to consider—source-side document-level context when judging each target sentence. We perform evaluation on all the WMT 2021 language pairs (En→De, Zh→En, En→Ru) and domains (TED talks and news) for which MQM judgments are available.

We find that our document-level extensions of these four metrics outperform their sentence-level counterparts in 75% of cases considered. Excluding Zh→En news, where the human reference is of low quality (see § 4.1), we see improvements in 85% of cases. This provides strong evidence that document-level context is useful in the automatic evaluation of MT.

We also conduct analysis to better understand the performance improvement that we observe. We demonstrate that our document-level extension of COMET-QE significantly improves over its sentence-level counterpart on targeted tasks evaluating discourse phenomena, namely pronoun resolution and Word Sense Disambiguation (WSD).[4] This finding provides further evidence that our document-level metrics are using context to resolve ambiguities in the reference sentence. We also show that using reference context is better than using context from the MT output, likely because the MT output contains more errors than the reference.

In summary, our contributions are:

1. We present a simple but effective method to extend pretrained sentence-level metris to the document level, and apply it to four popular metrics.
2. We show that the proposed document-level metrics tend to have better correlation with human judgments than their sentence-level counterparts.
3. We improve over both COMET and COMET-QE, which appear to be the previous SOTA automatic metric and reference-free metric, respectively (Freitag et al., 2021b; Kocmi et al., 2021).
4. We conduct analysis to show that the improvements observed using our approach can be attributed to better context utilization, and also show that using reference context is better than using context from the hypothesis.

2 Related Work

Our work has parallels in human MT evaluation, where document-level judgments are required to distinguish human translation quality from MT system quality (Läubli et al., 2018; Toral, 2020). Castilho et al. (2020) showed that many source sentences are ambiguous, but that ambiguities are often resolved using only a few additional sentences of context. This suggests that we do not need to incorporate very many additional sentences of context into a document-level metric in order to see an improvement in quality.

Pretrained metrics are metrics which leverage large existing pretrained LMs or sequence-to-sequence models, and include YiSi (Lo, 2019), COMET (Rei et al., 2020), BERTscore (Zhang et al., 2020), Prism (Thompson and Post, 2020a), BLEURT (Sellam et al., 2020), and others. Pretrained metrics have been shown to consistently outperform surface-level metrics such as BLEU (Papineni et al., 2002), TER (Snover et al., 2006), and chrF (Popović, 2015) – see Mathur et al. (2020); Kocmi et al. (2021); Freitag et al. (2021b).

Prior to the rise of pretrained metrics, several works targeted discourse-level phenomena in MT metrics such as pronominal anaphora (Hardmeier and Federico, 2010; Miculicich Werlen and Popescu-Belis, 2017; Jwalapuram et al., 2019) and lexical cohesion (Wong and Kit, 2012; Gong et al., 2015). For a detailed overview of evaluation of discourse-level phenomena, we direct the reader to Maruf et al. (2021). Recently, Jiang et al. (2022) proposed BlonDe, a document-level metric that focuses on discourse phenomena in order to score a translated document. However, we find that BlonDe substantially under-performs modern pretrained metrics, despite taking advantage of document-level context (see § 5.1).

[4] The use of a reference would make these tasks trivial, so we limit our analysis to the reference-free COMET-QE.

Figure 1: To extend BERTScore to the document level, we add reference context (e.g. "Take your heavy jacket") to both the reference sentence (e.g. "It is freezing today") and hypothesis sentence (e.g. "The weather is cold today"). This context is used to improve the embeddings of the reference and hypothesis sentences (e.g. helping the model understand that "it" is likely referring to weather). However, the additional context is not used when performing alignment and scoring, which follows standard sentence-level BERTScore. The same methodology is applied to Prism and COMET/COMET-QE (not shown). Image adapted from Zhang et al. (2020).

3 Method

At a high level, we propose a very simple procedure for extending pretrained MT metrics to the document level: As in standard sentence-level metrics, we produce a score for a single hypothesis sentence compared to a single human reference translation sentence. However, we use additional context[5,6] from the reference translation when computing the contextual embeddings for both the hypothesis sentence and reference sentence. Once the hypothesis and reference sentence have been embedded, we discard the extra context sentences before computing metric scores following the same process as the corresponding sentence-level metric. Additional details are provided for each metric below.

For the following discussion, let s refer to the source sentence, h refer to the hypothesis (i.e. MT system output) sentence, r refer to the human reference translation sentence, and let c_s, c_h and c_r refer to the source, hypothesis, and reference context, respectively.

3.1 Document-level BERTScore

BERTScore (Zhang et al., 2020) is an unsupervised text generation metric that leverages the power of a pretrained large LM to score generated text. BERTScore encodes tokens of both the reference and the hypothesis with a pretrained LM and computes soft alignments based on token similarities. The alignment matrix is then used to calculate the precision, recall and F1 scores of the hypothesis compared to the reference.

To extend BERTScore to the document level, we use the reference context $\langle c_r \rangle$ while encoding the hypothesis or the reference with the LM. However, we align only the tokens of the reference/hypothesis sentence being scored (see Figure 1 for an illustration).

For BERTScore we use the default LM option for each language pair, which is the multilingual BERT-base (Devlin et al., 2019) for all En→* pairs and RoBERTa-large (Liu et al., 2019) for *→En pairs. BERT and RoBERTa are naively document-level; specifically, the LMs are trained on up to 512 tokens at a time, which is significantly longer than the average sentence length. Thus no changes to the underlying model were required to extend BERTscore to the document level.

3.2 Document-level Prism

Prism (Thompson and Post, 2020a,b) is an unsupervised text generation metric that uses a sequence-to-sequence paraphraser to evaluate how well a hypothesis paraphrases a human reference translation. Specifically, to score a translation the reference is fed to the encoder and the hypothesis is force-decoded in the decoder via teacher forcing. The token-level probabilities of the reference are aggregated to produce a score and the process is repeated with the hypothesis in the encoder side and the reference in the decoder. The final score is the average of the two scores.

In order to generalize Prism for document-level

[5] We use two preceding sentences from the reference as context, but our method could be applied to additional previous and/or subsequent sentences.

[6] We only use valid context. For example, when using a nominal value of two prior sentences as context, the first sentence in a document gets no context sentences and the second sentence gets one context sentence.

evaluation we concatenate the reference context c_r to both the reference and hypothesis $\langle c_r; r, c_r; h\rangle$. The context is used as a prompt; that is, we only aggregate token-level probabilities for the sentence being evaluated. The authors of Prism release the sentence-level multilingual MT model that they zero-shot paraphrase model. However, we require a document-level model to extend Prism to the document level. One option for extending Prism to the document level is to train a document-level, multilingual MT model. While document-level data collection methods and datasets do exist (Guo et al., 2019; Thompson and Koehn, 2020; Cettolo et al., 2012; Lison et al., 2018), document-level data is not currently available in nearly as many language pairs as sentence-level data. To extend Prism to the document level, we instead use mBART-50 (Tang et al., 2020), a multilingual encoder-decoder LM. mBART-50 is trained on document fragments of up to 512 tokens, in 50 languages, resulting in a multilingual document-level paraphraser. Note that while an mBART model fine-tuned on (sentence-level) translations is available, we do not use it because we require a document-level model. As a result, although the mBART model we use is multilingual, it is not a translation model so we cannot use it for the reference-free version of Prism.

3.3 Document-level COMET

COMET (Rei et al., 2020) is a supervised metric that is trained on human judgments. COMET encodes the source, hypothesis and reference via a multilingual pretrained LM and the representation of each sentence is the average of its output token embeddings. The encoded representations are further combined via subtraction and multiplication and fed to a regressor that predicts a score for each translated sentence. We use COMET-MQM_2021 (Rei et al., 2021), which is built on top of XLM-RoBERTa-large (Conneau et al., 2020). The COMET models are pretrained on direct assessment judgements from WMT 2015 to WMT 2020 and fine-tuned on MQM z-scores from Freitag et al. (2021a).

To extend COMET to the document level, we integrate source context c_s and reference context c_r by concatenating them with the source and hypothesis/reference in the encoder. We obtain sentence representations by averaging the output embeddings of the tokens of the current sentence only before passing them to the regressor.

As with BERTscore, the model underlying COMET is inherently document-level. However, the underlying LM is fine-tuned for a few epochs on human judgments from previous WMT campaigns that consist of a single (source, reference, and hypothesis) sentence and the corresponding score. As the amount of fine-tuning is quite limited, we hypothesize that the model has still retained its ability to handle text beyond sentence level, and this assumption appears to be confirmed by experimental results (see § 5.1).

3.4 Document-level COMET-QE

COMET-QE (Rei et al., 2021) is the reference-free version of COMET. We use the latest COMET-MQM-QE_2021, trained similarly to the COMET-MQM_2021 discussed above. Although COMET-QE does not does not have access to the reference it has been shown to perform reasonably well compared to strong reference-based metrics (Kocmi et al., 2021).

Similar to reference-based COMET, to extend COMET-QE to the document level, for each source s and hypothesis h, we concatenate the previous source and hypothesis sentences as context $\langle c_s; s, c_h; h\rangle$ and score the hypothesis h in question.

The pretrained model for COMET-QE is the same as the one used in COMET, therefore no further modifications are required to extend COMET to the document level.

4 Experiments

Motivated by the finding of Scherrer et al. (2019); Kim et al. (2019); Castilho et al. (2020) that two previous sentences are sufficient context to correctly resolve ambiguities in the majority of sentences, we use two previous reference sentences as context unless otherwise noted. Sentences are separated using the separator token of each model: [SEP] for RoBERTa and <\s> for XLM-R and mBART-50. We use reference context c_r as reference for the hypothesis, as opposed to hypothesis context c_h. This is done in order to avoid propagation of translation errors (see § 6.1 for an ablation using hypothesis context instead of reference context).

4.1 Human Judgment Experiments

We compare our document-level metrics judgments of MT outputs with those of the human-generated

Model	Input	TED talks			News

Table 1: System-level correlation with WMT 2021 MQM annotations for Prism, BERTScore, COMET and COMET-QE and their generalization for document-level evaluation (Doc-*, this work). Within each document/sentence-level pair, **bold** denotes the best correlation and "*" denotes a statistically significant ($p < 0.05$) difference. Excluding Zh→En news data, which has a very low-quality human reference (see § 4.1), our document-level metrics outperform their sentence-level counterparts in 17 of 20 (85%) of cases, and 6 of 6 (100%) of statistically significantly different cases.

MQM annotations from the 2021 WMT metrics shared task (Freitag et al., 2021a). We select MQM for several reasons: They are produced by professional translators (compared to crowd workers or translation researchers) and require explicit error annotations that are believed to lead to higher quality annotations. Also, MQM annotators are specifically instructed to "*identify all errors within each segment in a document, paying particular attention to document context*." In 2021, in addition to the news domain, annotations were also produced for translations of TED talks in three language pairs: En→De, Zh→En and En→Ru.

One potential problem with the metrics dataset is the quality of the Zh→En news human reference. The WMT metrics shared task organizers acquired MQM scores for the human references, in addition to MT system outputs. The Zh→En reference received an MQM score of just 4.27, only slightly better than the best MT system at 4.42 (Freitag et al., 2021b). For reference, 0.0 is a perfect score and a score of 5.0 corresponds to one major error (or many minor errors) per sentence. In contrast, for the same language pair, the TED reference has an MQM score of 0.42 vs the best MT system at 1.65.

4.2 Discourse Phenomena Experiments

In order to confirm that any gains we see from document-level metrics are in fact due to their ability to correctly handle ambiguities in the reference which can be resolved using document-level context, we also perform targeted evaluation of discourse phenomena using contrastive sets. These testsets are common in the evaluation of document-level MT systems where a context-aware model should ideally assign the highest probability to the correct translation; all translations are plausible and only the use of context can reveal the correct translations. For our case, since we are evaluating MT metrics, we treat each sentence as a different hypothesis and calculate how often our metric ranks the correct translation the highest. Since the use of a reference would make this task trivial for reference-based metrics, we only evaluate on COMET-QE. We use ContraPro (Müller et al., 2018), a selection of sentences from OpenSubtitles2018 (Lison et al., 2018) that contain the English anaphoric pronoun *it* in the source side. Starting from the correct translation in German, contrastive translations are automatically created to contain the German pronouns *er*, *sie* and *es*. In order to identify the correct translation the model must look into previous context. We also evaluate on a similar dataset for En→Fr created by Lopes et al. (2020) for the translation of *it* and *they* into *il*, *elle*, *ils*, *elles* in French. Finally, we evaluate on DiscEvalMT (Bawden et al., 2018), a contrastive test which consists of 200 examples of anaphoric pronoun translation for En→Fr and 200 examples of WSD.

4.3 Baseline Methods

For correlation with human MT quality judgments, in addition to the sentence-level version of each metric we extend, we also compare to

Model	En→De			En→Fr				
	Intra	Inter	Total	Intra	Inter	Total	Anaphora	WSD
Lopes et al. (2020)	-	-	70.8	-	-	83.2	82.5	55.0
COMET-QE	78.2	40.9	48.4	76.3	76.6	76.5	50.0	50.0
Doc-COMET-QE (this work)	**80.5**	**72.6**	**74.2**	**88.7**	**88.0**	**88.3**	**83.5**	**68.0**

Table 2: Accuracy (percentage correct) for targeted evaluation of contextual phenomena. Our document-level version of COMET-QE substantially outperforms the sentence-level COMET-QE, and also outperforms the best methods proposed by Lopes et al. (2020), demonstrating that it is successfully incorporating contextual information.

BlonDe (Jiang et al., 2022), an overlap-based document-level metric that focuses on discourse phenomena.[7] We also compare to Prism using the m39v1 model released by the authors of Prism.

For discourse phenomena, we compare our document-level COMET-QE model to the sentence-level COMET-QE as well as the best reported results of Lopes et al. (2020).

5 Results

5.1 Correlation with Human Judgments

We present the system-level Pearson correlation with the human annotations of the 2021 WMT metrics task for all metrics (sentence- and document-level) in Table 1. Statistical significance ($p < 0.05$) is computed for each sentence- vs document-level metric pair following Freitag et al. (2021b) using the PERM-BOTH hypothesis test (Deutsch et al., 2021). We also provide the results of BlonDe (only for *→En since this metric relies on entity taggers and discourse markers that are only trained in English) and Prism with the original model (m39v1) for comparison.

Overall, adding document-level context leads to improved correlation with human judgments for all metrics. Our document-level metrics outperform their sentence-level counterparts in 18 of 24 (75%) of cases considered. Excluding Zh→En news data, which has a very low-quality human reference (see § 4.1), our document-level metrics outperform their sentence-level counterparts in 17 of 20 (85%) of cases. Looking at only pairs with statistically significant differences, our document-level metrics outperform their sentence-level counterparts in 6 of 7 cases (86%), and 6 of 6 (100%) of cases excluding Zh→En news.

We see that document-level metrics outperform sentence-level metrics in only 1 of 4 cases on Zh→En news This suggests that the document-level metrics are sensitive to errors in the reference context. This hypothesis is further supported by analysis in § 6.1.

For Prism, we observe that the sentence-level results with the original m39v1 model are better than the sentence-level results with mBART-50. However, by using document-level context we are able to improve over the sentence-level Prism with mBART-50 in every language pair/domain. This narrows the gap between Prism with mBART and Prism with m39v1, outperforming the stronger m39v1 model in two TED language pairs.

Although the COMET models are fine-tuned on single sentences, experimental results suggest they are able to retain their ability to handle inter-sentential dependencies. We considered retraining COMET excluding older direct assessment judgments which did not take document-level context into account; however this would have severely limited the amount of (already very limited!) training data.

Finally, we observe that BlonDe performs significantly worse than the pretrained metrics as well as our document-level extensions, underperforming everything except document-level COMET-QE in TED Zh→En.

5.2 Discourse Phenomena Improvements

We provide the results of targeted evaluation on contrastive datasets for COMET-QE and Doc-COMET-QE in Table 2. We also provide the scores of the best-performing document-MT model for each dataset from Lopes et al. (2020) for comparison. The reference-based metrics are not considered in this section as the use of a reference would make the task trivial.

We observe that the document-level COMET-QE substantially outperforms the sentence-level COMET-QE, and even outperforms document-

[7] We report BlonDe results in English only, as BlonDe uses a discourse marker script from Sileo et al. (2019) which was trained only in English. BlonDe could likely be extended to other languages but we did not attempt to do so.

	Context	Doc-Prism	Doc-BERTScore	Doc-COMET
hypothesis	$\langle c_s; s, c_r; r, c_h; h\rangle$	0.595	0.624	0.630
reference	$\langle c_s; s, c_r; r, c_r; h\rangle$	**0.649**	**0.650**	**0.659**

Table 3: Average correlation with MQM human judgments of our document-level metrics using previous hypothesis sentences as context vs. previous reference sentence as context. COMET-QE is excluded because it does not depend on the reference. For all three methods, we see better correlation using the reference for hypothesis context. We hypothesize that this is because using previous hypothesis sentences allows for propagation of errors (i.e. an error in a previous sentence can impair the judgment of the current sentence).

level translation models optimized for discourse tasks. Surprisingly, we observe improvements in the evaluation of pronoun translation not only when the necessary information is located in a previous sentence (Inter) but even in the case where the antecedent can be found in the same sentence (Intra), suggesting additional context is helpful in these cases as well. Apart from pronoun translation, our approach also improves over both the sentence-level metric and the document-level MT of Lopes et al. (2020) at WSD. These findings all support our hypothesis that our document-level metrics are resolving ambiguities in the reference sentence by using additional context.

6 Ablations

6.1 Hypothesis vs Reference Context

For our document-level MT metrics described prior to this point, we use the reference context c_r (as opposed to the hypothesis context c_h) as context for the hypothesis. Our reasoning behind this decision is that previous translations could contain errors that might bias the document-level metric into rewarding erroneous translations. To test this, we conduct an ablation experiment in which we concatenate the hypothesis context to the hypothesis while the context of the remaining inputs (i.e. the reference and the source sentence) remains unchanged. Table 3 shows the average correlation across all language pairs and domains using either the hypothesis context or the reference context. We do not provide these scores for COMET-QE as it does not have access to the reference.

We observe that the use of the hypothesis context degrades performance for all metrics, which is in line with the findings of Fernandes et al. (2021) for document-level MT. We suspect that this is because the previous hypothesis sentences contain more errors than previous reference sentences, and thus using previous hypothesis sentences allows for more propagation of errors (i.e. an error in a previous sentence can impair the judgment of the current sentence).

One disadvantage of using reference context for the hypothesis is that we cannot measure document-level fluency, that is, how well a document flows from one sentence to the next. Our analysis suggests that either document level fluency is of less concern than error propagation, and/or that MQM judgments are not adequately capturing document-level fluency.

6.2 Amount of Context

In our experiments so far we have used the previous two sentences as context, motivated by the finding of Scherrer et al. (2019); Kim et al. (2019); Castilho et al. (2020) that two previous sentences are sufficient context to resolve ambiguities in the majority of sentences. Figure 2 shows the results for [0, 1, 2] previous sentences as context for news articles and TED talks. In the news domain we observe that for En→De and En→Ru), adding more context helps. On the other hand, for Zh→En, adding context appears to be harmful. We believe this is likely explained by the relatively low-quality human references in Zh→En (see § 4.1). For TED talks, although the results are somewhat noisy, we also observe that more context tends to improve correlation across all three language pairs.

7 Conclusion

We proposed a simple and effective approach to generalize pretrained MT metrics to the document level. We apply our approach to BERTScore, Prism, COMET-QE, and COMET-QE, and we believe that it could easily be extended to other pretrained sentence-level metrics. To the best of our knowledge, our work is the first example of pretrained document-level MT metrics.

We demonstrate that the use of document-level context in pretrained metrics improves correlation with human judgments, and that the improvements

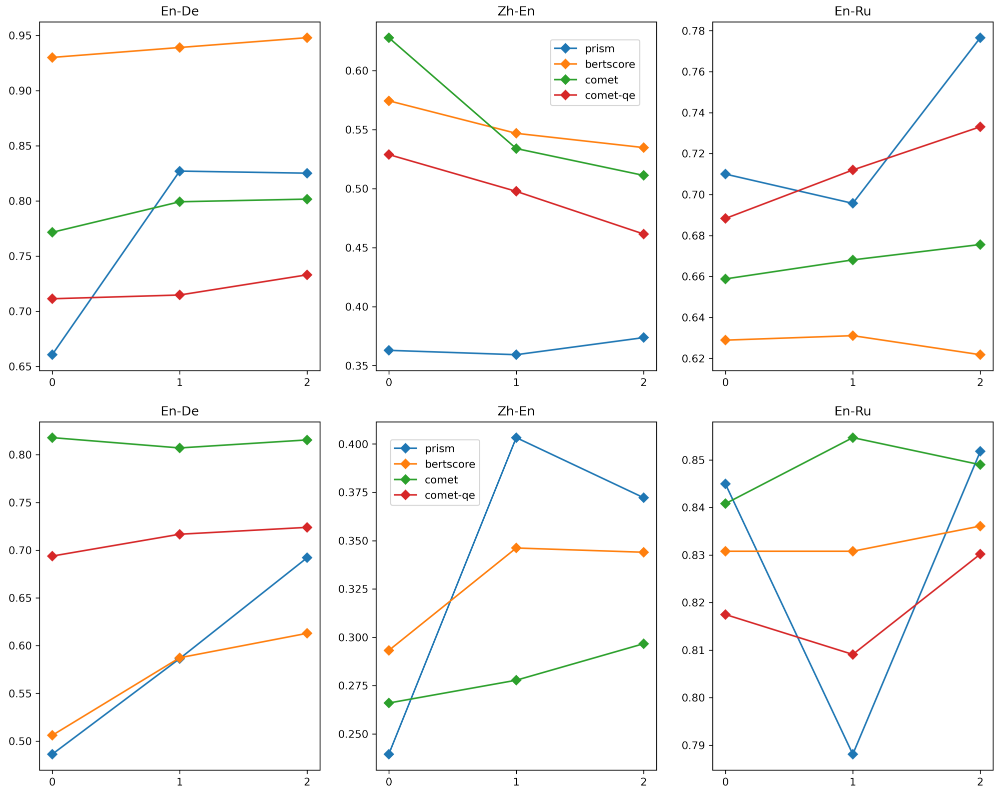

Figure 2: System-level Pearson correlation with human correlation vs. number of sentences of context for News (upper) and TED talks (lower). Although the results are noisy, in general we observe that correlation improves as the amount of context increases. The one exception is Zh→En News, which we attribute to poor human references (see § 4.1).

are likely due to fact that the document-level metrics can resolving ambiguities in the reference sentence by using additional context. We present results on MT evaluation but our approach may also be beneficial in other Natural Language Generation (NLG) tasks where discourse phenomena are present (e.g paraphrasing, data to text generation, chatbots, etc).

In conclusion, we argue that the MT community (and possibly the greater NLG community) should adopt metrics—such as those presented in this work—which take document-level context into account. This would better align automatic metrics with human evaluation, where document-level judgements have been shown to be more discriminative than sentence-level judgements. We also recommend that future research in metrics explore novel ways to incorporate context.

Searching for a higher power in the human evaluation of MT

Abstract

In MT evaluation, pairwise comparisons are conducted to identify the better system. In conducting the comparison, the experimenter must allocate a budget to collect Direct Assessment (DA) judgments. We provide a cost effective way to spend the budget, but show that typical budget sizes often do not allow for solid comparison. Taking the perspective that the basis of solid comparison is in achieving statistical significance, we study the power (rate of achieving significance) on a large collection of pairwise DA comparisons. Due to the nature of statistical estimation, power is low for differentiating less than 1-2 DA points, and to achieve a notable increase in power requires at least 2-3x more samples. Applying variance reduction alone will not yield these gains, so we must face the reality of undetectable differences and spending increases. In this context, we propose interim testing, an "early stopping" collection procedure that yields more power per judgment collected, which adaptively focuses the budget on pairs that are borderline significant. Interim testing can achieve up to a 27% efficiency gain when spending 3x the current budget, or 18% savings at the current evaluation power.

1 Introduction

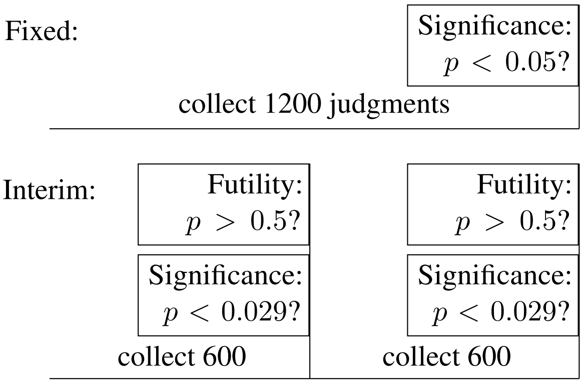

Figure 1: A graphical representation of evaluation with different testing procedures. Currently, our evaluation uses fixed testing, and our current budgets (depicted) often result in underpowered comparison (§5). To get a notable increase in power, we will need to spend more (§6), and interim testing is a way to spend efficiently. Interim testing allows for early stopping by trading off power for additional peeks. In MT, such a tradeoff is a favorable and can yield more power per judgment (§7).

In machine translation (MT), pairwise evaluations are conducted to identify the better system over a test domain. MT has long taken intrinsic quality as an object of interest, and assumes it can be determined directly from the output (Gatt and Krahmer, 2018). Most practitioners accept that human judgments reflect such quality, and take human evaluation as the gold standard (Bojar et al., 2016). In conducting an evaluation, the experimenter must allocate a budget to collect human judgments, and so evaluation can be an expensive endeavor. No one in the history of MT research has ever been satisfied with the cost or reliability of human evaluation (Graham et al., 2017; Chaganty et al., 2018; Saldías Fuentes et al., 2022, inter alia). Likewise, we were keen to find savings, upon the foundation of statistically rigorous inference.

Evaluation is a noisy process, and we may not expect a repeat experiment to declare the same winners. For one, we may want a holistic answer of the best system over the entire test domain, but we can only evaluate on a small and finite set of input source sentences (Koehn, 2004; Dror et al., 2018). This introduces a sample bias that our conclusion must be wary of. For another, human judgments on the same output may diverge, so we assume that humans are only a noisy reflection of the true intrinsic quality (Graham et al., 2015). This introduces additional noise when drawing a conclusion from our observations. Intuitively, using a larger test set or averaging over more human judgments should yield more consistency in pairwise comparison.

Inferential statistics is necessary in MT evaluation to declare "winning" MT systems under un-

[*] Work done at Microsoft.

certainty. Basic usage of statistical testing covers the use case of pairwise MT system comparison (Mathur et al., 2020). After data collection is complete, we can declare significance by computing a p-value (statistical primer in §3). When the p-value is low, a real effect is likely to exist. When the p-value is high, repeat experiments will be inconsistent (effectively tossing a coin), and no good decisions can be made even if you used the gold standard Direct Assessment (DA; Graham et al., 2015) annotation. Significance is the meta-analysis that guards against falsely declaring winners due to noise, with some level of guarantee.

Our work takes the perspective that the basis of solid comparison is in achieving significance. The rate/likelihood an experiment will observe significance is the *power*, and we would like it to be high. At the same time, we would like to minimize human effort and keep costs low. This paper investigates several aspects of the relationship between power and cost in human evaluation:

1. *How can we reason about the power of an evaluation?* We recommend a sensitivity perspective to evaluation, where we characterize an evaluation by its minimum detectable effect (MDE), or the smallest pairwise difference the evaluation will reliably yield significance on. By retrospectively analyzing significance in pairwise comparisons, we can derive an empirical MDE. **Our evaluations can reliably detect up to 2-3 point of DA difference, but comparisons often exhibit even smaller differences.**

2. *How can we notably increase the sensitivity of an evaluation?* With the appropriate power analysis, we can get a rough estimate of the number of samples required to achieve an acceptable sensitivity. To increase the sensitivity to the desired level, we might hope variance reduction techniques can give us the necessary sample efficiency. **If we wanted half of the past comparisons to reliably achieve significance, we needed at least 2x more samples, far beyond the ~1.2x sample efficiency variance reduction offers.**

3. *How can we spend more money efficiently?* If we are not satisfied with the power of our current evaluation, increasing the budget and collecting more judgments is necessary. Crucially, if we accept that small differences can't be known, our evaluation can be more efficient by focusing the budget elsewhere. **We verify that an "early stopping" procedure (interim testing) can can achieve up to a 27% efficiency gain when spending 3x our current budget, or 18% savings at our current evaluation power.**

2 Related work

There is a tradition of using test sets to estimate system performance over the general domain in machine learning (Hastie et al., 2001). There have been calls for statistically rigorous evaluation in natural language processing using significance testing (Dror et al., 2018), however its adoption in reporting has been mixed. For a classic task such as part-of-speech tagging, evaluation is generally significant/consistent even for small gains (Gorman and Bedrick, 2019). In MT, even moderate differences in metric gains (e.g. DA, MQM) may not be consistent, so there is a stronger need for significance testing. Historically, MT evaluation has been heavily based on statistical significance (Koehn, 2004).

MDEs have been used to describe the power of experiments in contexts such as education (which program results in increased test scores?) and sociology (Bloom, 1995). Berg-Kirkpatrick et al. (2012) empirically investigate the conventional wisdom that a certain metric gain corresponds to significance (e.g. 0.5 for BLEU). This threshold is exactly an evaluation's MDE. They find that a threshold has strong empirical backing, but a few experimental parameters affect this threshold. In our work, we propose taking a sensitivity perspective to evaluation, and reporting the expected MDE of an experiment instead of the other experimental parameters.

Any statistical technique that reduces the cost of human evaluation is, in another view, improving the power offered by some fixed budget. Chaganty et al. (2018) first proposed applying control variates to human evaluation. Control variates increase the sensitivity of an evaluation by leveraging information from a metric. This formulation conveniently allows us to analytically understand its performance based on the experimental conditions. In realistic experimental conditions, they found that the sample efficiency gain is at most 20%, which is in line with results reported in MT (Saldías Fuentes et al., 2022). Mendonça et al. (2021) propose using online learning to adaptively spend the evaluation budget on determining the best MT systems. However, their technique lacks in statistical rigor for decision making.

Knowing when to "early stop" an evaluation allows us to adaptively spend the budget on difficult pairs and save on easily distinguished pairs. It is known that peeking at the p-value while data collection is ongoing is problematic. Peeking inflates the chance of observing significance and the chance that such significant observation is incorrect (Albers, 2019). While always valid p-values can be calculated that adjust for this error and can be reported at any time, they are mathematically difficult to apply (Johari et al., 2015). Interim testing has been used in medical trials, where experimenters have an ethical consideration in stopping the experiment early (O'Brien and Fleming, 1979). By planning the number of peeks in advance, interim testing can offer rigorous statistical inference while potentially saving time and effort, packaged in an easy to understand technique (Lakens et al., 2021). Our work investigates whether the tradeoff between power and savings is favorable for MT evaluation.

3 A primer on inferential statistics

We consider pairwise comparisons as the basic unit of evaluation echoing calls from Mathur et al. (2020) and Kocmi et al. (2021). Pairwise comparisons are more interpretable than correlations, and more practical for production deployment scenarios. In a pairwise comparison we test the difference between two systems A and B. If you were just to collect a number of DA judgments for each system and declare a winner, a repeat experiment could yield different results due to experimental noise.

A statistical test guards against making an incorrect conclusion due to experimental noise. To do this, we assume a null hypothesis (that A is better than B) and examine how likely we could have made observed our data under this assumption. There are two outcomes of conducting a test:

(i) there is evidence of a significant difference which rejects the null hypothesis, or

(ii) the evidence is insufficient and we are unable to reject the null hypothesis.

In the case of (i), a significance test usually guarantees a false detection rate of at most α, where usually $\alpha = 0.05$. Therefore, the best outcome of statistical testing is the presence of significance, where our inferences enjoy a low false detection rate. The rate at which we can declare significance is called an experiment's *power* (typically denoted as $1-\beta$, where β is the false negative rate). In pairwise comparison, our evaluation should have an accuracy $(1-\alpha)(1-\beta)$ against the true, pairwise judgment.[1]

Intuitively, statistical testing can be loosely thought of as reducing the width of two confidence intervals, spaced by the true system difference of A and B (Krzywinski and Altman, 2013). The power of an experiment is then a function of these three aspects:

(a) First, the true system difference plays a role in the power. When the distance between the true scores is large relative to the noise, noise is unlikely to obfuscate the true pairwise ranking of the systems.

(b) Second, the variance of human judgment. The larger the variance in a single judgment, the more judgments that will be needed in an average to get a consistent estimate.

(c) Finally, the sample size or the budget. The number of judgments you collect shrinks the confidence intervals by a factor of $\sqrt{N}$ from the single judgment variance.

The more judgements you can collect the smaller these confidence intervals will be. When the confidence intervals don't overlap, the comparison is likely to achieve significance. These three factors all play a role in whether the intervals will be narrow enough.

If we know two of (a), (b), or (c), we can use the appropriate power analysis to deduce the third. Typically, we will observe the (b) human judgment variance, and make a guess at what the true difference (a) would be, to compute what (c) the budget we would have to spend is. When providing estimates for the budget, we would provide estimates under a range of guesses at what the true difference is (Card et al., 2020). Alternatively, we may also ask what the minimum detectable effect is for some fixed budget. Wei and Jia (2021) conducted power analysis in MT and found that small differences

[1] This pairwise accuracy holds if you assume that different MT systems always have different quality. By randomizing the systems, the null hypothesis will be true exactly half of the time.

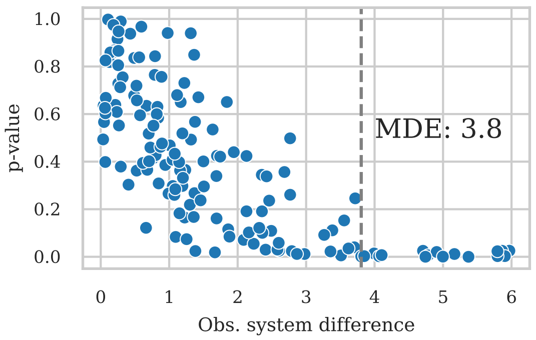

Figure 2: The minimum detectable effect (MDE) is illustrated in the ENU → FRA language pair. Each point represents a pairwise comparison conducted for this language pair. When evaluating pairs exhibiting differences larger than the MDE, 95% of pairs will achieve significance at the $\alpha = .05$ level, which totals to a pairwise accuracy of 90%. Unfortunately, most pairs are on the left hand side of this line. This is also the case for many other language pairs in the ShipData.

	Significant / insignificant	Obs. MDE	Median difference
ENU → FRA	30 / 153	3.8	1.2
ENU → DEU	19 / 151	3.5	0.7
FRA → ENU	3 / 140	2.4	0.6
DEU → ENU	27 / 130	1.9	0.6
JPN → ENU	78 / 127	2.9	3.2
ENU → JPN	40 / 94	3.8	1.8
ITA → ENU	2 / 81	2.8	0.5
CHS → ENU	30 / 78	2.6	1.5
ENU → PTB	28 / 74	1.0	0.6
ENU → SVE	31 / 73	4.4	1.4

Table 1: Significance and MDE results in the top-10 language pairs (by number of comparisons). Significance is calculated at the $\alpha = 0.05$ level. Observed MDEs are calculated for 90% pairwise accuracy. The median system difference is observed from the data. For most language pairs, less than half of the pairs had a significant observation. MDEs are small but most of the system differences appear to be even smaller.

require an infeasible amount of budget. This gives a hint that most of our MT evaluation is underpowered. Consistently conducting underpowered experiments run the risk of inflating the error rate in significant observations (Ioannidis, 2005).

4 Dataset

MT evaluation has an established tradition of conducting human evaluation and releasing public datasets. At the time of writing, the current annotation method of choice in MT is *Direct Assessment* (DA; Graham et al., 2015; Akhbardeh et al., 2021). Direct Assessment asks annotators to rate a translation's quality on a sliding point scale from 0-100. We study the **ShipData** presented in Kocmi et al. (2021), which is the largest human evaluation dataset of pairwise comparisons, accumulated over two years from internal evaluation campaigns at Microsoft Translator. No text is contained i.e. source, references, or outputs, but the raw DA scores are sufficient for our purposes. We focus on this dataset because it is large and often contain comparisons between state-of-the-art systems. It contains 4004 pairwise comparisons between two systems, where each system pair contains about 600 human judgments per system (1200 for both systems).

5 The sensitivity approach to evaluation

The basis of solid comparison is significance. Therefore, we need a way to reason about the power of an experiment. In this section, we recommend a sensitivity approach to evaluation, and retrospectively deduce the power of previous evaluations. By looking at the observed effect sizes we can also set a meaningful target power.

5.1 Minimum detectable effects (MDEs)

The pairwise evaluation of two MT systems is not a one-size fits all procedure, even though the MT literature uses a consistent annotation method (Federmann, 2018). Rather, an evaluation is our best attempt to answer which MT system is better with the evaluation annotation budget at hand. How much budget to allocate should depend on the circumstantial factors. Statistical inference can give us a probabilistic answer to this question with whatever evidence we are able to collect.

In the best case scenario, a significant result is observed and a winner is declared after the data is collected. However, significance depends on the conditions of the experiment (see §3), where the size of the pairwise difference, annotation variance, and number of samples all play a role. The pairwise difference and annotation variance are determined by the annotation method. Since most prefer to use a widely accepted annotation such as Direct Assessment (DA; Graham et al., 2015), these are factors we may not be able to change. However, we can increase the budget, and the larger the budget, the more likely we will be able to achieve significance for some fixed difference.

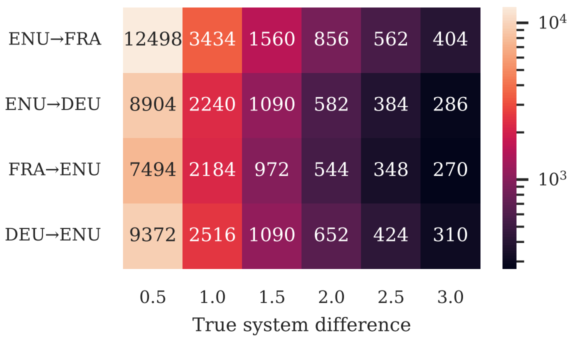

Figure 3: Power analysis for the total number of judgments required to achieve an MDE with 90% inference accuracy. These figures are calculated through simulation with distributional assumptions on the human scoring function (see §6.1). Compared to the observed MDEs, figures here serve as a lower bound. As the differences decrease linearly, the number of samples required increases exponentially.

		Variance (std. dev.)	Reducible variance
WMT21	`⋆-en`	866.2 (29.4)	23.1%
pSQM	`zh-en`	683.2 (26.1)	9.8%
pSQM	`en-de`	705.4 (26.5)	53.4%

Table 2: Total annotation variance and the reducible proportion of that variance. pSQM scores are provided by Freitag et al. (2021) and are collected from professional annotators. WMT21 scores are provided by Akhbardeh et al. (2021) and are collected from crowdworkers. pSQM scores are normalized from 0-100 for ease of interpretation. At least half of the variance is irreducible.

ρ	WMT21	pSQM(zh-en)	pSQM (en-de)
1.0	1.30	1.20	4.33
0.5	1.06	1.12	3.09
0.2	1.01	1.11	2.94

Table 3: Data efficiencies for the control variates estimator under different conditions. Each column represents a different condition of reducible variance, instantiated from observed statistics from Table 2. ρ is the correlation of the metric that would be used in the control variates estimator. With the exception in pSQM `en-de`, variance reduction is far from giving us the 2x-10x multiplier we need.

We recommend to think about an MT evaluation in terms of its sensitivity. With a fixed budget and annotation method, there is some deducible minimum detectable effect (MDE; Bloom, 1995), where evaluating differences larger than the MDE will enjoy a comfortable level of power (rate of significance). Alternatively, if we did not observe significance for some experiment, we may suspect that the true difference is likely to be lower than the experiment's MDE. With a sensitivity perspective, our consideration is now to conduct DA evaluations with a budget large enough to exhibit an appropriate MDE. Ideally, our evaluation exhibits an MDE small enough where we believe any smaller differences are not practically meaningful (more in §6.1). Realistically, we would set up an evaluation with MDEs as small as our budgets allow.

5.2 Observed MDEs

In this section, we attempt to retrospectively understand the MDEs/sensitivity of our past evaluations. Refer to Figure 2 for graphical intuition. We can empirically estimate (as opposed to making assumptions and simulating, see Card et al., 2020) an (observed) minimum detectable effect by sorting all the pairs by their observed absolute system difference, and choosing the difference where comparisons with a larger system difference (effect size) will have at least 95% of experiments showing significance (corresponding to experimental power $1 - \beta = 0.95$) at a level of $\alpha = 0.05$ by the Mann Whitney U (MWU) test. This ensures that at least $(1 - \alpha)(1 - \beta) \approx 0.9$ of the pairs should be accurate (Wei and Jia, 2021). We can interpret this as the threshold at which our experiments will stop being accurate at the 90% level.

The minimum detectable effects (MDE) are small, but differences between systems are even smaller. Refer to Table 1. Our evaluations have been able to detect up 1 or 2 points of system-level DA difference, but often a third of the comparisons are still not significant. Looking at the density of the differences (see the x-axis in Figure 2) we see that most of the pairs exhibit small differences. An immediate consequence is that most of the budget is being spent to declare ties. Most of our comparisons are underpowered, and where the p-value is high the experiments are not much better than a coin toss. The median difference provides a target MDE if we want half of our evaluations to show significance (alternatively, declaring ties in half of the evaluations is acceptable).

6 Known unknowns

Now that we have established a way to reason about experimental power, we conduct power analysis to understand how much more gain we need to improve our power to a desired sensitivity. We investigate whether variance reduction techniques are sufficient, and conclude that the only way forward is to increase the annotation budget.

6.1 Power analysis for the desired sensitivity

As suggested in Card et al. (2020), we can roughly determine the number of samples for a fixed power using simulation. As with any power analysis, we must make some assumptions to estimate the number of samples needed. Here we assume that the judgments for a given system's translation is distributed as $s \sim 100 - \text{Gamma}(k, \theta)$ where $k = \frac{\mu^2}{\sigma^2}$ and $\theta = \frac{\sigma^2}{\mu}$ are fit to match the average mean and variance of a system for that language pair. We choose the use of the Gamma distribution because the resulting scoring distribution is such that most of the scores are high, and the more severe the translation error the more rare it is, which matches what we observe in Kocmi et al. (2021). We then use the bisection method to determine the integer whose power has the closest match to our desired β value. We find that the simulation reasonably matches empirically observed MDEs.

Power analysis shows that most pairs needs not a little, but a lot more judgments. Refer to Figure 3. Comparing to the observed MDEs, the power analysis is *optimistic*, where the figures we provide can be seen as a lower bound. Even a reduction of our MDE to 1 point can require up to 2x times more judgments (than originally used in the ShipData). We highlight the fact that as differences get linearly smaller, the number of samples is an exponential growth. The nature of statistical estimation is that smaller differences are increasingly elusive.

In the search for higher power, we must also keep in mind that arbitrarily small differences require arbitrarily large budgets. Therefore, for modern state-of-the-art comparisons, some differences will be left unknown. We can not fantasize about detecting every single small difference out there just by spending more budget or applying some strong statistical technique (see §6.2). Perhaps this may be taken in stride, as mathematicians learned to accept the existence of unprovable theorems nearly a century ago (Gödel, 1934). Many other important fields such as domain adaption also grapple with their unknowns (Ben-David et al., 2010).

6.2 Variance reduction is inadequate

Generally, we assume that a human evaluator scores a segment with the true segment level quality score, plus some noise. If $H(x)$ is the human scoring function on system translations x, there are 2 parts to the scoring variance. We can decompose the variance of H to

$$\begin{aligned} \text{Var}(H(x)) = \mathbb{E}[\text{Var}(H(x)|x)] \\ + \text{Var}(\mathbb{E}[H(x)|x]) \end{aligned} \quad (1)$$

by the law of total variance. The first part is the variance of the true translation quality scores, capturing the real difference in quality across output translations, and the second part is the rest of the variance. The second term, which we broadly term annotator noise, can include annotator biases, preferences, and even mood.

Using repeat judgments we can estimate the second term (annotator noise), which is similar to an inter-annotator agreement (Wei and Jia, 2021). Since the ShipData doesn't contain any repeat judgments, we provide estimate of the second term from a few similar datasets (Akhbardeh et al., 2021; Freitag et al., 2021). Refer to Table 2. In designing variance reduction techniques, we usually leverage metric scores to reduce the first term, but not annotator information to reduce the annotator noise (second term), as it is too difficult (Saldías Fuentes et al., 2022).

With variance reduction (VR) techniques, we can achieve a higher power with the current budget by leveraging side information (Owen, 2013). However, VR is not arbitrarily powerful, and its effectiveness is constrained by the amount of reducible variance present, and how much of the reducible variance you can actually reduce. Here, we look at the control variates technique[2] which leverages the linear information in a metric for the estimation of system quality. The data efficiency in Chaganty et al. (2018) describes how many times a control variates estimator improves over the regular sample mean estimate, and is characterized by

$$\text{DE} := \frac{\text{Var}(\hat{\mu}_{\text{mean}})}{\text{Var}(\hat{\mu}_{\text{cv}})} = \frac{1+\gamma}{1-\rho^2+\gamma} \quad (2)$$

[2] Equal proportion stratified sampling is a special case of control variates, so these results also apply (Owen, 2013). Any technique which uses a metric to bin outputs, where the same number of outputs are sampled for scoring within each bin, are constrained by these results as well.

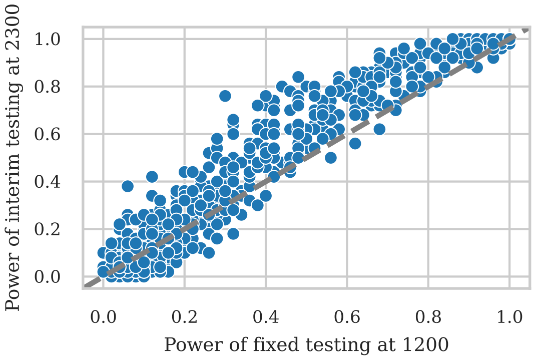

Figure 4: The average power of each pairwise comparison for fixed testing at 1200 against interim-futility testing at 2300. Each point represents a pairwise comparison. When planning for 2300 judgments with interim-futility, the actual amount of judgments collected in our simulation is about 1200. For the same budget, we see that interim-futility testing boosts the power of moderate to high-powered pairs, but drops that of the lower powered pairs.

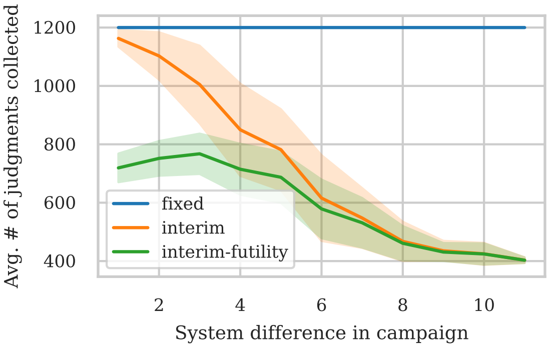

Figure 5: The average number of judgments collected by each sampling method. For interim and interim-futility, 1200 judgments were planned, and the actual judgments collected are strictly less. As the system differences grow larger, both methods have the potential to stop early. For interim-futility, pairs with small differences also incurred less judgments.

where ρ is the sentence-level Pearson correlation of the metric and

$$\gamma = \frac{\sigma_a^2}{\sigma_f^2} = \frac{\mathbb{E}[\text{Var}(H(x)|x)]}{\text{Var}(\mathbb{E}[H(x)|x])} \tag{3}$$

Refer to Table 3. **With the optimistic assumption of a perfect metric, we often only get a ~1.2x efficiency gain from VR, far from the 2-10x multiplier we need to obtain significant comparisons.** The gains we predict for VR is consistent with the practical results presented in Saldias et al. (2022). These reduction techniques work, but is far from achieving what we need, echoing the narrative of Chaganty et al. (2018).

7 Spending effectively

To have a notable gain in sensitivity, variance reduction alone is inadequate. Therefore, spending is necessary in the search for higher power. This section describes a simple yet statistically rigorous way of "early stopping" in a human evaluation campaign. Interim testing adaptively allocates the budget to borderline significant pairs, and can be seen as an efficient way to spend.

7.1 Peek-a-boo! Planning interim peeks

Savings can be achieved if we can stop data collection as soon as a result can be concluded. If the experimenter runs the preferred statistical test (at false detection rate $\alpha = 0.05$) periodically while data collection is on-going, the final process will have a false detection far higher than the α intended (Albers, 2019). There are a class of sequential sampling techniques, which allow you to test after every single sample while maintaining the false detection rate constant, but are mathematically difficult to apply (Johari et al., 2015).

A simpler solution is to use interim sampling and apply a correction for multiple testing (Lakens et al., 2021). For instance, the Pocock correction (Pocock et al., 1987) is appropriate when multiple comparisons are made, but we want a false detection to be maintained at a desired α.[3] Refer to Figure 1. For interim testing, we can plan in advance to collect batches of data, and test between each batch. To maintain a final false detection rate to the fixed procedure, your interim tests must have an α_0 appropriately adjusted with the Pocock correction. The downside is that this correction is conservative, and each test has less power.

At each interim point, we can also stop for futility, or when we see that even in completion of the data collection, we are unable to achieve significance. Practically, there are many ways to set up this stopping rule (Lakens et al., 2021), but in our simulation we find that a simple heuristic (checking if the $p > 0.5$) works well for our purposes. An alternative view of futility stopping is that we are unwilling to conduct the analysis of the original

[3] Here's why we need a correction: imagine 20 comparisons made at $\alpha = 0.05$ where the null hypothesis is true, then the probability of getting at least 1 significant result is actually $1 - 0.95^{20} \approx 0.63$.

experiment with the corresponding MDE.

7.2 Experimental setup

We compare three different kinds of testing methods. Refer to Figure 1.

- **Fixed** testing is most commonly used in evaluation. In fixed testing, the annotation budget is spent all at once, and the statistical test is performed at the end. The advantage of fixed testing is that only statistical test is performed with the highest (least conservative) alpha threshold (e.g. is $p < 0.05$?).
- **Interim** testing plans to spend the budget in equal sized steps, with an interim analysis between each step. If significance is observed at any point, the data collection is terminated. We always plan for 3 peeks, and use the Pocock correction (e.g. is $p < 0.0221$? at each peek). While the testing threshold is lower (more conservative), the savings obtained from some pairs can be used on others, by planning more judgments for all pairs.
- **Interim-futility** is the same as interim testing but also applies a futility stopping rule at each analysis. If $p > 0.5$ then the experiment is terminated early. Futility stopping does not affect the false detection rate so it does not need to be adjusted. Futility stopping results in strictly less power, but the savings can be used elsewhere, by planning more judgments.

To benchmark these testing procedures against each other, we simulate data collection from the pairs in the ShipData by sampling with replacement. For each pair we simulate each testing procedure 1000 times and record the number of times the procedure is able to achieve significance. For all tests we use the Mann Whitney U test (standard to machine translation; Akhbardeh et al., 2021) with a testing threshold of $\alpha = 0.05$. Within the ShipData, each pair only has about 1200 judgments, from which we often oversample. We note that this is our best faith attempt to study these testing methods in the large budget regime, and actual benchmarking would require infeasible cost, so the simulation can serve as our best synthetic testbed.

7.3 Results

Refer to Figure 5. For a fixed sampling procedure, the number of samples collected is constant for every effect size. This can be inefficient as pairs with large differences do not need as many judgments to declare significance. Interim testing is adaptive; as the differences get larger, interim testing can declare significance at an early step. For interim-futility, less judgments are also collected for the pairs with the smallest differences, where early steps may declare futility. We will later see that the interim-futility behavior is most favorable.

Refer to Figure 4. When comparing fixed and interim-futility, we compare two procedures that spend the same budget. Since interim sampling spends more on borderline pairs, the power for pairs with moderate to high differences increases. Savings are made on pairs with both large and small differences, with small difference pairs having a decrease in power. We highlight that interim-futility is a different kind of testing. **While the use of fixed testing seeks to best detect every difference no matter how small, the use of interim-futility prioritizes the pairs that have borderline significant differences.**

Refer to Figure 6(a). The main metric we benchmark these methods is by the average power, or the number of significant comparisons over all the ShipData. When comparing over all pairs, interim testing has slightly better performance, but interim-futility gives considerable gains even at current budget sizes. Our results show that to attain the fixed testing power at 1200, interim testing only needed to spend 990 judgments per comparison, which is an 18% saving[4]. The advantage of interim sampling over fixed sampling is even more pronounced when we are spending large budget sizes, where we can gain 28% savings at 3600 judgments (3x). Refer to Figure 6(b). When testing small differences interim sampling is worse than fixed sampling, as it has a stricter significance threshold. However, interim-futility is able to stop on pairs with little hope and prioritize the borderline significant pairs. Refer to Figure 6(c). On pairs with large differences interim sampling is best, with interim-futility achieving similar performance. For large differences futility stopping should rarely trigger, so the two methods should be similar.

We want to highlight that the distribution of the differences is key to the success of the interim-futility testing procedure. Since most of the pairs are concentrated either in the dense

[4] All the results in this paragraph are derived using linear interpolation, akin to using a ruler on Figure 6.

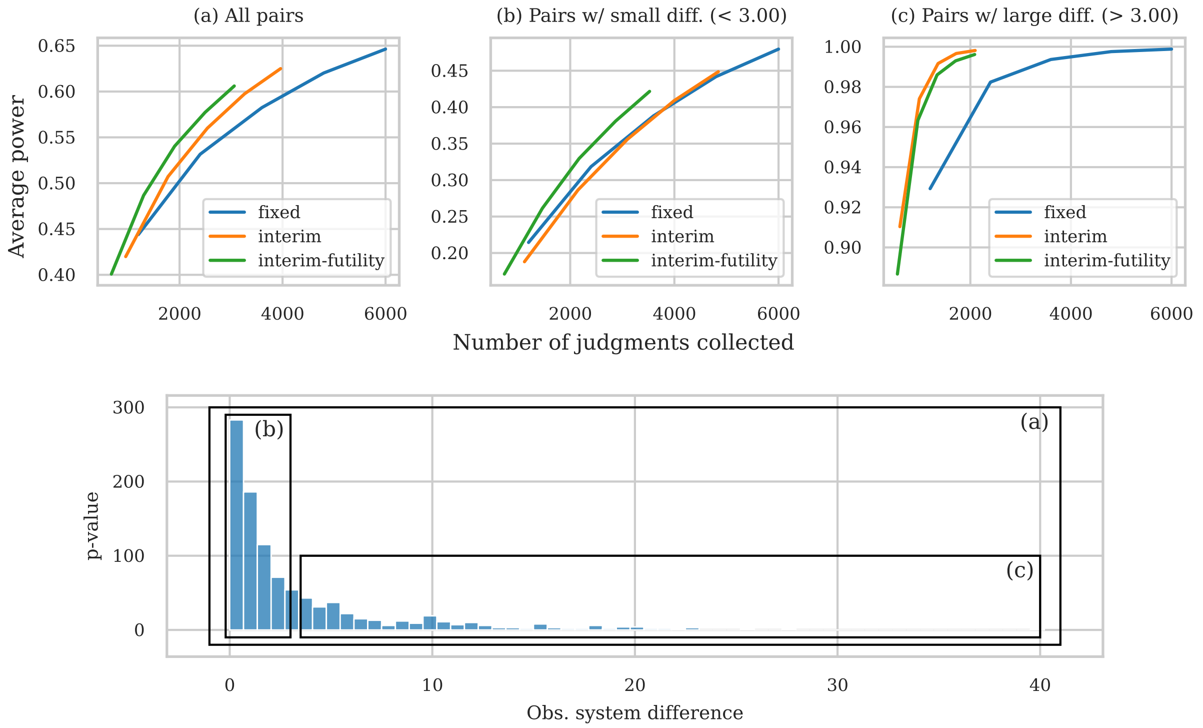

Figure 6: (Top) The average power of each testing procedure across the ShipData for different sized budgets. (a) Shows the average power across all data, and (b) shows it over pairs with large differences and (c) shows it for small differences. (Bottom) The histogram of the true differences in each pairwise comparison. These are true differences due to the simulation we used to test these procedures. Interim-futility is most favorable by average power in (a), (b) and (c). Interim testing is weaker in (c) due to its stricter significance threshold.

region of small differences or in the long tail of large differences, these are areas where interim-futility can early stop. Compared to fixed testing, interim-futility will be able to make savings here to spend elsewhere. Crucially, the application of futility stopping also requires a change in our evaluation mindset, as we must be willing to accept that some small differences are not worth detecting. If we can make this change, then interim-futility is most favorable in terms of average power.

8 Limitations

The most important assumption of our work is in the use of Direct Assessment (DA). While our methods can generalize to any real valued judgment, we analyzed DA because of its widely recognized, gold standard status in MT evaluation. DA is a particularly noisy judgment, and so the power and variance reduction results are pessimistic. However, we believe that the study of annotation will be the most important direction in MT evaluation.

Let's take Hassan et al. (2018), where one of the first claims of MT-human parity was made. By their evaluation, which was conducted according to the community standard, no significant difference was found between human and machine translations with a reasonable budget, and so a tie was declared. Toral et al. (2018) reassesses this claim, and essentially presents a series of alternative evaluations and observe significant differences that contradict with Hassan et al. (2018). This is just one of many studies which compels an alternative evaluation with qualitative insight (Läubli et al., 2018, 2020; Freitag et al., 2021).

Our perspective is that significance is only one pillar of MT evaluation. It is our hope that the analyses in this work will further our understanding of significance and evaluation power. However, the second pillar of MT evaluation is in the annotation method. While power is quantitative, the study of annotation methods will be qualitative. Going forward, understanding how we can change the annotation method to increase the power will be crucial. We will need good qualitative understanding to be able to move away from DA and establish new gold standards.

In addition, we showed that interim testing is only effective for pairwise comparison. Future work should look to make savings in the leaderboard styled evaluation of WMT. This may come in the form of generalizing interim sampling for multiple comparisons or formalizing the bandit results from Mendonça et al. (2021) in terms of statistical inference.

9 Conclusion

Our work is motivated by the cost of human evaluation in machine translation. Before searching for a higher power from our current budget, we determined how much more power was necessary. In doing so, we recommend taking a sensitivity approach to evaluation. From here we came to the conclusion that to achieve the power/sensitivity necessary, variance reduction alone would be insufficient, and spending is our only option. If we decide to allocate larger budgets, interim testing is a more effective way to spend, which can yield 18% savings at the current evaluation power, or 27% savings at 3x the original budget.

Test Set Sampling Affects System Rankings: Expanded Human Evaluation of WMT20 English–Inuktitut Systems

Rebecca Knowles and **Chi-kiu Lo**
National Research Council Canada (NRC-CNRC)
{rebecca.knowles,chikiu.lo}@nrc-cnrc.gc.ca

Abstract

We present a collection of expanded human annotations of the WMT20 English–Inuktitut machine translation shared task, covering the Nunavut Hansard portion of the dataset. Additionally, we recompute News rankings to take into account the completed set of human annotations and certain irregularities in the annotation task construction. We show the effect of these changes on the downstream task of the evaluation of automatic metrics. Finally, we demonstrate that character-level metrics correlate well with human judgments for the task of automatically evaluating translation into this polysynthetic language.

1 Introduction

Translation between Inuktitut[1] and English was featured as part of the 2020 News Translation task at WMT (Barrault et al., 2020). The English–Inuktitut machine translation system rankings published in Barrault et al. (2020) were incomplete, due to the delay in the 2020 annotation campaign and because they only cover the out-of-domain portion of the test set. In this work, we present:

- an expanded dataset of human annotations that covers the in-domain portion of the test set,[2]
- an analysis of both the existing (out-of-domain) human annotations and the new (in-domain) annotations,
- revised system rankings based on the new annotations and controlling for irregularities in the original data collection process,
- and correlations of automatic MT evaluation metrics with the revised system rankings and the newly collected human annotations.

Dataset	Segments
Hansard-A (H-A)	11404
Hansard-B (H-B)	7801
All Hansard	19205
WMT20-DA (N-1)	8000
WMT20-DA2 (N-2)	12002
WMT20-DACrowd (N-C)	9728
All News	29730
Total	48935

Table 1: Number of segments annotated in each dataset, without any data filtering. We use names corresponding to the dataset files, with short forms in parentheses.

Our aim with this work is to release a broader set of human annotations, for continued research on translation between English and Inuktitut, as well as to demonstrate the downstream impacts of irregularities in WMT data collection and publication. In particular, we draw attention to how errors in human annotation setup (not errors in the work of the annotators, but errors in the way that organizers constructed the annotation tasks) and the failure to account for their effects impact both the validity of the rankings themselves and the shared task on automatic metrics which relies on the rankings. In this way, the 2020 WMT task on Inuktitut serves as a case study of a broader issue in the field. We provide suggestions for how to account for irregularities in existing annotation task construction and release the code and data to replicate our results.

2 Data

The test set for the WMT 2020 English–Inuktitut shared task consisted of data from the Nunavut Hansard as well as from Nunatsiaq News, collected and shared with permission. The News test data consisted of documents collected from Nunatsiaq News between September and November, 2020, as was standard for the shared task. The Hansard data in the test set, however, was collected from earlier dates. The main training data available for building constrained systems was the Nunavut Hansard 3.0

[1] We use the term *Inuktitut* here because the website of the Legislative Assembly of Nunavut lists Inuktitut, Inuinnaqtun, and English (along with French) as the languages spoken in the House (https://assembly.nu.ca/faq#n113) and the version of the Hansard released as training data is the Inuktitut version, written in syllabics. See Appendix A.

Table 2: Number of segments annotated by annotator (anonymous annotator ID shown in the first column, with Un. representing all unknown annotators who annotated the crowd data) and dataset.

(Joanis et al., 2020), consisting of aligned proceedings of the Legislative Assembly of Nunavut. As a consequence, the Nunavut Hansard test data could be considered "in-domain", while the News data was "out-of-domain" (the development data was similarly divided between the two domains).

The annotators who did the work of human evaluation discussed here were fluent language experts at the Pirurvik Centre,[3] paid at professional rates. All the human annotations were collected in the segment rating with document context (SR+DC) style of direct assessment (DA; Graham et al. 2013, 2014, 2016) using the Appraise interface (see Barrault et al. 2020 for additional interface details). For each segment, annotators viewed the source sentence and a candidate translation, and scored the translation on a pseudo-continuous sliding scale from 0-100. These segments were displayed in document context, and annotators also provided document scores (we omit those from this work).

Each News story had a unique document ID, but the Hansard data was treated as a single document containing 1566 lines. This had two main consequences with respect to human annotation of system outputs. The first and most obvious is that the annotations collected at WMT (on which the Findings paper's rankings (Barrault et al., 2020) were at least partially based) only included annotations of the News data (out-of-domain). The reason for this is that the code used to generate sessions of annotations in the SR+DC DA human annotation task structures pooled all documents and then sampled documents "at random (without replacement) and assigned [them] to the current HIT [human intelligence task] until the current HIT comprise[d] no more than 70 segments in total"; since the Hansard data was treated as one document with more than 70 segments, it was never sampled.[4] The second is that the News documents were longer on average than News documents for other language pairs. English–Inuktitut News documents ranged from 12 to 137 lines in length, with a mean of 39.0 (standard deviation 20.5) and a median of 36. Documents for other language pairs that were evaluated in the SR+DC format ranged from 2 to 32 lines in length, with a mean of 12.0 lines (standard deviation 6.2) and a median of 11. As a consequence, each annotation session of English–Inuktitut News data is less likely to contain documents translated by the full set of submitted systems (12 submitted systems and human reference), which has the potential to cause problems when scores are normalized per-annotation session (Knowles, 2021).[5] Additionally, a portion of the source and reference data News segments contained spurious quotation marks (see Appendix B). We now discuss the News and Hansard annotation processes.

2.1 News Annotations

There are several other noteworthy issues about the News data collection. As shown in Table 1, there are three direct assessment datasets collected at WMT that contain News-only annotations of English–Inuktitut translations. The first, N-1, consists of 8000 segments and does not contain any annotations of reference segments. The second, N-2, contains 12002 segments and *does* contain annotations of reference segments. Both of these were annotated by fluent language experts at the Pirurvik Centre. There is a third set of data, N-C, which was annotated by other annotators (the Findings paper does not clarify who those annotators were, so we will focus our analysis on the first two datasets, known to be collected through Pirurvik). The fact that one set of data was collected with reference segments included and the other was not

[3] https://www.pirurvik.ca/

[4] Note that we will use HIT and annotation session interchangeably in this paper. An annotation session that received a single ID and thus was used as the basic chunk of data for computing z-scores typically (but not always) consisted of two HITs, each containing 100 segments. However, the way the data is released, the two HITs are not distinguishable from one another, hence our reference instead to the annotation session. Note that an individual annotator may have completed many such sessions.

[5] The use of z-score carries with it an implicit assumption that the annotation session, HIT, or set of data annotated by one annotator is representative of the whole. The raw scores for human references tended to be near-perfect, while one system's scores were zero, meaning that whether an individual annotation session contained one, both, or neither of these would unduly influence the z-score computation.

also has the potential to cause problems in generating system rankings. Because system rankings from SR+DC run through Appraise are typically calculated based on z-scores computed at the annotation session level, and because these sessions are *not* representative of the distribution of systems, they will be erroneously standardizing out real differences in quality. Even if they did compute z-scores over annotators, we can see in Table 2 that not all annotators completed annotation sessions in each dataset, meaning that some annotated reference segments and some did not; again, this means that it is inappropriate to calculate z-scores in the standard WMT fashion (even over annotators instead of over sessions). The data collection also contained quality assurance segments (these are called "BAD" segments, and quality assurance is described in more detail in Appendix C).

The system submitted under the name zlabs-nlp (no corresponding paper submitted) consisted of the exact source (English) data, but was nevertheless included in the annotation tasks. The annotators from Pirurvik received instructions to give a score of 0 to output that was not in the target language (i.e., Inuktitut) and this is reflected in their scores (almost all 0 for zlabs-nlp segments),[6] while the scores for the Crowd annotation set are much more wide-ranging (indicating that those annotators may not have received the same instructions).

2.2 Hansard Annotations

Following the completion of WMT 2020, we collected annotations of the Nunavut Hansard portion of the test set. Like the News annotations, fluent Inuktitut-language experts from Pirurvik Centre performed these segment rating with document context (SR+DC) annotations using the Appraise interface; with the help of the shared task organizers, we collected data using the same web interface as was used for the News data, allowing us to keep that portion of the annotation process consistent.

The data was processed and collected with the following noteworthy changes.[7] First, data from zlabs-nlp (exact copies of the source text) were omitted from annotation, as those scores are not representative of translation. Second, the Hansard was manually divided into pseudo-documents, ranging in length from 8 lines to 26 lines, with an average of 14.6 (standard deviation 3.7) and median 15. This is closer to the average document length for other language pairs, and enables annotation sessions to contain a more diverse set of system/document pairs. Third, in this set of annotations, references – and all systems – were more evenly distributed across annotators, improving validity of the z-score assumptions (Knowles, 2021). Finally, as shown in Table 1, the Hansard annotations were split into two parts. Wishing to ensure that all systems were annotated on consistent sets of documents, but unsure as to whether annotator time and budget would cover the full Hansard test set, we first randomly split the set of documents in two, and then generated annotation sessions by sampling from one half (Hansard-A) or the other (Hansard-B). Fortunately, annotators completed all sessions. We did not include quality assurance segments in this task, as all annotators were known to be qualified (see Appendix C).

2.3 Systems

Twelve systems were submitted to the English–Inuktitut task. In alphabetical order by team name, they were: CUNI-Transfer (Kocmi, 2020), Facebook_AI (Chen et al., 2020), Groningen (Roest et al., 2020), Helsinki (Scherrer et al., 2020), NICT_Kyoto (no corresponding paper),[8] NRC (Knowles et al., 2020), OPPO (Shi et al., 2020), SRPOL (Krubiński et al., 2020), MultiLingual_Engine_Ubiqus (Hernandez and Nguyen, 2020), UEDIN (Bawden et al., 2020), UQAM_TanLe (no corresponding paper), and zlabs-nlp (no corresponding paper). Of these twelve, Barrault et al. (2020) listed MultiLingual_Engine_Ubiqus and UQAM_TanLe as unconstrained entries (meaning that they chose to use additional data outside of those provided for the constrained version of the shared task). All systems for which we have a description used Transformer models (Vaswani et al., 2017).

3 Approaches to Rankings

In this work, we will generate two sets of rankings: system rankings over the Hansard data and system rankings over the News data. While there would be reason to desire a single ranking that covers both in-domain (Hansard) and out-of-domain

[6] The 7 scores of 1 may be simply due to slider operation.

[7] This data collection was completed prior to the publication of Knowles (2021), and as such only addresses a portion of the concerns raised in that paper. We seek to address other concerns from that paper in our analysis of the data.

[8] The Findings paper cites Marie et al. (2020) for NICT_Kyoto, but that paper does not describe an English–Inuktitut MT system.

(News), that would raise the question of how to balance the two, and would also be a challenge to produce given the differences in the data collection processes. Having two rankings also highlights differences in performance across those domains.

The Hansard rankings come from the annotations that will be released alongside this paper, while the News rankings are a reranking based on the data collected at the WMT shared task. Here we discuss how the rankings computed for this paper differ from those produced at WMT. A partial description of the WMT rankings can be found in Barrault et al. (2020). The main issues we try to address in our new rankings are those raised in Knowles (2021) around the instability of rankings, particularly when the annotation sessions contain distributional issues that make the usual z-score computation inappropriate. We attempt to handle these issues both in proactive ways (through modifications to the "document" lengths and system distributions in the setup of the annotation of Hansard data) and in reparative ways (when we make use of the existing WMT News annotations).

3.1 Hansard Ranking Approach

Ave.	Ave.z	System
89.9	0.249	SRPOL
87.5	0.201	Groningen
88.6	0.192	NICT_Kyoto
88.8	0.170	NRC
88.1	0.160	Human-A
87.1	0.133	CUNI-Transfer
85.9	0.120	Facebook_AI
85.6	0.046	UEDIN
83.6	-0.055	Helsinki
78.0	-0.127	MultiLingual_Engine_Ubiqus
76.5	-0.360	UQAM_TanLe
65.6	-0.789	OPPO

Table 3: Hansard ranking, computed using the standard WMT approach. Unconstrained systems in grey. Horizontal lines separate significance clusters.

For the Hansard rankings (Table 3), we compute them as follows. We have a mapping between annotators and annotation sessions, so for each annotator, we collect all of the data from all of their annotation sessions. Given one annotator's full set of annotations, we compute the mean m_a and standard deviation s_a (where a is the annotator). These are then used to compute the z-scores for every segment that they annotated. Given a raw score x produced by annotator a, its z-score is:

$$z = \frac{x - m_a}{s_a} \tag{1}$$

After z-scores have been computed for all segments annotated by all annotators, system scores can be computed. The first step is to average any instances of scores that share the same system ID, the same document ID, and the same sentence ID (regardless of whether they are annotated by the same or different annotators). Then, all segments produced by a particular system are averaged into the final system score. These last two steps are performed on both raw scores and z-scores, but the ranking is computed using z-scores. Clusters of systems are indicated by horizontal lines in the ranking (Tables 3 and 4), with such a horizontal line drawn below a system if and only if its z-scores are significantly better than all systems ranked below it according to a Wilcoxon ranked sum test ($p < 0.05$). The differences between this and the standard WMT data collection are the choice to compute z-scores over annotators rather than over annotator sessions and the fact that we did not collect any "BAD" quality assurance annotations.

3.2 News Ranking Approach

Ave.	Ave.z	System	Findings Ranking
90.3	0.652	Human-A	(1-2, 90.5, 0.574)
76.4	0.219	CUNI-Transfer	(3-9, 77.4, 0.409)
77.7	0.102	NICT_Kyoto	(3-9, 79.2, 0.364)
71.6	0.096	NRC	(3-9, 71.9 0.369)
76.2	0.053	Ubiqus	(1-2, 75.3, 0.425)
74.1	0.041	Helsinki	(3-9, 75.2, 0.296)
73.6	0.025	Facebook_AI	(3-9, 74.6, 0.368)
72.7	0.012	SRPOL	(3-9, 72.8, 0.282)
72.8	-0.052	Groningen	(3-9, 71.6, 0.339)
67.6	-0.305	UQAM_TanLe	(10-11, 68.9, 0.084)
65.0	-0.427	UEDIN	(10-11, 66.4, 0.081)
46.8	-1.223	OPPO	(12, 48.2, -0.384)
0.0	-3.181	zlabs-nlp	(not shown)

Table 4: News Rankings, with mean and standard deviation for z-score computed using only SRPOL (all annotators scored output from that system). The last column shows the systems' original rankings in the 2020 Findings paper: cluster range, raw average, and z-average.

For the News task (Table 4), we had the N-1 and N-2 datasets along with a mapping between annotators and annotation sessions. Starting from this, we modified the ranking computation process to attempt to account for the known concerns with the dataset. We were unable to replicate the Findings rankings (Barrault et al., 2020), nor the listed number of annotations for Inuktitut from the data released.[9] The Findings rankings may have been

[9] https://www.statmt.org/wmt20/results.html

computed from earlier, incomplete data.

Due to the high average document length (39.0 lines) and the extreme range of system quality (from human reference near 100 to zlabs at 0), we cannot expect annotation sessions to be comparable to one another and certainly not representative of the whole test data and systems. For this reason, it is already not appropriate to compute z-scores at the annotation session level. Additionally, it is not appropriate to compare z-scores that are computed in the standard way between the N-1 and N-2 datasets, since the former does not contain human references while the latter does. Adding to the challenges, not all annotators completed annotation sessions in both of the datasets, and not all annotators annotated data from all systems (or across systems in the same proportions). Thus, simply switching to the annotator-level z-score computation does not solve the problem. For this reason, we chose to compute the mean and standard deviation for each annotator based only on the SRPOL system segments that they had annotated. SRPOL and CUNI were at the intersection of all annotators' sets of annotated systems, but in different ratios, so we selected SRPOL because the annotator who had annotated the smallest number of segments had annotated more SRPOL than CUNI segments. We do not include "BAD" segments in the z-score calculations (as different annotators had different proportions of quality assurance data) and we also do not eliminate any data based on quality assurance measures. This does not guarantee that this is a perfectly fair comparison, as the specific documents and segments annotated are not consistent across annotators, but it does limit the influence of extreme outliers on the z-score computations. We then use those means and standard deviations to compute z-scores for all data across all systems.

In conjunction with these justifications, we note the following as additional support for our chosen approach to ranking the News data. The stated goal of using z-scores (rather than raw scores) in the official ranking is "to iron out differences in scoring strategies of distinct human assessors" (Barrault et al., 2020). If we had perfectly consistent annotators and were computing z-scores in such a way that they were standardizing annotator difference rather than other information in the data, z-scores and raw scores would produce matching orderings of systems. If all annotators were perfectly consistent but the z-scores did not correlate with the raw scores, then we would know that there was a problem with the z-score calculations or annotation setup. We simulate this by replacing all News human annotation scores with CHRF scores as pseudo-annotations and then calculate rankings in approximately the style of WMT20 by computing z-scores at the annotation session level[10] and then computing them using our approach. We find z-scores and raw scores produce identical system orderings under our approach, but produce less-correlated (i.e., non-identical) orderings using the WMT20 approach. Computing means and standard deviations for CHRF scores at the annotator level (but across all systems) does improve the most extreme differences between raw and z-scores, but the complete ordering is still not as well-correlated as with our new approach. While this does not guarantee that our approach fully solves the problem, it does demonstrate that our approach does not introduce the same error as the WMT20 approach.

If we were to use only SRPOL data for computing the annotator means and standard deviations for the Hansard ranking, we would obtain the same ordering of systems that we obtained via the approach described in Section 3.1 (though of course with different z-scores), with the only difference being that using SRPOL only would put UEdin and Helsinki in the same significance cluster.

4 Rankings

We observe several similarities and differences between the Hansard (Table 3) and News (Table 4) rankings. As expected, the authentic Human translations consistently score highly (with raw scores of 90.3 for News and 88.1 for Hansard) and are in the top cluster of the rankings. In the case of News, the authentic human translations are in a cluster of their own, while in the case of the Hansard data, they are in a cluster alongside the four top-performing MT systems. The raw scores for the News rankings are consistently lower than those for the Hansard rankings (both overall and on a system-by-system basis). This reflects the fact that there is less data in the News domain and the fact that the Hansard domain is highly repetitive. We will explore both of these topics in Section 5.3.

[10] This is intended to be closer to what we believe was done at WMT20; however, the WMT20 calculation for means and standard deviations likely included "BAD" reference segments, which we must omit because we do not have the "BAD" reference text to be able to compute CHRF scores against the reference.

The system that shows the smallest gap in raw scores between Hansard and News and the greatest improvement in clustering, moving from the fifth cluster for Hansard to the second for News was Ubiqus, which saw a difference of just 1.8. In comparison, the systems with the greatest drops in rankings (UEdin from third cluster to sixth, and Groningen from one to four) saw raw score average drops between 14.7 and 20.6. The OPPO and NRC systems also saw large drops in raw average scores (18.8 and 17.2, respectively) but with smaller or no corresponding ranking drops (in the case of OPPO, it was ranked last in Hansard so no drop was possible).

5 Discussion

5.1 System Performance

Here we discuss system performance across the different test sets. Table 5 summarizes some of the features of the approaches used in different submissions, while Figure 1 visualizes our two rankings and the published Findings ranking from Barrault et al. (2020). All submitted systems for which we have information used Transformer models, implemented in a range of toolkits.

System	Toolkit	BT	Tag	News Dev
CUNI	tensor2tensor	Y	-	-
Facebook	fairseq	Y	Y	75%
Groningen	Marian	Y	Y	76%
Helsinki	OpenNMT-py	Y	-	-
NICT				
NRC	Sockeye	Y	Y	100%
OPPO	fairseq	Y	-	-
SRPOL	Marian	Y	-	-
Ubiqus	OpenNMT-py	Y	-	-
UEdin	Marian	Y	-	-
UQAM				
zlabs				

Table 5: Table summarizing system features (where known), including toolkit used, use of backtranslation (BT), use of tags for domain and/or backtranslation (Tag), and whether News development data was used in training. For systems without a corresponding system description, unknown information is left blank. Unconstrained systems are marked in grey.

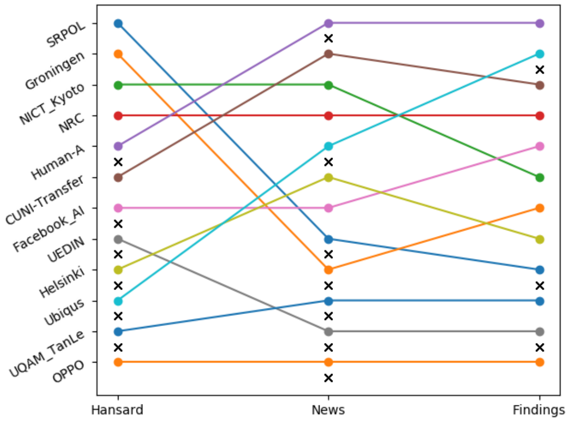

Figure 1: Summary of differences in clusterings and rankings. Black x marks indicate the demarcation between clusters and the systems are listed from best performing (top) to worst performance (bottom) across our Hansard ranking, our News ranking, and the ranking from the Findings paper (which used only News data).

Two systems participated as "unconstrained" systems (incorporating additional data), with differing levels of success. Multilingual_Engine_Ubiqus moves from the bottom half of the systems when ranked on Hansard to the top half when ranked on News, and their system incorporated additional data from news and magazine domains. This may account for some of the performance improvement they observed, though we cannot say with certainty if this is the main or only factor. On the other end, UQAM's system was also unconstrained but did not perform as well on News data. While examining the annotation data, we observed that despite its relatively low ranking, the UQAM system had a high number of segments with perfect automatic metric scores (CHRF of 100.0), meaning they were identical to the reference. Upon closer inspection, we found that 24.6% (295 of 1201) of UQAM segments annotated and labeled TGT (target) in the human annotation were identical to the reference. This compares to just 1.2% (183 of 14772) of all other systems' TGT annotated segments (excluding Human, which is itself the reference). The UQAM segments that were identical to the reference received very high scores, in line with the general trend for human translations. While there was not a paper submitted with the UQAM submission, the fact that it was marked as unconstrained suggests that their approach included additional data collection, and it appears that this included some of the test data.

All systems that had corresponding papers incorporated backtranslation. Three systems incorporated training on News development data (in various quantities) and these same three used tags to indicate domain and backtranslation. While this may have benefited the systems that incorporated it, it's clear that it was neither necessary nor sufficient to guarantee that a system placed in the top cluster.

Other techniques that systems used included pretraining, monolingual tasks, BPE dropout, ensembling, transfer learning, and more. There remains work to be done to identify which approaches produce the most positive impacts on translation quality. As it stands, a major challenge is that the development of the systems relied on automatic metrics, without knowing for sure which automatic metrics might be best suited to this language pair (several papers note the use of character-level metrics due to their prior results on morphologically complex languages). In Section 6 we will discuss the correlation between automatic metric scores and the human annotation results, in the hopes that this will be useful for future work on this language pair.

In addition to the rankings, we take a closer look at the performance of systems in Figures 2 and 3, which show raw human annotations averaged by document. These provide a rough visualization of system performance across different documents, as well as highlighting differences between the domains. The visualization shows both the lower overall scores assigned to the News data, as well as the greater coverage of the annotations in the Hansard data. We also see that certain documents are easy for most systems to translate, while others are consistently more difficult across systems. For example, the two documents with the highest median segment level scores, Hansard sub-documents 106 and 107, both consist of lists of names and positions, as well as standard parliamentary text about the house adjourning. Those documents with the lowest median segment scores contain longer sentences of members' speeches across varied topics like the Indspire awards, Red Seal program trades, and so on. We can also see how some systems perform relatively consistently across documents, while others exhibit more anomalous behaviour. For example we can see that the UQAM system exhibits some extremes (and the high-scored News document from 2019-11-12 is one where we note that the system output is identical to the reference, likely due to the system being unconstrained).[11]

5.2 Annotation Data Coverage

For the Hansard data collection, all systems were annotated over at least 97% of test segments, whereas for News data, coverage ranged from 47%

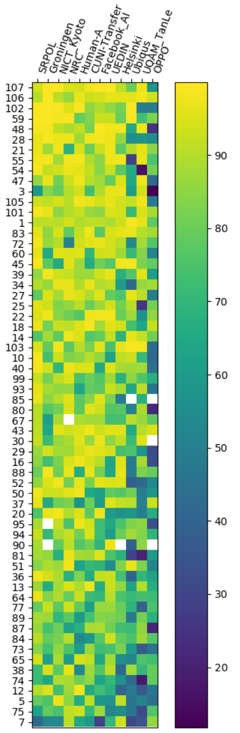

Figure 2: Raw annotation scores, averaged per document, for Hansard data. Lighter/brighter colors indicate higher scores; systems are ordered according to the rankings, while documents are ordered according to median segment score across all systems for that document. Blank spaces indicate no annotation for that document-system pair.

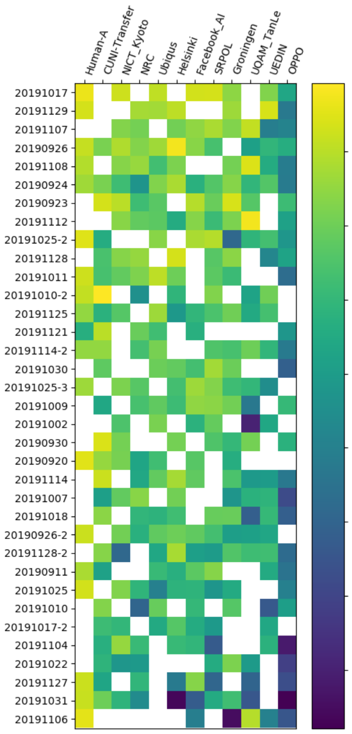

Figure 3: Raw annotation scores, averaged per document, for News data.

[11] The other systems that do see particularly high-performing documents do not have those as exact matches to the references, and in one case it is likely due to the fact that the news article is about a bill in the Legislative Assembly.

to 73% of test segments (with the human reference translations the least annotated).[12] This means that most Hansard "documents" were annotated for most systems (101 out of 107 had annotations for every system), while there were no News documents (out of 36) annotated for all systems. As we observe that some documents may be easier or more difficult for most systems, annotating all systems over nearly the same set of documents aims to alleviate this potential source of error.

5.3 Repetition and Novelty

Of the approximately 1.3 million sentence pairs in the Hansard training data, 59.8% of these are unique pairs, while the remainder are duplicates. The 2971 lines of the test set are all unique, and of these 15 sentence pairs were observed in the Hansard training data. If we consider only the source side, there are 155 source (English) sentences that appear in the test set that also appeared in the English side of the training data. Even though the target side of 140 of these segments is not identical to the target reference in the test set, systems still performed better on these previously observed segments than they did on segments that were previously unobserved. In fact, for all but the three lowest-performing systems, the raw scores on segments where the source had been observed in training averaged over 90.

In addition to the exact matches, the Hansard contains much boilerplate text, with small differences between what has been observed in training and the data in the test set. This includes segments like those at the start of a session, that indicate the date and time, as well as formulaic parliamentary speech (such as addressing the Speaker). All in all, the Hansard test data is more similar to the Hansard training data than the News test data is to the Hansard training data. Within each domain, there is not a strong correlation between source side similarity to training data and raw direct assessment scores, but across domains this may contribute to the differences we observe. This is also an imperfect analysis, as some systems used additional data and some incorporated development News data into their training. Nevertheless, we expect that the domain differences, compounded by the difference in data sizes, explain much of the difference in raw scores between the two domains.

6 Automated MT evaluation

Another important area of research on English–Inuktitut machine translation is accurate automated MT evaluation metrics for a polysynthetic language. Language model based metrics usually correlate better with human judgments when evaluating translation in non-polysynthetic languages but they suffer from a training resource scarcity problem when evaluating polysynthetic languages. Character based metrics are more commonly used for evaluating translation in low resource and polysynthetic languages (Mager et al., 2021) but there is not enough study on their correlation with human judgments. A complete collection of human annotations on both domains of the English–Inuktitut test set with translation output from diverse MT systems enables further studies on automated MT evaluation metrics, with the caveat that caution should be taken with News, due to the issues in the data collection described above and in Appendix B.

6.1 Setup

We rerun the correlation analysis of the WMT20 Metrics shared task (Mathur et al., 2020b) at system level and segment level with the updated system rankings on News and the newly-collected annotations on the Hansard data. Following the Metrics shared task setup, we use `mt-metrics-eval`[13] to conduct the correlation analysis.

The correlation analysis includes all the systems, except Human-A and zlabs-nlp. Human-A is excluded because a second reference was not available for the reference based metrics to score against and zlabs-nlp is excluded because this system was not included in the WMT20 Metrics shared task test set and thus none of the participants provided scores for it.

Following the official results in WMT20 Metrics shared task, we use Pearson's coefficient to examine system level correlations of metrics with and without outlier systems. The outlier systems[14] (Mathur et al., 2020a) for the News Rankings are OPPO, UEDIN and UQAM_TanLe while those for the Hansard Rankings are OPPO and UQAM_TanLe. It is important to note that for both domains, the outlier systems are all on the lower quality side.

[12] Adding in the Crowd annotations does not increase coverage, it simply increases the number of annotations for the sentences already annotated.

[13] https://github.com/google-research/mt-metrics-eval

[14] Systems that are greater than 2.5 median average deviation from the median.

Table 6: System-level Pearson's correlation of WMT20 Metrics shared task participants with z-score reported in WMT20, table 4 and 3. For WMT20 News and table 4 rankings, the outlier systems are UQAM_TanLe, UEdin and OPPO. For Hansard, the outlier systems are UQAM_TanLe and OPPO.

6.2 System-level correlation

Table 6 shows system-level Pearson's correlations of metrics with revised rankings on the News domain and new rankings on the Hansard domain.

When the outliers are included, the system-level correlations with the revised rankings are similar to those reported in the WMT20 Metrics shared task, based on the Findings rankings. However, we have several striking observations on the correlation with the revised rankings excluding the outlier systems:

- Most metrics show negative correlations with the revised rankings on the News domain.
- Reference-less metrics correlate better with revised rankings than reference based ones do.
- The rankings of the automated metrics change drastically when comparing against those obtained by correlating with the rankings in Barrault et al. (2020).
  - prism (Thompson and Post, 2020) and OpenKiwi-XLMR (Kepler et al., 2019) change from having the lowest correlation with the Findings rankings to being some of the very few metrics with a positive correlation with the revised rankings.
  - Similar changes can also be observed in YiSi-2 (Lo and Larkin, 2020) and TER (Snover et al., 2006) where they change from having the lowest correlation to the middle of the pack.
  - On the contrary, BLEURT-extended (Sellam et al., 2020), COMET (Rei et al., 2020), COMET-MQM and characTER (Wang et al., 2016) demote from the middle of the pack to having the lowest correlation with the revised rankings.

As we have established in section 3.2 that we believe the revised News rankings to be more accurate, the negative correlations with human achieved by the majority of the metrics reflect the difficulty in evaluating translation quality of low-resource polysynthetic languages for out-of-domain settings. It is important to note that the range of z-scores in the revised News rankings is [-0.052, 0.219]. It is a noticeably smaller range as compared against the range of z-scores in the Hansard rankings, which is [-0.127, 0.249]. The small variation of MT system performance in the News domain also increases the difficulty of the automated evaluation task.

Prism performs consistently well across domains with and without outliers. This is perhaps because it is one of the very few metrics that used the constrained English–Inuktitut data to train their metrics to evaluate translation quality in Inuktitut.

For the Hansard domain, it is not surprising to see YiSi-1 (Lo, 2020) correlating very well with hu-

Table 7: Segment-level Kendall's correlation of WMT20 Metrics shared task participants with raw scores collected in News (N-1 and N-2), Hansard (H-A and H-B) and News+Hansard.

mans when the outliers are excluded. It is because YiSi-1 is based on XLM (Lample and Conneau, 2019) trained on the constrained English–Inuktitut parallel training data in Hansard domain. Another observation is that for evaluating in-domain systems, character-based metrics, characTER and YiSi-0, correlate very well with humans. This is the first scientific evidence that character-based MT evaluation metrics are a better choice for evaluating translation quality in low-resource polysynthetic languages.

6.3 Segment-level correlation

Table 7 shows the segment-level Kendall's correlations of metrics. We observe much more consistency in metrics' correlation with humans at segment level than that at system level across domains. This is possibly due to the fact that there are more data points used for correlation analysis at the segment level than the system level. Similar to correlations at system level, prism consistently correlates the best with humans at segment level.

We see even stronger evidence here at segment level that all character-based metrics (Wang et al., 2016; Popović, 2015, 2017; Stanchev et al., 2019; Lo, 2019) correlate very well with humans for evaluating translation quality in polysynthetic languages across domains. This is a particularly important finding because these character-based metrics are resource-free. That means we now have strong confidence in using character-based metrics for evaluating translation quality in a low-resource polysynthetic language.

7 Conclusion

In this work we present additional human annotations for the Hansard portion of the WMT 2020 English–Inuktitut machine translation shared task test set. We provide new system rankings on this portion of the data and present revised rankings on the News portion. We demonstrate that these changes in rankings have downstream effects on the evaluation of automatic metrics for the shared task, and examine the difficulty of performing automatic evaluation on out-of-domain text in a polysynthetic language. When it comes to automatic metrics, we find that the top-performing system incorporated training data in the low-resource target language. However, character-level automatic metrics (which did not require training) also performed amongst the top systems, demonstrating their appropriateness for evaluating translation into Inuktitut. While additional research will be required to confirm that this finding generalizes to other polysynthetic languages, we release this expanded dataset to enable more study of automatic metrics for low-resource and polysynthetic languages.

Acknowledgements

We thank the language experts and our contacts at Pirurvik Centre for their work on the annotation tasks. We thank Roman Grundkiewicz, Tom Kocmi, and Christian Federmann for their assistance in preparing and hosting the second round of Appraise annotations. We thank Eric Joanis for his work on organizing the WMT20 task, preparing the data for the task and annotation, providing information about task details, and for his feedback. We thank Roland Kuhn for his role in organizing the shared task and for his feedback, and Darlene Stewart and Samuel Larkin for work during the WMT20 shared task that informed this work. We thank Gabriel Bernier-Colborne, Cyril Goutte, Michel Simard, Yunli Wang, Patrick Littell, our colleagues, and the anonymous reviewers for their suggestions and comments.

A Context and Related Work

There is a dialect continuum of Inuit languages, including Inuktitut, that spans Arctic communities from Alaska to Greenland. The term Inuktut is often used to refer to parts of that dialect continuum, including Inuktitut.[15] There are two main orthographies used to write these languages: Roman orthography (Latin alphabet, *qaliujaaqpait*) and syllabics (*qaniujaaqpait*).[16] The language is morphologically complex – individual words are constructed of multiple morphemes – and a word may correspond to a whole phrase or more when translated into English.

There has been a range of computational work on Inuktitut over the past decades. This includes early work on alignment and the Nunavut Hansard (Martin et al., 2003, 2005) and the recent release of a new version of the aligned Nunavut Hansard, used as training data in this task (Joanis et al., 2020). Morphological analysis and segmentation have also been areas of interest (Farley, 2009; Micher, 2017). There is also prior work on machine translation (Micher, 2018; Schwartz et al., 2020; Joanis et al., 2020; Le and Sadat, 2020).

There has been limited to no work on human and automatic evaluation of machine translation into Inuktitut prior to this work. Prior work has shown that character-based automatic metrics demonstrate promising performance on morphologically rich languages, at least in part because they do not penalize morphological variation as much as word-level exact-match metrics do (Stanojević et al., 2015; Popović, 2016). Put another way, they award "partial credit" when a system produces some but not all of the morphemes of a word correctly. This is particularly important when translating into polysynthetic or morphologically complex languages. While our results in this paper show the promise of character-level metrics, it would be useful for future work to provide a more in-depth examination of their performance to better understand their success, perhaps with analysis at the word level and not simply the sentence level.

B Quotation Marks

During the test set submission period at WMT20, it was noted that a number of segments in the test set were wrapped in ASCII quotes. This was specifically an issue with the News portion of the test set; 844 News segments exhibited this ASCII quote wrapping on source, target, or both, while just 561 of the News segments were unaffected by this. As the submission period was already underway, the task organizers made the decision not to change the test set and indicated that the annotators would be told not to take the quotation mark issues into account during their evaluation.

There remain, however, several ways that this problem may have impacted the task and its results. The first is that it may have altered the behavior of MT systems, as different systems may be more or less robust to this kind of variation in input. As we do not have access to most of the MT systems, we cannot test this. The second is that teams may have handled this differently, with some adding specialized preprocessing to deal with the wrapped quotation marks and others not, and not all system description papers indicate whether or not there was special handling of this issue. Lastly, it can have an effect on automatic metric behavior. We explore that briefly below.

If we examine just the set of segments with these spurious quotations on the target side, and compute BLEU using the segments with quotes as the reference, and identical segments but with the quotes removed as the hypothesis, we see the BLEU score drop more than 10 points (from a perfect score). Since there are so many segments with these quotation marks, we still see drop of more than 5 points when we expand to the full news portion of the test data. The impact on CHRF scores is smaller.

These spurious quotation marks, while not semantically meaningful, have varied impacts on automatic metric scores, and may have also had varied impacts on translation performance across MT systems. Unfortunately, because they make up such a large portion of the News portion of the test set, omitting them dramatically shrinks the pool of data available for computing rankings and correlations. Thus, we present this work with them included, and provide these caveats about the data.

C Quality Assurance

The quality control task used in out-of-English translation directions at WMT 2020 was "BAD reference pairs", which are segments where a short segment of a translation is randomly replaced with an equal length segment randomly selected from a different reference segment. For more details on their construction see (Barrault et al., 2020). The theory is that an annotator should score the "BAD" version of a segment lower than the original version of the same segment. If an annotator does not do so over the course of an annotation session, that session would be removed.

We note that there is a reason to not fully trust this particular approach to quality control for the News dataset. The system submitted under the name zlabs-nlp (no corresponding paper submitted) consistently received scores of 0 because it was identical to the English source. In most cases, the "BAD" references paired with zlabs-nlp segments also received scores of zero, but in a few cases they received low but non-zero scores. Unfortunately, because the text of the "BAD references" were not released by the organizers, we cannot examine this more closely, or determine whether this problem may also extend to other systems.

The quality assurance tasks typically used at WMT are included in order to exclude annotators' data from the final evaluation; in particular this would include annotators who are not adequately familiar with the language pair, who are not performing careful analyses, or who might be attempting to game a crowdsourcing task. While it may be easy to simply replace annotators for certain language pairs with very large bilingual populations, there is a much smaller number of fluent bilingual speakers of English and Inuktitut. This, combined with the very high demand for their language skills (e.g., in translation), meant that we chose to work with the Pirurvik Centre, who recruited a small number of highly-skilled fluent speakers to participate in this work. Thus, the annotators' language skills and quality of work (in different language-related tasks) are known to be high (unlike in a crowdsourcing scenario, where little information is typically known about participants).

In future work and under less tight constraints as regards annotator time and budget, we would encourage the collection of repeated annotation data. This could include repeated annotations performed by the same annotator (intra-annotator agreement) as well as repeated annotations across annotators (such as a calibration HIT that all annotators complete to examine inter-annotator agreement).

Continuous Rating as Reliable Human Evaluation of Simultaneous Speech Translation

Dávid Javorský **Dominik Macháček** **Ondřej Bojar**

Charles University, Faculty of Mathematics and Physics
Institute of Formal and Applied Linguistics
{surname}@ufal.mff.cuni.cz

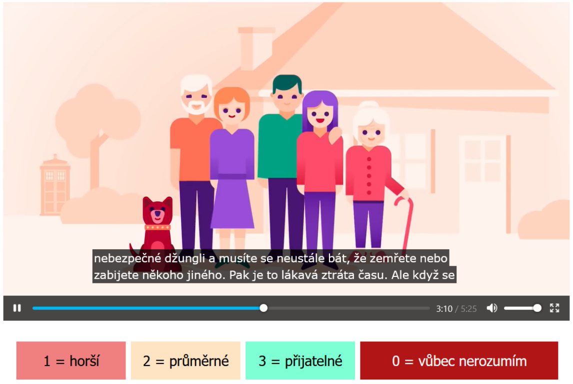
Abstract

Simultaneous speech translation (SST) can be evaluated on simulated online events where human evaluators watch subtitled videos and continuously express their satisfaction by pressing buttons (so called Continuous Rating). Continuous Rating is easy to collect, but little is known about its reliability, or relation to comprehension of foreign language document by SST users. In this paper, we contrast Continuous Rating with factual questionnaires on judges with different levels of source language knowledge. Our results show that Continuous Rating is easy and reliable SST quality assessment if the judges have at least limited knowledge of the source language. Our study indicates users' preferences on subtitle layout and presentation style and, most importantly, provides a significant evidence that users with advanced source language knowledge prefer low latency over fewer re-translations.

1 Introduction

Simultaneous speech translation (SST) is a technology that assists users to understand and follow a speech in a foreign language in real-time. The users may need such an assistance because of limited knowledge of the source language, the speaker's non-native accent, or the topic and vocabulary. The technology can be used for the target languages, for which human interpretation is unavailable, e.g. due to capacity reasons.

Candidate systems for simultaneous speech translation differ in quality of translation, latency and the approach to stability. Some are streaming, only adding more words (Grissom II et al., 2014; Gu et al., 2017; Arivazhagan et al., 2019; Press and Smith, 2018; Xiong et al., 2019; Ma et al., 2019; Zheng et al., 2019; Iranzo Sanchez et al., 2022), some allow re-translation as more input arrives (Müller et al., 2016b; Niehues et al., 2016; Dessloch et al., 2018; Niehues et al., 2018; Arivazhagan et al., 2020). Finally, subtitle presentation options (size of subtitling window, layout, allowed reading time, font size, etc.) also affect users' impression. The combination of the re-translating approach and limited space for subtitles is challenging because of "flicker", i.e. the updates to the text that the user is reading at the moment, has already read, or that has been scrolled away. The subtitling options impact the amount of flicker, reading comfort and delay and may affect the general usability.



nebezpečné džungli a musíte se neustále bát, že zemřete nebo
zabijete někoho jiného. Pak je to lákavá ztráta času. Ale když se

Figure 1: A detail of the default layout with the video document "Dinge Erklärt: Impfen...".[1] The video is at the top, overlaid by two lines of subtitles in Czech, followed by buttons for Continuous Rating. The button labels are: 1: Worse; 2: Average; 3: Good; 0: I do not understand at all.

The evaluation of the traditional, text-to-text machine translation (MT) has been researched for many years (see e.g. Han, 2018 or developments and discussion within the series of WMT, Akhbardeh et al., 2021). It targets only the translation quality. SST evaluation faces new challenges: simultaneity, latency, and readability to humans. Evaluating only selected aspects in isolation is reasonable (as MT quality in Elbayad et al., 2020, latency in Ma et al., 2018; Cherry and Foster, 2019), however, a complete evaluation must be end-to-end, from sound acquisition to subtitling, and take into

account the intent of communication. We generalize the intent to passing pieces of information from the speaker (sender) to a participant in an online session (receiver).

Our Contributions In this paper, we run an experimental evaluation campaign on 2 hours of documents with German-Czech SST using 32 judges with different levels of source language proficiency. (i) We contrast two methods of SST evaluation: Continuous Rating and factual questionnaires. We find out that Continuous Rating by bilinguals is easy and reliable for assessing the comprehension. (ii) We measure how much comprehension is lost by simultaneity, flicker and presentation options. (iii) We evaluate different presentation options and layouts and find the most preferred one. (iv) We find a statistically significant evidence that the users with an advanced, but limited knowledge of the source language reach higher comprehension with low latency subtitles than with large latency and low flicker. (v) We publish our implementation of the subtitling tool, web application for simulating live events with SST subtitling, and SST human evaluation framework.

Since Continuous Rating is easily applicable to any speech documents, even to those without transcripts and reference translations, and requires minimal time overhead for both preparation and user evaluation, we believe it is suitable to become a standardized way for human manual evaluation of SST.

2 Related Work

Hamon et al. (2009) propose user evaluation of speech-to-speech simultaneous translation. To test the adequacy and intelligibility, they prepared questionnaires with factual questions from the source speech. The judges listened either to the interpreter, or the machine, and answered the questions. They evaluated the offline mode, the judges were allowed to stop and replay the audio while answering. This way the authors measured the comprehension loss caused by the automatic translation or interpretation. Each sample was processed by multiple judges, to eliminate human errors. Fluency was assessed by the judges on a scale.

Macháček and Bojar (2020) propose a technique for collecting continuous user rating while the user watches video and simultaneous subtitles. The user is asked to express the satisfaction with the subtitles at any moment by pressing one of four buttons as the rating changes.

Müller et al. (2016a) analyzed the feedback from foreign students using KIT Lecture Translator within two semesters. Such a long-term and informal evaluation differs considerably from judging in controlled conditions. On one hand, it summarizes the real-life situation with all the variables and corner cases that a lab test could only approximate or omit. On the other hand, the users may not be motivated to give the feedback, and can give only personal opinions that may be biased. This way it is also difficult to compare multiple system candidates.

3 Evaluation Campaign

In our evaluation, we simulate live events on which participants need assistance with understanding the spoken language. The source and target languages in our study are German and Czech, respectively. This is an interesting example of two neighbouring countries, distinct language families and yet a relatively well studied pair with sufficient direct training data.

3.1 Translation System

We use the ASR system originally prepared for German lectures (Cho et al., 2013). It is a hybrid HMM-DNN model emitting partial hypotheses in real time and correcting them as more context is becoming available. The same system was used also by KIT Lecture Translator (Müller et al., 2016b).

The system is connected in a cascade with a tool for removing disfluencies and inserting punctuations (Cho et al., 2012), and with a German–Czech NMT system.

The machine translation is trained on 8M sentence pairs from Europarl and Open Subtitles (Koehn, 2005; Lison and Tiedemann, 2016), and validated on newstest. The Transformer-based (Vaswani et al., 2017) system runs in Marian (Junczys-Dowmunt et al., 2018) and reaches 18.8 cased BLEU on WMT newstest-2019.

Despite the translations are pre-recorded and only played back in our simulated setup, we ensured we keep the original timing as emitted by the online speech translation system.

3.2 Selection of Documents

We selected German videos or audio resources that fulfilled the following four conditions: 1) Length 5 to 10 minutes (with some exceptions). 2) The

Type	#	Length	Description
TP	3	18:08	European Parliament
TP	3	17:34	DG SCIC, Repository for interpretation training
A	3	27:52	A mock interpreted conference at interpretation school
V	2	14:43	Maus, Educative videos for children
A	2	18:48	DW, For learners of German
V	2	16:09	Dinge, Educative videos for teens
All	15	114:52	

Table 1: Summary of domains of selected documents. Type distinguishes audio only (A), talking person only (TP) and video (V) with illustrative or informative content. Length is reported in minutes and seconds.

translations had to be of a sufficient quality. Based on a manual check, we discarded several candidate documents: a math lecture and broadcast news due to many mistranslated technical terms and named entities. Another group of documents was mistranslated and discarded because they were not long-form speeches, but isolated utterances with long pauses. 3) Informative content. We intend to measure adequacy and comprehension by asking the judges complementary questions. We thus excluded the documents where the speaker is not giving information by speech, but uses mostly paralinguistic means, e.g. singing, poetry, or non-verbal communication. 4) Non-technicality. We expect the judges answer in several plain words in their mother tongue. They may lack knowledge of any specialized vocabulary.

We selected audios, videos with informative or illustrative content, and videos of talking persons, to compare user feedback for these types of documents. Table 1 summarizes the selected documents.

3.3 Subtitler: Subtitle Presentation

Subtitler is our implementation of the algorithm by Macháček and Bojar (2020) extended by automatic adaptive reading speed in addition to the "flicker" parameter as defined in Macháček and Bojar (2020). The speed varies between 10 and 25 characters per second depending on the current size of the incoming buffer. The default font size is 4.8 mm. The default subtitling window is 2 lines high and 163 mm wide.[2] By default, we use the maximum flicker and the lowest delay (presenting all translation hypotheses, not filtering out the partial and possibly unstable ones), no colour highlighting, and smooth slide-up animation while scrolling. The example of the setup can be seen in Figure 1.

With the default subtitling window, 90% of the words in the test documents are finalized in subtitles at most 3 seconds after translation. In 99%, it is at most 7 seconds. More details and the comparison to fixed reading speed are provided in Appendix A.1.[3]

3.4 Web Application as Simulation Environment

We implemented a web application for presenting video and audio documents with embedded Subtitler. We use it for simulation of live subtitled events. The application is equipped with a tool for collecting users' feedback. It also allows administrators to design experiments with different variables (document, subtitling layout, subtitling option) and distribute them to individual judges.[4]

3.5 Types of Feedback

Continuous Rating Inspired by Macháček and Bojar (2020), we add 4 buttons below the audio/video document. While watching, the participants are asked to press the buttons to indicate their current satisfaction with the subtitles. We let participants decide the frequency of rating but we suggest clicking each 5-10 seconds or when their assessment has changed. We encourage them to provide feedback as often as possible even if their assessment has not changed. The scores of the rating range between 0 (the worst) and 3 (the best). The order 1, 2, 3, 0 matches the keyboard layout; participants are encouraged to use keyboard shortcuts. The layout is illustrated in Figure 1.

Questionnaires Answering questions as an evaluation approach has been already used (Hamon et al., 2009; Berka et al., 2011). Our questionnaires were composed of two parts: factual questions and general questions.

For **factual questions** we used the open style, i.e. asking for a short response, instead of yes/no or multiple choice to exclude guessing. We asked a Czech teacher of German to prepare the questions and an answer key from the original German documents, regardless of the machine translation. The teacher wrote the questions in Czech, and was instructed to prepare one question from every 30

seconds of the stream and distribute them evenly, if possible. The questions had to be answerable only after listening to the document, and not from the general knowledge. The complexity of the questions was targeted on the level that an ordinary high-school student could answer after listening to the source document once, if the student would not have any obstacles in understanding German. To reduce the effect of limited memory, the judges had an option in the questionnaire to indicate they knew the answer but forgot it. Furthermore, they had to fill, from which source they knew the answer: from the subtitles, from the speech, from an image on the video, or from their previous knowledge.

Finally, we evaluated the factual questions manually against the key, rating them at three levels: correct, incorrect, and partially correct.

After the factual questions, all the questionnaires had a common part with **general questions** where we asked the judges on their impression of translation fluency, adequacy, stability and latency, overall quality, video watching comfort, and a summary comment.

3.6 Judges

We have conducted two groups of experiments, each with different and distinct groups of judges.

In Comprehension and Layout experiments (Sections 4.1 and 4.2), we examined distinct subtitling features. We selected 14 native Czech speakers as judges. Their self-reported knowledge of German had to be between zero and B2 on the CEFR[5] scale, to ensure they need some level of assistance with understanding German. We also ensured they do not have knowledge of any other language which could help them understanding German.

Type	w. avg±std	t-test
Offline+voting	0.81±0.11	
Offline	0.59±0.16	***
Online, without flicker	0.36±0.16	***
Online, flicker, top layout	0.33±0.13	
Online, flicker, least preferred	0.31±0.16	

Table 3: Comprehension scores on all documents and judges. The average weighted by number of questions in document. *** denote the statistically significant difference (p-value< 0.01) between the current and previous line.

For Flicker experiments (Section 4.3), we found other 18 native Czech speakers with an unrestricted German proficiency, to contrast their feedback and level of German. For further analyses, we divided them into three groups. For brevity further in the paper, we denote the judges with no proficiency of German as "Zero" level group, with proficiency between A1 and A2 as "Beginners", and the others as "Advanced". See summary of the judges in Table 2.

The judges were paid for participation in the study. Each judge spent in total 2 hours on watching and 3 hours on the questionnaires. They watched the videos at their homes on their own devices. They were asked to customize their screen resolution and eye-screen distance to suit their comfort.

4 Results

First, we analyzed the comprehension levels (Section 4.1) and presentation layouts (Section 4.2). Then, we selected the most preferred layout and used it for examining the impact of flicker on comprehension in Flicker experiments (Section 4.3).[6]

4.1 Comprehension Levels

In our study, we assume comprehension can be assessed as a proportion of correctly answered questions. We assume the following model: A person without any language barrier and with non-restricted access to the document during answering the questionnaire can answer all questions correctly. With a language barrier and offline MT (unlimited perusal of the document while answering), some information may be lost in machine translation. More information is lost with one-shot access to online machine translation because of forgetting and temporal inattention. Some more information may be

[5] Common European Framework of Reference for Languages

[6] The collected data are available at http://hdl.handle.net/11234/1-4913

lost because of flicker, and some more because of suboptimal subtitling layout.

Our results confirm the assumed hierarchy of comprehension levels. Moreover, we notice that even the judges with offline MT give inconsistent answers. Combining them and counting answers as correct if at least one judge is correct leads to higher scores. We explain it by insufficient attention.

Table 3 summarizes the results on all documents. We measured that on average, 81% of information was preserved by machine translation (Offline+voting, i.e. one of two judges answered correctly). A single judge could find 59% of information (Offline). In an oracle experiment without flicker, when the machine translation gives the final hypotheses with the timing of the partial ones (i.e. as if it knew the best translation of the upcoming sentence), a single judge could answer 36%. In real setup with flicker and the most preferred subtitling layout (Online, flicker, top layout), 33% information was found, and 31% with less preferred. The standard deviation is between 11 and 16%.

We found statistically significant difference (two-sided t-test) between offline MT with voting and without it, and between offline and online MT.

4.2 Layout Preference

We analyzed effects of distinct subtitling features by contrastive experiments differing only at one feature, see the paragraphs in this section. We distributed them randomly among the judges, regardless of their German skills. After watching each document, the judge fills the questionnaire.

In all cases, the results show a slight insignificant preference towards one variant of the feature in all three types of feedback that we collect: "Comprehension" is the proportion of correctly answered factual questions, "Averaged Continuous Rating" is an averaged feedback from button clicks, and "Final rating" summarizes the responses in the general section of questionnaires.

For visually informative videos, we separately report the scores of "Watching comfort" which we collected in the general section of questionnaires. Some judges provided also textual feedback, examples are in Appendix B.2.

Side vs Below For videos and videos with a talking person, we consider two locations for the subtitle window: on the left side of the video, or below. The side window can be high but narrow (17 lines of 60 mm width, to match the height of the video), while the window underneath is short and wide (2 lines of 163 mm width). The first is more comfortable for reading, the latter for watching the video.

The results are in Table 4 on the left. There is a preference for the layout "below" when the video is informative, and for "side" otherwise.

Below vs Overlay The subtitling window can be placed over the video, as in films, or below. In the first case, the subtitles possibly hide an informative image content, in the latter case, there is a larger distance between the image and the subtitles. The results on non-German speaking judges are insignificantly in favor of overlay, see the middle of Table 4.

Highlighting Flicker Status The underlying rewriting speech translation system distinguishes three levels of status for segments (automatically identified sentences): "Finalized" segments no longer change. "Completed" segments are sentences which received a punctuation mark. They can be changed by a new update and the prediction of the punctuation may also change or disappear. They usually flicker once in several seconds. "Expected" segments are incomplete sentences, to which new translated words are still appended. They flicker several times per second.

It is a user interface question if the status of the segments should be indicated by highlighting, or if this piece of information would be rather disturbing. We experimented only with colouring text background in large and medium subtitling window for audio-only documents.

Our experiments show that the judges prefer highlighting flicker status in the large window. For the medium window, this inclination is less clear, see Table 5.

Size of Subtitling Window The subtitling window can be of any size. If the window is short and narrow, there is a short gap between an image and subtitles, which simplifies focus switching. On the other hand, a small window contains short history, so the user can miss translation content if it disappears while paying attention to the video. A small window may also accidentally cause a long subtitling delay if the translation was updated in the scrolled-away part of text. In this situation, Subtitler has to "reset" the subtitles and repeat the part. With a large window, the distance between the growing end of the subtitles and the image is

		Side vs Below		Below vs Overlay		Size of subtitling window

Table 4: Results of the contrastive experiments for Side vs Below, Below vs Overlay and Subtitling window size: 2 lines height × 163 mm width vs 5 lines height × 200 mm width. The three numbers in each row and cell are the number of experiments, average and standard deviation. The higher score, the better. Comprehension rate is between 0 and 1, average continuous rating is between 0 and 3, the others on a discrete scale 1 to 5. Higher score in each experiment is bolded. The last row of each section summarizes the scores across document types.

Highlighting	No	Yes	No	Yes	No	No
Size [lines,mm width]	18×250 ("Large")		5×200 ("Medium")		18×250	5×200
Final rating	14 2.93 ±0.80	13 **3.31 ±1.14**	2 2.50 ±0.50	1 **4.00 ±0.00**	11 **2.91 ±0.79**	8 2.75 ±0.97
Comprehension	14 0.25 ±0.15	13 **0.30 ±0.12**	2 **0.44 ±0.18**	1 0.39 ±0.00	11 0.23 ±0.14	8 **0.31 ±0.15**
Avg. Cont. Rating	14 1.32 ±0.82	13 **1.42 ±0.74**	2 **2.19 ±0.50**	1 2.12 ±0.00	11 1.50 ±0.79	8 **1.66 ±0.95**

Table 5: Results of highlighting experiments on audio documents and subtitling window size 5 lines × 200 mm vs 18 lines × 250 mm. Description of numbers as in Table 4.

larger. The content stays longer, but it is more complicated to find a place where the user stopped reading before the last focus switch.

Depending on spatial constraints, it is always recommended to use as large window as possible, especially for documents without visual information, where focus switching between an image and subtitles is not expected. We tested two pairs of sizes on the same documents. The results are in Table 4 on the right. As we expected, the window with 5 lines was rated insignificantly better than with 2 lines in most scales and setups, but the 2-line reached a higher average watching comfort (2.92) that the 5-line setup (2.62).

For an audio-only document, we also tested the large (18 lines) vs. medium (5 lines) window, observing users' reported preference for the large one but slightly higher comprehension and continuous feedback for the medium one, see the right part of Table 4.

4.3 Flicker Experiments

We assume that the user behaviour differs by knowledge of the source language. We hypothesize that the Zero group of users and Beginners read all the subtitles all the time and do not pay attention to the speech. They do not mind large latency, but demand high quality translation, and comfortable reading without flicker. On the other hand, the users with an advanced knowledge of the source language may listen to the speech, try to understand on their own, and look at the subtitles only occasionally, when they are temporarily uncertain or need assistance with an unfamiliar word. They need low latency, and do not mind slightly lower quality.

To empirically test our hypothesis, we prepared two realistic setups: With flicker, the subtitles are presented immediately as available, but with frequent rewriting which discomforts the reader. Without flicker, the translations are delayed until the SST system confirms they will not change, and that usually happens during uttering the next sentence. We selected two videos for this experiment and distributed these setups uniformly between all groups of judges.

The results of comprehension are in Table 6. It shows that Advanced users achieve higher compre-

	Zero level	**Beginners**	**Advanced**
flic.	27 **0.34 ±0.16**	33 **0.33 ±0.16**	91 **0.58 ±0.19**

	insignificant	insignificant	$p < 0.01$

Table 6: Comprehension scores on a setup with flicker and no flicker, as rated by judges with different source language proficiency. The three numbers in each row and cell are the number of samples, average and standard deviation. Higher scores bolded. The difference between setups within Advanced group is statistically significant with $p < 0.01$.

		χ^2**-test** p**-values**	
	Zero level	**Beginners**	**Advanced**
OK/OK-	0.24	$\mathbf{1.8 \cdot 10^{-5}}$	$\mathbf{5.6 \cdot 10^{-5}}$
unknown	0.033	$\mathbf{1.7 \cdot 10^{-4}}$	$\mathbf{9.1 \cdot 10^{-4}}$
wrong	0.59	0.45	$\mathbf{2.9 \cdot 10^{-3}}$
forgot	0.9	0.48	0.019

Table 7: The results of χ^2-test for independence of Continuous Rating and answer correctness. Bolded values are where the two variables are **dependent** with statistical significance $p < 0.01$.

hension with flicker (58%) than without (49%). We found the difference statistically significant, which confirms the second part of our hypothesis.

The Zero level speakers and Beginners also report higher comprehension with flicker (Zero: 30% vs 34% and Beginners: 31% vs 33%), but this difference is statistically insignificant. Even though the preference inclines towards flicker, it is less noticeable compared to the Advanced group, and we consider this difference negligible. The other types of feedback (Average Continuous Rating and Overall rating from the end of questionnaire; not shown) confirm the trend of Comprehension for all groups.

4.4 Comprehension vs Continuous Rating

We collected Continuous Rating of the overall quality of subtitles at given times. For every comprehension question, we know the time span when the answer appears in the source speech document. Based on this timing information, we can relate comprehension and Continuous Rating. For a given time span answering a particular question, we find the most frequent Continuous Rating (button clicked most often) for every annotator. This gives us a histogram of Continuous Rating scores reported by different judges. In Figure 2 top, we show the correct ("OK") or partially correct answers ("OK-") and the histogram of Continuous Ratings by judges of distinct German proficiency levels. For a more detailed plot including all evaluation classes see Appendix B.1. This data aggregates observations for all documents and all setups excluding the offline SST and the oracle online SST without flicker.

For the judges with zero knowledge of German, we can not see any dependency of their comprehension to their Continuous Rating. On the other hand, the more the judges are proficient in German, the more their Continuous Rating reflects their comprehension. For example, for the C1 judges (Advanced) we can estimate their comprehension (and thus subtitle quality) from their clicking well: When they understand the content, the most probable given rating is 3 or 2. A less probable rating is 1, and they almost never rate 0 when they understand the content.

Listening while Rating In Figure 2 bottom, we show, from which source the judges knew the correct answer, either from the subtitles, or from sound. We can observe that indeed, the judges with German proficiency level B1 and higher listen to the source sound and understand, while the Zero level judges and Beginners rely only on subtitles.

Statistical Test To test the relation rigorously, we divide the judges into three groups by proficiency levels, their counts (see Table 2), their relation of Continuous Rating to correct answers and approach to listening versus reading (Figure 2). We run χ^2-test for statistical independence of Continuous Rating and answer results on the three groups. Test results are in Table 7. It shows that for the judges with Zero level of German, their Continuous Rating is independent on answer results. They do not follow the sound at all because they do not understand it, and rate only the readability and flicker. In case of the Beginners (A1 and A2, recall Table 2), we observe the dependency of their Continuous Rating on correct answers ("OK/OK-") and on cases when they did not answer ("unknown"). Their wrong answers and forgetting is independent of Continuous Rating, they probably make random mistakes uniformly. The Advanced group of judges give their correct, unknown or wrong answers consistently with their Continuous Rating. We therefore assume that they follow and understand the source speech and include the adequacy in their Continuous Rating.

We can also see that in all the three groups, the forgotten answers are independent on Continuous Rating. We assume that random and uniform out-

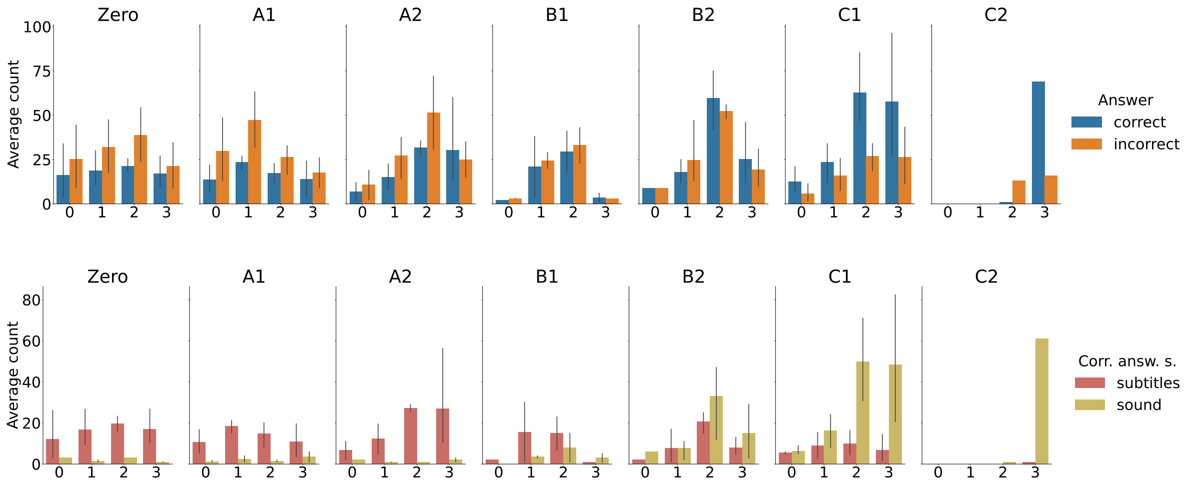

Figure 2: The average count of answers per judge for each proficiency level. Top: Correct (OK/OK-, blue bars) and incorrect (wrong/unknown, orange bars) answers vs Continuous Rating at the time when the answer was disclosed in the original document (x-axis, 0 means worst, 3 the best), distributed by source language proficiency level of the judges. Bottom: From which source the judges learned the correct or partially correct answer; subtitles in red, sound in yellow.

ages may be characteristic for human memory.

Practical Conclusions We conclude that Continuous Rating is a suitable for manual evaluation of simultaneous machine translation. The judges who speak the source language on at least B2 level on CEFR scale have an ability to assess SST quality reliably only by Continuous Rating, without the need for questionnaires which are laborious to prepare, answer and evaluate.

5 Conclusion

We proposed a novel and effective method for end-to-end user evaluation of simultaneous speech translation SST called Continuous Rating, publishing an open source evaluation tool for the future use. We showed that this method can be used for measuring comprehension and evaluating subtitling parameters. We demonstrated how user comprehension differs from offline MT to online MT. We showed that the users with a knowledge of the source language prefer low latency despite higher instability. We demonstrated that Continuous Rating can be used as a time-efficient human evaluation metric when employing judges with at least B2 (or, preferrably, C1) level of source language proficiency.

Limitations

This work is limited to only one direction of SST and lacks the comparison of multiple SST variants. Additionally, due to the number of investigated subtitling features and the smaller sample of judges, the results of layout experiments show only statistically insignificant preference towards one variant.

	Delay						
	70%	80%	90%	95%	99%	max	resets
ARS	**0.01**	**1.44**	**3.06**	**4.51**	**7.05**	**12.06**	8.80
FRS	1.74	3.54	5.18	7.52	10.65	16.78	**5.47**

Table 8: The adaptive reading speed (ARS) in comparison to the fixed reading speed (FRS), set to 18 char/sec. Percentages denote the proportion of words that have a delay less than the given number. The delay is in seconds, resets in the average count per document.

A Subtitler

A.1 Adaptive Reading Speed: Delay

We compared adaptive to fixed reading speed, averaging over all documents. We set the value of fixed reading speed to 18 characters per seconds, which we obtained by averaging all delays in the setting without adaptive reading speed.

The comparison is in Table 8. The delay was measured for all presented words. We used a subtitling window of 2 lines ×163 mm because it represents an upper bound for the delay of bigger subtitling windows.

B Results

B.1 Comprehensions vs Continuous Rating

In Figure 3, we show the average count of answers per judge for each proficiency level. Note two observations: 1) The number of already known answers is negligible, which proves that the questions were selected based on the content of documents. 2) The number of answers whose source was not given is high for all answers (Figure 3, right column), whereas it is low when correct and partially correct answers were selected (Figure 3, middle column). It means that judges provided the source when they answered a question.

B.2 Textual Feedback

In Table 9, we depict several textual ratings from Flicker Experiment. We select judges with C1 source language proficiency and contrast their feedback for flicker and no flicker.

The judges report higher satisfaction with flicker. They notice increased latency when the presentation mitigate flicker. This is consistent with our findings in Flicker experiment for Advanced group.

	Feedback
Setting	C1 proficiency, Overlay layout
Flicker	The subtitles weren’t so bad in terms of content or latency.
	The subtitles were very good, they just got stuck in the middle of the video, but after a short pause they worked again without any problems.
	The subtitles were relatively good, but despite their intelligibility and relative linguistic accuracy, they seemed very chaotic and very uncomfortable to read.
No flicker	A big delay of subtitles was sometimes inconvenient. If the subtitles are very delayed, it is almost impossible to follow them.
	The subtitles were small and dense, it was hard to orientate, especially when they were even delayed.
	At first, the delay was small. Then, at one point the subtitles got stuck and there was a lot of delay behind the sound.

Table 9: The selection of textual feedback from judges.

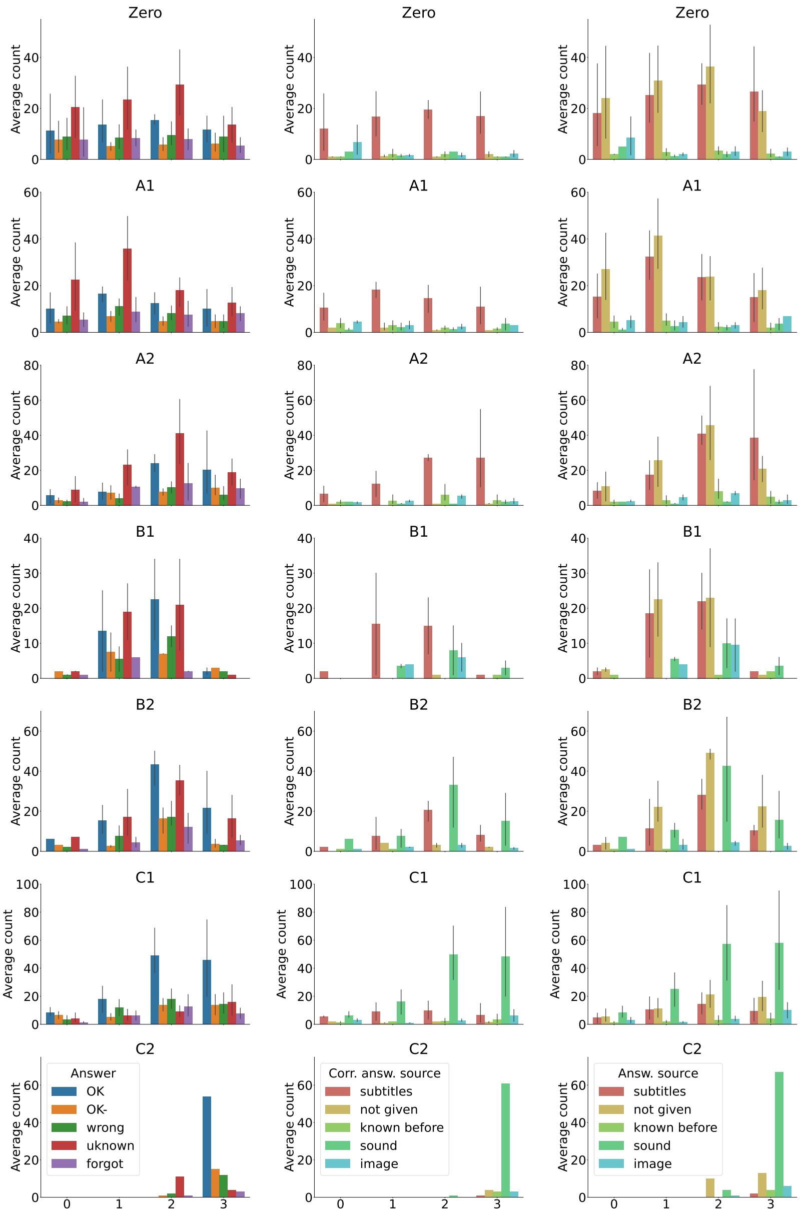

Figure 3: The average count of answers per judge for each proficiency level. Left: OK, OK-, wrong, unknown and forgotten answers vs Continuous Rating at the time when the answer was disclosed in the original document (x-axis, 0 means worst, 3 the best), distributed by source language proficiency level of the judges: from zero through beginners (A1, A2) and intermediate (B1, B2) to advanced (C1, C2). Middle: From which source the judges learned the correct (OK) or partially correct (OK-) answer. Right: From which source the judges learned all answers, regardless of their evaluation.

Gender Bias Mitigation for NMT Involving Genderless Languages

Ander Corral and **Xabier Saralegi**
Orai NLP Technologies, Basque Country, Spain
a.corral@orai.eus, x.saralegi@orai.eus

Abstract

It has been found that NMT systems have a strong preference towards social defaults and biases when translating certain occupations, which due to their widespread use, can unintentionally contribute to amplifying and perpetuating these patterns. In that sense, this work focuses on sentence-level gender agreement between gendered entities and occupations when translating from genderless languages to languages with grammatical gender. Specifically, we address the Basque to Spanish translation direction for which bias mitigation has not been addressed. Gender information in Basque is explicit in neither the grammar nor the morphology. It is only present in a limited number of gender specific common nouns and person proper names. We propose a template-based fine-tuning strategy with explicit gender tags to provide a stronger gender signal for the proper inflection of occupations. This strategy is compared against systems fine-tuned on real data extracted from Wikipedia biographies. We provide a detailed gender bias assessment analysis and perform a template ablation study to determine the optimal set of templates. We report a substantial gender bias mitigation (up to 50% on gender bias scores) while keeping the original translation quality.

1 Introduction

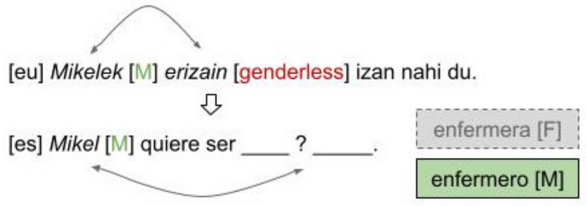
As the neural machine translation (NMT) field becomes more mature, there is a growing concern about the gender fairness of these systems (Stanovsky et al., 2019; Prates et al., 2020; Hovy et al., 2020; Savoldi et al., 2021). These data-driven approaches are trained on large real-world textual corpora which often exhibit implicit social gender stereotypes and biases. For example, Bolukbasi et al. (2016) noted that systems associate certain neutral occupations with males, such as doctor or programmer, and others with females, such as nurse or housekeeper. As a consequence, although not being required by the task, systems tend to inherit and amplify these social biases.

Several different solutions have been proposed to solve, or at least reduce, gender bias during the translation process: providing alternative masculine and feminine translations for some neutral words (Johnson, 2018); adding explicit gender information during training (Vanmassenhove et al., 2018; Stafanovičs et al., 2020; Saunders et al., 2020); removing bias from word embeddings (Font and Costa-Jussa, 2019); or fine-tuning on a small gender-balanced data set (Costa-jussà and de Jorge, 2020; Saunders et al., 2020). There have also been some efforts to construct some challenge sets to systematically assess gender bias (Stanovsky et al., 2019; Bentivogli et al., 2020).

Most of the previous work has focused on English as the source language which is then translated to languages with grammatical gender such as Spanish, French, German, etc. English is a notional gender language which encodes gender in a pronominal system (*he/she, his/her...*) (Savoldi et al., 2021). Consolidated evaluation benchmarks such as WinoMT (Stanovsky et al., 2019) or MuST-SHE (Bentivogli et al., 2020) are specially designed for English. However, for genderless languages such as Basque, existing previous work and benchmarks do not fully satisfy the requirements. For example, WinoMT uses pronominal references as a disambiguation signal for the correct inflection of occupations, which do not exist in Basque.

Gender information in Basque is explicit in neither the grammar nor the morphology. This fact implies that gender can only be determined when nouns correspond unequivocally to a female or a male, that is, person proper names or a limited number of gender-specific common nouns (e.g., *emakumea/gizona, aita/ama...*[1]), hereinafter referred to as gendered entities. Therefore, existing approaches and evaluation benchmarks need to be

[1] English translation: *woman/man, father/mother...*



[eu] Mikelek [M] erizain [genderless] izan nahi du.
[es] Mikel [M] quiere ser ____ ? ____.
enfermera [F]
enfermero [M]

Figure 1: An illustrative example for the task of sentence-level agreement between gendered entities and occupations when translating from genderless languages to gendered languages. English translation: *Mikel wants to be a nurse.*

adapted to meet the requirements of a genderless language.

In this work we address the specific task of sentence-level gender agreement between gendered entities and occupations when translating from genderless languages to gendered languages (see example in Figure 1). We focus on the Basque to Spanish translation direction, a translation direction that presents the peculiarities described above and that has not been studied in the literature. The main contributions of the paper are the following:

- A template-based fine-tuning method with explicit gender signals to debias pre-trained systems involving genderless languages.
- A detailed experimentation to determine the source of gender bias for the task, including an in-depth ablation study of the template-based method and a comparison against fine-tuning on a gender-balanced Wikipedia biographies set.

2 Related work

A wide variety of publications warn about the lack of fairness some of the commercial MT systems have and how they might contribute to amplify and perpetuate social gender stereotypes due to their widespread use (Stanovsky et al., 2019; Prates et al., 2020; Hovy et al., 2020). In the case of the Basque-Spanish language pair, Salaberria et al. (2021) found a preference for the stereotyped translation of occupations according to their historically assigned role.

Ideally, system bias could be mitigated by removing all the bias present in the training data. For example, by augmenting data samples with their corresponding counterfactual forms (Zhao et al., 2018; Zmigrod et al., 2019). Nevertheless, this task still poses some challenges for grammatical gender languages as it involves preserving the morphosyntactic agreement of the whole sentence by gender swapping pronouns, adjectives, verbs, entities, etc., (Stafanovičs et al., 2020).

As a result, several alternative methods have been proposed to alleviate gender bias from MT systems. Vanmassenhove et al. (2018) add a special gender token to source sentences in order to improve morphological agreement between the uttered sentence and the gender of the speaker. Stafanovičs et al. (2020) annotate source words with the grammatical gender information of their corresponding target words. Basta et al. (2020) provide the system with discourse context by adding the previous sentence, and in the same direction, Moryossef et al. (2019) propose a method to guide a black-box model by appending some contextual gender unambiguous hints to source sentences, such as "... *she told them*". Other more complex approaches have targeted gender bias effects by directly equalizing genders in word embeddings (Escudé Font and Costa-jussà, 2019).

Another promising line of research addresses gender bias as a domain adaptation problem by fine-tuning a pre-trained biased system with a gender-balanced data set. Costa-jussà and de Jorge (2020) automatically collect gender-balanced parallel data from Wikipedia biographies by selecting an equal amount of examples for each gender. Choubey et al. (2021) generate gender filtered parallel data by forward-translating a monolingual corpus. Saunders and Byrne (2020) generate a small, trivial, gender-balanced set of synthetic examples by inflecting a single handcrafted template with an equal number of masculine and feminine entities. In Saunders et al. (2020) they further improve the method by adding explicit word-level gender tags.

Our proposed method uses a controlled gender-balanced set of examples (Section 3) to fine-tune a pre-trained model (Section 4.1). We further provide the system with explicit gender tags for proper gender inflections (Section 4.2). We assume that providing a stronger gender signal is better than letting the system infer the proper gender of each gendered entity. In order to annotate source words, Stafanovičs et al. (2020) propose a complex method involving morphological tagging and automatic alignment, and Saunders et al. (2020) rely on the proper coreference resolution. In contrast, we directly annotate gendered entities and leave gender agreement to the system instead of directly providing gender inflection information for all the affected words. This assumption simplifies the annotation effort as only gendered entities lists are necessary to annotate the data.

3 Gender-balanced corpora

Existing previous work on gender bias has focused on high resource translation directions (English to Spanish, French, German, etc.). While consolidated benchmarks and data exist for these languages, they strongly rely on gendered pronouns which makes them difficult to adapt for Basque. Thus, we analyzed two different strategies to build gender-balanced corpora for the Basque to Spanish translation direction: a syntactically diverse set of handcrafted templates (Section 3.1), and real data extracted from Wikipedia biographies (Section 3.2).

3.1 Handcrafted templates

A Basque and Spanish native speaker manually designed a set of task-specific templates for the correct treatment of gender agreement at sentence-level between gendered entities and occupations. We argue that a single tiny template does not provide sufficient syntactic diversity, so we handcrafted a syntactically diverse set of 33 templates. Each of the templates has placeholders for an occupation and a gendered entity to help in the proper disambiguation of that occupation.

Saunders et al. (2020) reported that systems trained on single-entity templates tend to overgeneralize gender signals on multi-entity examples by indiscriminately applying the same gender to all the occupations regardless of the other entities' genders. For instance, the Basque source sentence "*Josean iragarlea zen eta Leirek idazkaria izan nahi zuen.*" [2] would be translated to "*Josean era adivino y Leire quería ser secretario.*" instead of producing the correct feminine form "*secretaria*". To address this issue, we also construct a set of 13 multi-entity templates with two gendered entities and their corresponding occupations.

We use an occupations list and a gendered entities list to automatically populate the templates. We slightly adapted the list of occupations from Salaberria et al. (2021) to obtain a set of 83 occupations in Basque and their respective translations for both genders in Spanish. The gendered entities list contains a set of 200 common Basque and Spanish person proper names. We further complemented that list with 14 gendered common nouns referring to humans in Basque (e.g., *emakumea/gizona, aita/ama...*[3]) by querying Basque WordNet (Pociello et al., 2011). We collected the same amount of gendered entities for each gender.

We randomly divided the handcrafted templates[4] into disjoint training and test sets, keeping 6 single entity templates and 3 multi-entity templates for testing purposes. For each gender, 20 proper names and 4 gendered terms are used to inject these test templates. A total amount of 3,120 single entity examples and 1,800 multi-entity examples were created, hereinafter referred to as *Templ_test* and *Multi_test* test sets. The rest, 27 and 10 templates respectively, are kept to create training data (*Templ_train* and *Multi_train*) and were injected in different ways as explained in Section 4.1. Some examples of the handcrafted templates are shown in Table 1.

3.2 Back-translated Wikipedia biographies

In order to generate a gender-balanced set of real data, we turned to Wikipedia biographies. We focused on the extraction of examples that present gender agreement between people and occupations for the Basque-Spanish language pair. Unlike the strategy proposed by Costa-jussà et al. (2019), we extract task specific examples from Spanish monolingual biographies which are then back-translated to Basque, instead of directly extracting parallel data. The reason behind this decision was that more task specific examples could be gathered from leveraging Spanish monolingual data only, as Basque biographies constrained the amount of examples that could be gathered.

We searched the Spanish Wikipedia (extracted using WikiExtractor[5]) for biographies of living persons using Petscan[6]. We found 160,641 biographies matching this criteria. Using the Wikidata API, we automatically detected the gender of these persons. We only extracted the first sentence from each biography, which generally includes examples

[2] English translation: *Josean was a fortune-teller and Leire wanted to be a secretary.*

[3] English translation: *woman/man, father/mother...*

[4] All the handcrafted templates and occupations and gendered entities lists are included in the supplementary material.

SINGLE-ENTITY TEMPLATE
eu: {entity}k {occupation} izan nahi du.
→ *Mikelek erizain izan nahi du.*
es: {entity} quiere ser {occupation}.
→ *Mikel quiere ser enfermero*
en: {entity} wants to be a {occupation}.
→ *Mikel wants to be a nurse.*

SINGLE-ENTITY TEMPLATE
eu: Nire lagun {entity} {occupation}a zela esan nizunean haserratu egin zinen.
→ *Nire lagun Ainara errementaria zela esan nizunean haserratu egin zinen.*
es: Cuando te dije que mi amigo|a {entity} era {occupation} te enfadaste.
→ *Cuando te dije que mi amiga Ainara era herrera te enfadaste.*
en: When I told you my friend {entity} was a {occupation} you got angry.
→ *When I told you my friend Ainara was a blacksmith you got angry.*

MULTI-ENTITY TEMPLATE
eu: {entity}k {occupation} izatea gustuko du, baina {entity2}k {occupation2} izatea gorroto du.
→ *Mikelek erizain izatea gustuko du, baina Ainarak errementari izatea gorroto du.*
es: A {entity} le gusta ser {occupation}, pero {entity2} odia ser {occupation2}.
→ *A Mikel le gusta ser enfermero, pero Ainara odia ser herrera.*
en: {entity} loves being a {occupation} while {entity2} hates being a {occupation2}.
→ *Mikel loves being a nurse while Ainara hates being a blacksmith.*

Table 1: Examples of the handcrafted templates for the gender agreement task between gendered entities and occupations. Along with the templates we provide an injected example and the corresponding English translation.

of gender agreement between persons and occupations. For example:

***Elisabeth Rynell** es una **escritora** sueca que ha incursionado principalmente en los géneros de la novela y poesía.*[7]

Finally, the extracted examples were automatically back-translated to Basque with the baseline system described in Section 4. This process guarantees gender agreement is not altered during the translation process as Basque is a genderless language.

We obtained a final set of approximately 42,000 examples per gender with the required gender agreement (*Wiki_train*).

In addition, in order to have an in-domain test from Wikipedia, we manually created a disjoint test set by selecting 100 examples for each gender. In this case, translations were manually corrected to ensure their final quality. Hereinafter referred to as *Wiki_test* test set.

4 Experimentation

All the systems use the default configuration for the Transformer architecture (Vaswani et al., 2017) as implemented in the PyTorch version of the OpenNMT toolkit (Klein et al., 2017). We apply BPE tokenization (Sennrich et al., 2016) trained on 32,000 operations on the joint training data. Sentences larger than 100 tokens are discarded from the training set.

The baseline systems were trained on the Basque-Spanish portion (1.77M examples) of the Paracrawl (v8) data (Bañón et al., 2020). The gender-balanced systems are trained by fine-tuning the baseline system on the gender-balanced data sets described in Section 3. As in Costa-jussà and de Jorge (2020), to avoid catastrophic forgetting, where systems tend to forget about previous knowledge, we follow a mixed fine-tuning strategy (Chu et al., 2017). A weighted combination (10:1 ratio[8]) of general domain data from Paracrawl and task specific data, such as *Templ_train* or *Wiki_train*, is used during training and validation steps. For

[7] English translation: *Elisabeth Rynell is a Swedish writer who has mainly dabbled in the genres of novels and poetry.*

[8] Initial experiments showed that 10:1 ratio for general domain and task specific data respectively works well.

validation purposes, we concatenate 5,000 general domain examples and 1,000 task specific examples randomly extracted from the training data.

The baseline and the fine-tuned systems have been trained until convergence on the perplexity results on the validation set, stopping the training process if there was no improvement for 5 consecutive checkpoints. Validation is performed every 10,000 steps in the case of the baseline system whereas fine-tuning validation is performed every 1,000 steps.

We evaluate our systems using **BLEU** and **chrF++** scores from the sacreBLEU tool (Post, 2018). Additionally, we also provide **COMET** (Rei et al., 2020) scores[9], a metric which focuses on the semantic similarity by leveraging the recent breakthroughs in neural language modeling. These scores are computed on the test sets extracted from three publicly available corpora: **EiTB** (Etchegoyhen and Gete, 2020) a news domain data set, **EhuHac** (Sarasola et al., 2015) a collection of classic books, and **TED** (Reimers and Gurevych, 2020) comprising TED talks transcriptions. From each set, we randomly extracted 5,000 examples. Although BLEU, chrF++ and COMET metrics measure the overall translation quality of the systems, task specific metrics are required to evaluate gender bias with more precision. To that end, we measure the **accuracy** of the correctly translated and gender inflected occupations and we propose a new metric called **swap**. Swap is defined as the percentage of the occupations which are inflected with the opposite gender. Thus, errors are divided into unrecoverable errors where occupations are translated in a different way (errors) and gender swapped occupations (swap). A higher swap score means higher bias towards the opposite gender. These scores are computed on the task specific test sets mentioned in Section 3.

4.1 Gender bias assessment

We conducted a detailed experimentation to determine the source of gender bias in the agreement between gendered entities and occupations. We analyze four different strategies to inject different subsets of the gendered entities and occupations lists in the training templates in order to generate gender-balanced data:

- **Full** system uses all the available gendered entities and occupations, both training and test subsets, to inflect training templates. Therefore, the test subsets of the gendered entities and occupations are seen during training. We produce 772,896 training examples.

- **Unknown entities (Unk_ent)** system only uses the training subset of the entities to inflect training templates. There is no overlap between the entities used for fine-tuning the system and those for the test set. 693,880 training examples are produced.

- **Unknown occupations (Unk_occ)** system only uses the training subset of the occupations to inflect training templates, resulting in 633,216 training examples.

- **Unknown pairs (Unk_prs)** system only inflects templates with disjoint combinations of entities and occupations. For instance, if *Mikel-doctor* is present in the test, *Mikel-plumber* and *Jon-doctor* are seen during training. A total of 758,616 training examples are produced.

We remark that, in all the cases, training (27) and test (6) template sets are disjoint, and only single entity templates are used for fine-tuning.

In general terms, all the fine-tuned systems on gender-balanced data keep the baseline's translation quality on the general domains test sets (see Table 2). Specially, **Full** system performs at par with the baseline across all the test sets and metrics, except for the chrF++ score on the EhuHac test set.

In order to analyze bias effects, in Table 3 we report gender bias accuracy and swap scores. The baseline model shows a clear bias towards the masculine inflection of the occupations with significantly higher swap scores and lower accuracy scores for females. We note that a negative value for the swap difference means there exists masculine bias. Lower swap scores are obtained with the baseline system on the *Wiki_test*, suggesting stereotyped occupations from Wikipedia (Wagner et al., 2015) are being well inflected by the baseline.

Fine-tuning the baseline system on the **Full** set significantly drops the swap score on the *Templ_test* which indicates the fine-tuned system is able to correctly inflect the gender of the occupations for seen entities. In contrast, **Unk_ent** system shows higher swap scores. Despite the system is clearly less biased than the baseline, it is having

[9] The recommended model *wmt20-comet-da* was used and it already covers both Basque and Spanish.

Table 3: Accuracy and swap scores for systems fine-tuned on gender-balanced data. We report mean swap scores and swap differences for a better picture of the bias. Best scoring systems are highlighted in bold.

more difficulties inferring the gender of unseen entities. This behaviour is further corroborated on the *Wiki_test* as all the experiments show similar (slightly better) results of those obtained by the baseline system. A manual inspection of the translations showed that most of the swap errors are associated to foreign person names. In such cases, systems tend to provide the default masculine.

With respect to the lower accuracy scores in **Unk_occ**, most of the errors made were the result of the system not being able to produce the correct translation. Most of the time it produces correct but alternative translations for the given occupations such as *lechero/vendedor de leche (milkman)*. In any case, we remark that in these cases the correct gender is generally inflected: *lechera/vendedora de leche (milkwoman)* or *camarógrafo/el cámara (cameraman)*. This behavior blurs swap and accuracy results as the bias can not be automatically computed for those occupations.

Remarkably, accuracy and swap scores in **Unk_prs** obtains comparable enough results of those obtained in **Full**, which suggests the system does not require to see all the possible combinations of entities and occupations during training. Instead, in the light of the results obtained by the **Unk_ent** and **Unk_occ** systems, providing the system with all the gendered entities and occupations is more relevant than producing all their combinations.

In general terms, we can conclude that fine-tuning a pre-trained system with a mixed combination of gender-balanced examples and general domain data is useful to mitigate gender bias from NMT systems without a substantial drop in general domain translation quality.

Finally, we note that all the experiments show higher swap scores on the *Multi_test* test. A manual inspection of the translations suggests that, as stated in (Saunders et al., 2020), systems simply learn to indiscriminately apply the same gender inflection to all the occupations when presented with multi-entity templates. This issue is addressed in Section 4.2.

4.2 Gender tagging entities

From the previous bias assessment section, we conclude that gender disambiguation for unknown entities is not obvious for the systems. Yet, it is essential to correctly inflect occupations with the corresponding gender. Therefore, in the line of the previous work by Saunders et al. (2020) and Stafanovičs et al. (2020), we propose using word level annotations to provide a stronger gender signal for gender disambiguation of gendered entities. (Stafanovičs et al., 2020) annotate all the source words with the grammatical gender information of their corresponding target words while (Saunders et al., 2020) add explicit word-level gender tags to the occupations that need to be inflected. In contrast to these methods, we only apply gender annotations to gendered entities and leave sentence-level gender agreement to the system. The main advantage of this approach is that it does not require any complex annotation step. During inference, a list of proper names and other gendered entities can be used to properly annotate the entities. This list can be dynamically updated without fine-tuning the whole system again.

We annotate each word in the source side of the **Full** set via source factors (Sennrich and Haddow, 2016) with three possible values (**Full_tag**): 1 for male entities, 2 for female entities and 0 for the rest of the words. For example,

Mikelek erizain izan nahi du.[10] → 1 0 0 0 0

These tags are then appropriately mapped to their corresponding subword tokens during the fine-tuning step.

Additionally, as noted in Saunders et al. (2020) and corroborated in Section 4.1, in cases where multiple entities are present in a sentence, systems tend to overgeneralize gender signals by applying the same gender to all the occupations. Accordingly, we add the *Multi_train* set (see Section 3.1) during the fine-tuning step to help the **Full_tag** system better handle these cases.

Likewise, we follow the same gender tagging strategy on the Wikipedia biographies set (*Wiki_train*), described in Section 3.2, to assess whether using real data extracted from Wikipedia is a feasible approach. We remark that due to the characteristics of the biographies it is not possible to extract multiple entity examples. We fine-tune the baseline system with (**Wiki_tag**) and without gender tags (**Wiki**).

Overall, all the systems keep the baseline's translation quality in terms of BLEU, chrF++ and COMET for the general domain test sets, either fine-tuned with templates or with real Wikipedia data (see Table 4).

Moreover, Table 5 shows gender bias accuracy and swap scores for the gender tagged systems along with their untagged version. **Full_tag** considerably outperforms **Full**. Despite the swap difference on the *Templ_test* is slightly higher for **Full_tag**, the total swap score is lower. Adding unambiguous gender tags to the entities provides a stronger signal that helps reducing gender bias from the system. We report a substantial improvement on the *Multi_test*, which further encourages the use of a stronger gender signal via gender tags. Remarkably, **Full_tag** obtains perfect scores on the *Multi_test*, showing that providing multi-entity templates during training helps mitigating the gender signal overgeneralization issue.

Fine-tuning on *Wiki_train* also helps improving the baseline system and adding gender tags further improves those results. As expected, **Wiki_tag** obtains the best bias reduction results on the in-domain *Wiki_test*, as most of the occupations overlap between training and test data. Notice that the Wikipedia occupations set is potentially small and closed. As reported by Costa-jussà and de Jorge (2020) using real gender-balanced data instead of manually created templates can also contribute to reduce bias, although the results we achieved are not as good as those obtained with the template-based version. However, we note that systems fine-tuned on *Wiki_train* still perform poorly when multiple entities are present, showing a clear tendency towards masculine overgeneralization.

4.3 Templates ablation study

In this section we report the results of the template ablation experiments conducted to determine the optimal amount of templates needed in order to reduce the manual effort to build them. We focused on their complexity too, as generating simpler templates might be easier without a strong knowledge

about the language.

We sorted all the training templates, both single entity templates and multi-entity templates, according to their complexity. Word counts are used as an indicator of their complexity. We wanted to analyze the simplest scenario with just one single entity template and one multi-entity template (**1_1**), as this is the case in (Saunders and Byrne, 2020). Additionally, we analyzed scenarios with different numbers of single entity templates and multi-entity templates, hereinafter referred to as **2_2**, **5_5**, **10_10**, **20_10**[11]. To analyze the influence of the complexity, for all the combinations we produced a simple version (**S**), which comprises the less complex templates and a complex version (**C**) including the most complex ones. All these ablation experiments were compared against the baseline system and the **Full_tag** system fine-tuned with all the handcrafted templates possible (27 single entity and 10 multi-entity templates). All the experiments use gender tags.

In general terms, all the systems comply with the requirement of keeping the baseline's translation quality for the general domain test sets (see Table 6). We therefore focus on the task specific metrics as shown in Figure 2.

All the systems, even for **S_1_1**, significantly improve swap scores when compared to the baseline. Mean swap curves show a clear descending trend which suggests that having a more syntactically diverse set helps generalizing gender signals. Remarkably, from **S_10_10** and **C_10_10** systems on, the curve tends to converge, showing little improvement with more templates. This is an interesting

insight, as there seems to be a limit in the amount of templates, which considerably reduces the manual effort to create templates.

In general terms, systems fine-tuned on simpler templates perform at par or even better than the ones trained on more complex templates. This indicates that generating complex and syntactically rich templates is not worth the effort. Also, results suggest that multi-entity templates present a strong signal which solves the overgeneralization issue for systems with 10 or more templates. Thus, it emphasizes the hypothesis that templates can be easily adapted to small specific tasks with little effort.

System	Templ	Multi	Multi
S_1_1	7.72	1.22	5.88
S_10_10	**1.44**	**0.03**	**2.79**
S_10_10_limit	1.70	0.25	3.41

Table 7: Mean swap scores for the **S_10_10_limit** system compared against its complete version (**S_10_10**) and **S_1_1**. The system was fine-tuned on only 32,200 examples as **S_1_1**. Best scoring systems are highlighted in bold.

Finally, we tested whether having more templates improves the results because of the syntactically diverse templates or just because of the mere fact that more training examples are generated. To that end, as we observed some convergence with 10 templates, we fine-tuned the baseline on randomly selected 32,200 examples, namely **S_10_10_limit**, that is, the same amount of templates used in **S_1_1** (Table 7). **S_10_10_limit** performs slightly worse than **S_10_10** and it clearly outperforms **S_1_1**. This suggests that the improvement comes to a greater extent from syntactic diversity rather than from a higher amount of templates.

5 Conclusions

In this work we addressed gender bias mitigation from an already pre-trained system. In particular, we focused on the specific task of sentence-level gender agreement between gendered entities and occupations when translating from genderless languages to gendered languages.

The proposed template-based fine-tuning strategy with explicit gender tags helps mitigating gender bias from NMT systems. We proved that the mixed fine-tuning strategy using a weighted combination of general domain and task specific data is beneficial to overcome catastrophic forgetting and keep the original translation quality.

We demonstrated that adding explicit gender tags to gendered entities provides a stronger gender signal and helps the system to gender inflect occupations correctly. At inference, entities can be easily annotated by using a list of proper names and other gendered entities, which can be dynamically updated without fine-tuning the system again.

Our results on the Basque to Spanish translation direction showed substantial bias mitigation and confirmed that handcrafted templates are suitable to create task specific training examples, to the point of improving the results obtained by using gender-balanced real examples extracted from Wikipedia. The ablation study showed that with little manual effort a set of useful templates can be created for gender bias mitigation. Therefore, the proposed method can be applied to other language pairs.

Limitations

The ablation study in Section 4.3 showed that with little manual effort a set of useful templates could be created for gender bias mitigation. In this sense, the proposed method still requires some linguistic knowledge about the languages involved in order to manually create the templates. Some of the entities and the occupations list should be adapted to the new language pair too. We acknowledge that this requirement can be a limiting factor for a massive deployment of our method. However, we believe that some challenges in NMT require a prior linguistic knowledge of the languages at hand in order to detect the possible errors and flaws and to provide a solution or mitigation response.

Furthermore, our work focuses on the Basque to Spanish translation direction as an example of the translation direction from a genderless language to a language with explicit grammatical gender. Although, the proposed gender tagging method does not rely on Basque or Spanish exclusive linguistic features, we believe that adding additional language pairs would have shown a broader picture of our method's potential. We leave this discussion for future work where different language families could be analyzed.

Finally, it must be noted that we approach the task using a binary gender representation schema. This decision should not be interpreted as a denial of a more complex reality.

Exploring the Benefits and Limitations of Multilinguality for Non-autoregressive Machine Translation

Abstract

Non-autoregressive (NAR) machine translation has recently received significant developments, and now achieves comparable quality with autoregressive (AR) models on some benchmarks, while providing an efficient alternative to AR inference. However, while AR translation is often used to implement multilingual models that benefit from transfer between languages and from improved serving efficiency, multilingual NAR models remain relatively unexplored. Taking Connectionist Temporal Classification (CTC) as an example NAR model and IMPUTER as a semi-NAR model, we present a comprehensive empirical study of multilingual NAR. We test its capabilities with respect to positive transfer between related languages and negative transfer under capacity constraints. As NAR models require distilled training sets, we carefully study the impact of bilingual versus multilingual teachers. Finally, we fit a scaling law for multilingual NAR to determine capacity bottlenecks, which quantifies its performance relative to the AR model as the model scale increases.

1 Introduction

Non-autoregressive (NAR) models generate output tokens in parallel instead of sequentially, reducing potentially expensive inference dependencies. They rely on sequence-level knowledge distillation to reach the quality of autoregressive (AR) models (Gu et al., 2018). As the notion of NAR has expanded to include semi-NAR models that generate their outputs in multiple steps, with each step generating several tokens non-autoregressively (Lee et al., 2018; Ghazvininejad et al., 2019), we have begun to see NAR matching the quality of AR (Saharia et al., 2020). Prior works have benchmarked NAR models for machine translation (MT) on a number of language pairs, but with very few exceptions, the NAR models under test have been bilingual as opposed to multilingual.

Multilingual MT models (Dong et al., 2015; Firat et al., 2017; Johnson et al., 2017), translating between multiple languages, have two major advantages. First, they offer better parameter efficiency than bilingual models via multi-tasking. Second, they are able to transfer knowledge from high-resource languages to low-resource ones. Therefore they have become an attractive solution for expanding the language coverage of AR MT (Aharoni et al., 2019; Fan et al., 2021; Siddhant et al., 2022). The capability of multilingual modeling is a major feature of the AR regime, and it is one that we should seek to maintain in NAR models.

However, it is unclear to what extent the benefits of multilingual AR models transfer to NAR modeling (Caruana, 1997; Arivazhagan et al., 2019). Do related languages help each other as easily (*positive transfer*)? Do unrelated languages interfere with one another more (*negative transfer*)? Furthermore, NAR modeling raises a new issue of multilingual distillation. To retain the training-time efficiency of multilingual modeling, it is crucial that NAR works well with multilingual teachers; otherwise, the prospect of training many bilingual teachers would greatly increase the effective training cost. It may actually be the case that multilingual teachers are better suited than bilingual ones, as the effective capacity reduction may result in less complex (Zhou et al., 2019) and less multi-modal outputs (Gu et al., 2018).

We present an empirical study of multilingual NAR modeling. Taking CTC (Libovický and Helcl, 2018) as our canonical NAR method, and IMPUTER (Saharia et al., 2020) as our canonical semi-NAR model, we study how they respond to multilinguality through a series of "stress-tests", first in a six-language scenario designed to emphasize negative transfer (§4), and then in two-language scenarios designed to emphasize positive transfer under data resource constraints (§5). Lastly, we fit a scaling law for our six-language sce-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 177 - 187
December 7-8, 2022 ©2022 Association for Computational Linguistics

nario to measure the potential of increasing model sizes (§6). The main findings can be summarized as follows:

1. Multilingual NAR models work equally well whether datasets are distilled from bilingual or multilingual teachers.
2. Multilingual NAR models do benefit from positive transfer in scenarios that encourage it; however, in comparison to AR models, they suffer more from negative transfer and benefit less from positive transfer.
3. The scaling law demonstrates that this trend continues as model size increases.

Our extensive analysis on outputs from the NAR models suggest that they still struggle to generate "valid" tokens with desired output length. Furthermore, our results indicate that scaling up the NAR models is not going to close the gap to multilingual AR, but our analysis points to promising directions for future work throughout the paper.

2 Non-Autoregressive Multilingual NMT

Let, $D^l = (x, y) \in X \times Y$ denote the bilingual corpus of a language pair, l. Given an input sequence x of length T', an AR model (Bahdanau et al., 2015; Vaswani et al., 2017) predicts the target y with length T sequentially based on the conditional distribution $p(y_t \mid y_{<t}, x_{1:T'}; \theta)$. NAR models assume conditional independence in the output token space; that is, they model $p(y_t \mid x_{1:T'}; \phi)$. Due to this conditional independence assumption, training NAR models directly on the true target distribution leads to degraded performance (Gu et al., 2018). Hence, NAR models are typically trained with sequence-level knowledge distillation (Kim and Rush, 2016) to reduce the modeling difficulty.

2.1 Non-Autoregressive NMT with CTC

In this work, we focus on NAR modelling via CTC (Graves et al., 2006) due to its superior performance on NAR generation and the flexibility of variable length prediction (Libovický and Helcl, 2018; Saharia et al., 2020; Gu and Kong, 2021).

CTC models an alignment a that provides a mapping between a sequence of predicted and target tokens. Alignments can be constructed by inserting special *blank tokens* ("_") and token repetitions into the target sequence. The alignment is monotonic with respect to the target sequence and is always the same length as the source sequence x. However, in MT, the target sequence y can be longer than the source sequence x. This is handled via upsampling the source sequence x, to s times its original length. An alignment is valid only if when collapsed, i.e., merging repeated tokens and removing blank tokens, it results in the original target sequence. The CTC loss marginalizes over all possible valid alignments $\Gamma(y)$ compatible with the target y and is defined as:

$$p(y \mid x) = \sum_{a \in \Gamma(y)} \prod_{1 \leq t' \leq T'} p(a_{t'} \mid x_{1:T'}; \phi).$$

Note that each alignment token $a_{t'}$ is modeled independently. This conditional independence allows CTC to predict the single most likely alignment non-autoregressively at inference time, which can then be efficiently collapsed to an output sequence. This same independence assumption enables efficient minimization of the CTC loss via dynamic programming (Graves et al., 2006). While CTC enforces monotonicity between the target and the predictions, it does not require any cross- or self-attention layers inside the model to be monotonic. Hence, CTC should still be able to model language pairs with different word orders between the source and the target sequence. Following Saharia et al. (2020), we train encoder-only CTC models, using a stack of self-attention layers to map the source sequence directly to the alignments.

2.2 Iterative Decoding with Imputer

IMPUTER (Saharia et al., 2020) extends NAR CTC modeling by iterative refinement (Lee et al., 2018). At each inference step, it conditions on a previous partially generated alignment to emit a new alignment. While IMPUTER, like CTC, generates all tokens at each inference step, only a subset of these tokens is selected to generate a partial alignment, similar to iterative masking approaches (Ghazvininejad et al., 2019). This is achieved during training via marginalizing over partial alignments as follows:

$$p(y \mid x) = \sum_{a \in \Gamma(a)} p(a \mid a_{\text{Mask}}, x; \phi),$$

where a_{Mask} is a partially masked input-alignment. At training time, the a_{Mask} alignment is generated using a CTC model trained on the same dataset, and its masked positions are selected randomly. This training procedure enables IMPUTER to iteratively refine a partial alignment over multiple

	Tgt Word Order	Size	Script Difference	White Space	Avg. Src Length	Avg. Tgt Length

En-Fr	SVO	38.1M	✗	✓	29.2	32.8

Table 1: Details on training data used. Target word orders are the ones that are dominating within the language according to (Dryer and Haspelmath, 2013), but there may be sentence-specific variations. English follows predominantly SVO (Subject-Verb-Object) order. Size is measured as the number of parallel sentences in the training data. Source (Src) and Target (Tgt) length are averaged across sentences after word-based tokenization.

decoding steps at inference time — consuming its own alignments as input to the next iteration. With $k > 1$ decoding steps, the IMPUTER becomes *semi-autoregressive*, requiring k times more inference passes than pure CTC models.

IMPUTER differs from Conditional Masked Language Modeling (CMLM) (Ghazvininejad et al., 2019) in that it uses the CTC loss instead of the standard cross-entropy loss, removing the need for explicit output length prediction. Also, IMPUTER is an encoder-only model that makes one prediction per source token, just like CTC. The cross-attention component from encoder-decoder is replaced by a simple sum between the embeddings of the source sequence and the input alignment (a_{Mask}) before the first self-attention layer.[1]

2.3 Multilingual Modeling

Multilingual AR and NAR models are trained on datasets from multiple language pairs, $\{D^l\}_{l=1}^{L}$. We prepend each source sequence with the desired target language tag (<2tgt>) and generate a shared vocabulary across all languages (Johnson et al., 2017). The models encode this tag as any other token, and uses it to guide the generation of the output sequence in the desired target language.

2.4 Efficiency

Inference We refrain from wallclock inference time measurements since these are dependent on implementation, low-level optimization and machines (Dehghani et al., 2021). We instead compare generation speed in terms of the number of tokens that get generated per iteration N_{gen} (Kreutzer et al., 2020), which is < 1 for AR models,[2] T for fully non-autoregressive models like CTC and $\frac{T}{k}$ for iterative semi-autoregressive models like IMPUTER. *While the potential for faster inference motivates our interest in* NAR, *our core contribution is a comparison of multilingual modeling capabilities; therefore, we do not measure inference speed experimentally.*

Training At training time, NAR models are less efficient than AR models because their quality depends on distillation (Gu and Kong, 2021). Extra cost is incurred to train a teacher model (usually AR) and to use it to decode the training set.

Multilinguality Multilingual models multi-task over language pairs, so that a single multilingual model can replace several bilingual models. Thanks to transfer across languages, model size needs to be increased less than m-fold for modeling m language pairs.

Considering all of the above factors, an ideal model needs only a few iterations (decoder passes or steps), requires no teacher or a cheap teacher, and covers several languages, while incurring the smallest drop in quality compared to less efficient models. CTC is desirable as it uses only one pass, while IMPUTER gives up some efficiency to improve quality. Both require a teacher, but we can try to reduce the cost by training fewer teachers.

3 Experimental Setup

Data We perform our main experiments on six language pairs, translating from English into WMT-14 German (De) (Bojar et al., 2014), WMT-15 French (Fr) (Bojar et al., 2015), WMT-19 Russian (Ru) (Barrault et al., 2019), WMT-20 Japanese (Ja), WMT-20 Polish (Pl) (Barrault et al., 2020) and Samanantar Hindi (Hi) (Ramesh et al., 2021). The lower-resourced WMT-19 English-Kazakh (Kk) (Barrault et al., 2019) is used for an additional transfer experiment in Section 5. The properties

[1] We experimented with an encoder-decoder variant of IMPUTER but it did not change the overall output quality in multilingual scenarios or otherwise.

[2] 1 for greedy search, < 1 to account for scoring and expansion of multiple hypotheses in beam search.

of the datasets are listed in Table 1. Target word order and writing script notably differ across these languages, so we focus on translating *into* these languages as this is a more challenging direction. A shared sub-word vocabulary of 32k is trained with SentencePiece (Kudo and Richardson, 2018), with the number of sub-words allocated for each language being proportional to its data size.

Evaluation Metrics Translation quality is evaluated with BLEU (Papineni et al., 2002) as calculated by Sacrebleu (Post, 2018) with default tokenization ("13a") except for EN-JA, where we use character-level tokenization. [3]

Architecture We train the IMPUTER model using the same setup as described in Saharia et al. (2020): We follow their base model with d_{model} = 512, d_{hidden} = 2048, n_{heads} = 8, n_{layers} = 12, and $p_{dropout}$ = 0.1. AR models follow Transformer-base (Vaswani et al., 2017) and have similar parameter counts. We train both models using Adam with learning rate of 0.0001. We train CTC models with a batch size of 2048 and 8192 sentences for 300K steps for the bilingual and multilingual models respectively. We train the IMPUTER using CTC loss using a Bernoulli masking policy for next 300K steps with a batch size of 1024 and 2048 sentences for the bilingual and multilingual models respectively. We upsample the source sequence by a factor of 2 for all our experiments.[4] We pick the best checkpoint based on validation BLEU for bilingual models, and the last checkpoint for multilingual models, following Arivazhagan et al. (2019).

Distillation We apply sequence-level knowledge distillation (Kim and Rush, 2016) from AR teacher models as widely used in NAR generation (Gu et al., 2018). Specifically, when training the NAR models, we replace the reference sequences during training with translation outputs from Transformer-Big AR teacher model with a beam width of four. We also report the quality of the AR teacher models, both bilingual and multilingual. The configurations for training the big AR teacher models also follow Vaswani et al. (2017).

4 Negative Transfer Scenario

Our main experiment compares bilingual, multilingual, AR and NAR models for the six high-resource languages from Table 1. These languages are typologically diverse, and they each have enough data so that we do not expect them to benefit substantially from joint modeling. We use this challenging scenario to test the impact of multilingual teachers, and to measure each paradigm's ability to model several unrelated languages. Results are shown in Table 2.

4.1 Multilingual Teacher Comparison

Inspecting the AR teacher models (rows 1 and 2 of Table 2) confirms the negative transfer that we aimed to design: multilingual teachers have substantially reduced BLEU compared to bilingual teachers. How much is this drop in quality affecting NAR students? First of all, we see that bilingual CTC models trained from the multilingual teacher (5) do not reflect the entirety of this drop when compared to training with the bilingual teacher (4): An average teacher gap of −1.8 BLEU is causing −1.1 drop for the corresponding students.[5] The comparison becomes more interesting as we shift to multilingual students: multilingual CTC (8, 9) does not suffer at all from having a multilingual teacher (average BLEU gap of −0.1), and multilingual IMPUTER (10, 11) likewise suffers very little (−0.3). These three results taken together suggest that *datasets distilled from multilingual models are likely simpler, but easier to model non-autoregressively* by the multilingual NAR models, which makes up for the teacher's lower BLEU. Our analysis in Section 4.3 supports this hypothesis.

We hope that highly multilingual models, trained with similar target language pairs to enhance positive transfer (Tan et al., 2019), are even better suited to serve as teachers for multilingual NAR models, which we leave to future work.

4.2 Multilingual Student Comparison

Returning to the "Bilingual Models" section of Table 2 with `AR-big` teachers, we can see that we have reproduced the results of Saharia et al. (2020): Bilingual CTC (4) performs well for a fully NAR method, but does not reach AR quality (3). IMPUTER (6) ably closes the gap with AR, surpassing

[3] SacreBLEU (short) signatures: nrefs:1|case:mixed|eff:no|tok:13a,char|smooth:exp|version:2.0.0

[4] We do not vary the upsampling ratio due to small difference in the performance of the resulting NAR models (see Table 6, Gu and Kong (2021)).

[5] As the quality of CTC generated alignments from the multi-AR-big is worse than the alignments generated from the CTC with the AR-big teacher, we do not train IMPUTER on CTC-generated alignments from the multi-AR-big models.

	Model	Teacher	N_{gen}	En-Fr	En-De	En-Pl	En-Ru	En-Hi	En-Ja	Avg.

Table 2: Test BLEU scores for multilingual and bilingual AR and NAR models and their teachers.

or coming within 0.4 BLEU of the AR-base models on 3/6 language pairs, with the largest gap in performance for the distant En-Ja. Does this story hold as we move to multilingual NAR students?

To understand each model's multilingual capabilities, we can compare its bilingual performance to its multilingual performance. Comparing bilingual AR-base (3) to its multilingual counterparts (7) gives us a baseline average drop of −2.8 BLEU, confirming that this is indeed a difficult multilingual scenario that leads to negative transfer. Comparing bilingual CTC (4) to multilingual CTC (8) with AR-big teachers, we see an average drop of −4.1. This larger drop indicates that CTC *suffers more from negative interference than its* AR *counterpart*. We hypothesize that CTC models need more capacity than AR models to achieve similar multilingual performance, motivating our scaling law experiments in Section 6.

Performing the same bilingual-to-multilingual comparison for Imputer (6 vs. 10) shows a similar −3.9 average drop due to negative transfer. So although Imputer is indeed better than CTC (2 BLEU), it does not seem to be better suited for multilingual modeling in this difficult scenario.

4.3 How do the bilingual and the multilingual distilled datasets differ?

Table 3 summarizes different statistics for the original (R) and distilled datasets from both multilingual (M) and bilingual (B) AR teacher models. We report the number of types and average sequence length (in tokens) for the target side of the dataset. We compute the complexity of the dataset based on probabilities from a statistical word aligner (Zhou et al., 2019). The FRS (Talbot et al., 2011) score represents the average fuzzy reordering score over all the sentence pairs for the respective language pair as measured in Xu et al. (2021), with higher values suggesting that the target is more monotonic with the source sequence. We also report BLEU for the distilled datasets relative to the original training references.

The datasets distilled from the bilingual AR models (B) are shorter, less complex, have reduced lexical diversity (in number of types) and are more monotonic compared to the original corpora (R), which corroborates findings from prior work (Zhou et al., 2019; Xu et al., 2021). One exception is En-Ja, where the distilled translations are slightly less monotonic than the original references. Moving to multilingual teachers (M), the resulting datasets have further reduced types, are shorter and less complex than those distilled from bilingual teachers. In particular, their monotonicity increased (FRS) for the more distant language pairs, En-Ja and En-Hi. As shown in Xu et al. (2021) and Voita et al. (2021), reduced lexical diversity and reordering complexity can help bilingual NAR models to learn better alignments between source and target, improving the translation quality of the outputs. More work is needed to better understand

Figure 1: Brevity penalty scores for bilingual (-B) and multilingual (-M) models, the closer to 1 the better.

Effect of Length Figure 1 shows the brevity penalty (BP) scores (Papineni et al., 2002) for all languages. EN-PL and EN-JA have lowest BP scores across the board, meaning that their translations are shorter than the references. Manual inspection reveals that this could be attributed to the subject pronouns being dropped in both of these target languages. Multilingual modeling results in shorter outputs relative to bilingual models for both AR and NAR models and most language pairs. While IMPUTER models tend to have fewer issues with output length compared to CTC models, they still lag behind AR models, suggesting that the length might need to be controlled explicitly for these language pairs (Gu and Kong, 2021).

Invalid Words CTC frequently generates *invalid* words, i.e. tokens that are not present in the target side of the bitext but are being composed from multiple sub-words. These sub-words represent alternative translations that the model fails to distinguish. In the Hindi example below, the invalid (or made-up) word in the sentence is marked in red. The correct word should be जहरीले as the dependent vowel "ी" can only be used once.

Hindi: इससे ग्रामीण महिलाओं को जहरीीले धुएं से मुक्ति मिली हैं।

English: This has relieved the rural women from the poisonous smoke.

Figure 2 reports the percentage of sequences that include at least one invalid word in the test set. CTC generates many invalid words compared to both AR and IMPUTER, with multilingual modeling leading to an average increase in invalid words by 37%. The shared vocabulary of the multilingual model results in shorter sub-words, hence longer sequences, and the conditionally independent generation leads to more clashing adjacent sub-words.[6]

[6] One might hope to alleviate this by increasing vocabulary size, but preliminary experiments showed that an increased vocabulary was less efficient in improving quality than increasing overall model size, which is explored in Section 6.

IMPUTER's iterative decoding alleviates this for some languages. Increasing the number of iterations could help, but would also erode the efficiency arguments that make NAR models attractive. As pointed out by Xiao et al. (2022), better modeling of target token dependencies is crucial to closing the gap in translation quality to AR models.

	FR	DE	PL	RU	HI	JA
AR-B	0.04	0.23	0.14	0.17	0.03	0.12
AR-M	0.05	0.30	0.17	0.25	0.03	0.15
CTC-B	0.32	0.62	0.69	0.71	0.12	0.32
CTC-M	0.56	0.79	0.91	0.85	0.40	0.48
IMPUTER-B	0.14	0.40	0.40	0.44	0.06	0.20
IMPUTER-M	0.29	0.57	0.63	0.61	0.19	0.28

Figure 2: % of outputs with invalid words for bilingual (-B) and multilingual (-M) models, the lower the better.

5 Positive Transfer Scenario

In this section we present two experimental setups designed to emphasize positive transfer, where languages are related and training data is limited.

English→{German, French} To isolate the effect of transfer via multilingual modelling, we relax the capacity bottleneck and competition for parameters: We combine the two most related languages (DE, FR) (Kudugunta et al., 2019, Figure 2) and give them smaller, balanced training sets (1M sentences). We compare bilingual and multilingual AR and NAR models trained on this reduced data.

Table 4 shows that NAR *models benefit from training with multiple language pairs in this relaxed scenario* — all models exhibit positive transfer (in green). IMPUTER achieves higher positive transfer than CTC for both languages, but lags behind the AR multilingual model in EN-FR. However, for EN-FR the bilingual IMPUTER is already ahead of the bilingual AR model by 0.4 BLEU.

MODEL	EN-DE	EN-FR
Bilingual Models		
AR	22.8	27.7
CTC	21.5	26.5
IMPUTER	22.8	28.1
Multilingual Models		
AR	**24.3** +1.5	**29.0** +1.3
CTC	22.1 +0.6	26.9 +0.4
IMPUTER	23.7 +1.3	28.5 +0.4

Table 4: Results on subsampled (1M) training data.

English→{Russian, Kazakh} Does this positive transfer survive data imbalance? We test the performance of the multilingual NAR model on the low-resource task of translating English into Kazakh, for which the size of clean training data is insufficient to train a bilingual AR model from scratch. We instead distill translations from the publicly available multilingual AR model, PRISM (Thompson and Post, 2020). We then pair it with the higher-resource but related language Russian to encourage positive transfer to Kazakh. Given the huge difference in data sizes for Russian and Kazakh (see Table 1), we sample training data from the two languages based on the data size scaled by a temperature value τ, $p_l^{1/\tau}$ (Arivazhagan et al., 2019), where, $p_l = \frac{D_l}{\sum_k D_k}$. We experiment with multiple temperature values (1, 3, 5, 10, 20) and pick the best value ($\tau = 5; p_{\text{RU}}^{1/\tau} = 0.75, p_{\text{KK}}^{1/\tau} = 0.25$) based on the performance on the validation set.

MODEL	TEACHER	EN-KK	EN-RU
PRISM	-	**8.9**	**27.0**
Bilingual Models			
AR	PRISM	4.4	-
CTC		1.2	-
Multilingual Models			
AR	PRISM	7.1 +2.7	26.0
CTC		2.8 +1.6	20.4

Table 5: Results on English → Kazakh, Russian.

As can be seen in Table 5, both AR and CTC show positive transfer when translating into Kazakh when trained in combination with Russian. The multilingual CTC model is able to improve over the bilingual CTC model, but the overall quality of the outputs is very low compared to the teacher model (BLEU: -5.3). This experiment showcases that *current* NAR *models do not perform well on very low-resource language pairs* and might need further data augmentation (Song et al., 2022) or transfer from other similar languages.[7]

6 Impact of Model Scale

We hypothesized in Section 4 that CTC might require more capacity than AR models. If we increase the parameters for NAR models sufficiently, could we reach AR quality? Scaling laws can characterize the relationship between MT quality, the cross-entropy loss and the number of parameters

[7] We do not train IMPUTER for KK as the quality of the distilled dataset and alignments from CTC is very low.

used for training the model (Ghorbani et al., 2021; Gordon et al., 2021).

We derive the relationship between BLEU and the number of parameters for our AR and CTC models directly from the scaling laws proposed by Gordon et al. (2021) and Ghorbani et al. (2021) as follows:

$$\begin{aligned} L(N) &\approx L_0 + \alpha_n (1/N)^{\alpha_k} \text{ (Ghorbani et al., 2021)} \\ \mathrm{BLEU}(L) &\approx C\mathrm{e}^{-kL} \text{ (Gordon et al., 2021)} \\ \mathrm{BLEU}(N) &\approx a\mathrm{e}^{-b(1/N)^c} \text{ (this work)} \end{aligned}$$

where L is the test loss, $\{\alpha_n, \alpha_k, L_0, C, k\}$ are fitted parameters from previous power laws, and $\{a, b, c\}$ are the collapsed fitted parameters of our power law. Ghorbani et al. (2021)'s L_0 corresponds to the irreducible loss of the data (here: a).

Setup We train seven models with varying capacity for AR and CTC models. The number of layers and model sizes are varied as: (6, 128), (6, 256), (12, 256), *(12, 512)*,[8] (24, 512), (12, 1024), (24, 1024). The feed-forward size is 4× the model size. AR models have equal numbers of encoder and decoder layers. The number of attention heads is given by $(8/(512/\text{Model Size}))$. For a fair comparison, we train both AR and CTC models on distilled outputs from `AR-big` in Table 2. The evaluation is conducted in the challenging six-language negative-transfer scenario from Section 4, where capacity bottlenecks are likely to be most pronounced. We report BLEU averaged across six languages.

Results Figure 3 shows the fitted parameters using the scaling law, which can almost perfectly describe the relationship between the number of parameters and the development BLEU (R^2: 0.99). We can see that CTC*, even with many more parameters, do not come even close to the performance of* AR *models and plateaus early* at a BLEU of 26.7, while AR models plateau at 30.8. By projecting the curves out to 1 billion parameters, we show that increasing the capacity of NAR is insufficient to reach the quality of AR models.

7 Related Work

Multiple approaches with varying architectures (Gu et al., 2018, 2019; Chan et al., 2020; Xu and Carpuat, 2021), custom loss functions (Ghazvininejad et al., 2020; Du et al., 2021) and training strategies (Ghazvininejad et al., 2019; Qian et al., 2021) have been used to enable parallel generation of output tokens for MT with sequence-level knowledge distillation as one of the key ingredient in the training of NAR models. Both supervised, and unsupervised (Sun et al., 2020) MT have benefitted from training with multiple languages, especially those that have tiny (Siddhant et al., 2020) to no training data (Zhang et al., 2020). However, multilingual modeling has not yet received any attention in the NAR literature, which we explore in this work. One limitation of our study is that we choose one representative system for NAR and semi-NAR modeling over the full breadth of NAR options.

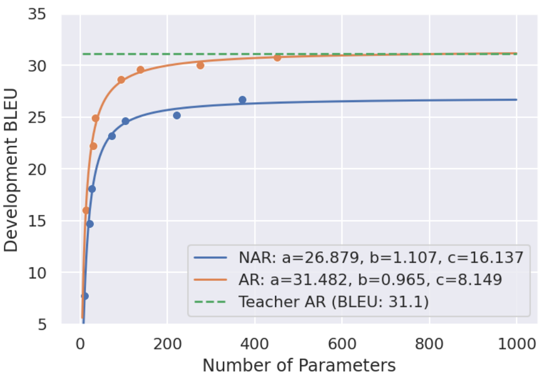

Figure 3: BLEU versus number of parameters and fitted power-law curves (R^2 AR: 0.99, R^2 CTC: 0.99).

8 Conclusion

Multilingual translation is a valuable feature of AR models, therefore, we have tested NAR models for that same capability. We focus on challenging scenarios to discover potential weaknesses and to identify areas for future work. In a relaxed setting with little interference between languages and balanced data, multilingual NAR models nicely exhibit positive transfer, practically closing the gap to AR models with a few decoding iterations. However, we do not see the same positive transfer in a true low-resource scenario. Experiments in a six-language scenario reveal that multilingual NAR models suffer proportionally more from negative interference than AR models. Our derived scaling laws show that scaling up CTC model parameters is not a sufficient remedy. Our analysis identified two issues that hurt translation quality and worsen with multilinguality, namely output length control and the generation of invalid words. We have also shown beneficial properties of using multilingual teachers for distillation. We hope that this work will serve as a call for increased focus on multilingual modeling in NAR research.

Learning an Artificial Language for Knowledge-Sharing in Multilingual Translation

Danni Liu and **Jan Niehues**
Karlsruhe Institute of Technology
{danni.liu, jan.niehues}@kit.edu

Abstract

The cornerstone of multilingual neural translation is shared representations across languages. Given the theoretically infinite representation power of neural networks, semantically identical sentences are likely represented differently. While representing sentences in the *continuous* latent space ensures expressiveness, it introduces the risk of capturing of irrelevant features which hinders the learning of a common representation. In this work, we *discretize* the encoder output latent space of multilingual models by assigning encoder states to entries in a codebook, which in effect represents source sentences in a new artificial language. This discretization process not only offers a new way to interpret the otherwise black-box model representations, but, more importantly, gives potential for increasing robustness in unseen testing conditions. We validate our approach on large-scale experiments with realistic data volumes and domains. When tested in zero-shot conditions, our approach is competitive with two strong alternatives from the literature. We also use the learned artificial language to analyze model behavior, and discover that using a similar bridge language increases knowledge-sharing among the remaining languages.

1 Introduction

A promising potential of multilingual (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016; Johnson et al., 2017) neural machine translation (NMT) is knowledge-sharing between languages. To enable knowledge-sharing, a prerequisite is the ability to capture common features of languages, especially between related ones. *Constructed languages* such as *Interlingua* and *Esperanto* are excellent examples of human-designed structures based on the commonalities of a wide range of related languages. For data-driven models, however, it is difficult to leverage such resources due to data scarcity: There is little parallel data to these constructed languages, and creating new translation heavily depends on expert curation. Instead of relying on manually-created data, we aim to learn an artificial language in a more unsupervised fashion in parallel with training the NMT model. Specifically, our goal is to learn a sequence of tokens to represent the source sentences, which then serves as context for the NMT decoder. Table 1 illustrates this idea.

source sentence (English)	learning	a	new	language
	↓	↓	↓	↓
discrete codes	3	609	57	1042
source sentence (Indonesian)	belajar	bahasa	baru	
	↓	↓	↓	
discrete codes	3	57	258	

Table 1: We aim to learn a sequence of discrete codes to represent source sentences in multilingual NMT models. Our goal is to 1) improve inference-time robustness, 2) have more interpretable intermediate representations.

A potential advantage of representing inputs in discrete tokens is *robustness*, a property especially relevant when NMT systems must cope with unexpected testing conditions. By discretization, we restrict the continuous latent space to a finite size, providing the possibility for model intermediate representations to fall back to a position seen in training. For instance, in zero-shot translation, where the model translates directions never seen in training, the inference-time behavior is often unstable (Gu et al., 2019; Al-Shedivat and Parikh, 2019; Rios et al., 2020; Raganato et al., 2021). In practice, pivoting through an intermediate language typically gives a strong performance upper bound difficult to surpass by direct zero-shot translation (Al-Shedivat and Parikh, 2019; Arivazhagan et al., 2019a; Zhu et al., 2020; Yang et al., 2021b). Mapping the source sentences to discrete codes could act as a *pseudo*-pivoting step, which we hope to make the model more robust under zero-shot conditions.

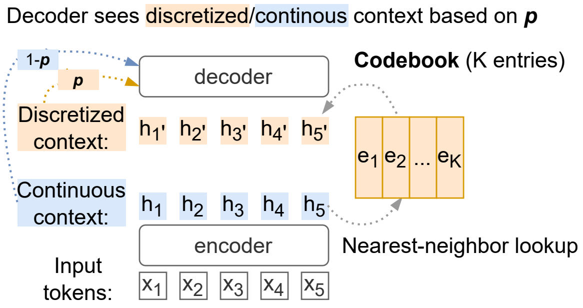
The discrete codes also provide a new way to interpret model representations. While there are a

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 188 - 202
December 7-8, 2022 ©2022 Association for Computational Linguistics

wealth of methods to analyze knowledge-sharing in multilingual NMT (Aji et al., 2020; Mueller et al., 2020; Chiang et al., 2022), they mostly either measure translation performance as a proxy, or involve sophisticated post-processing after model training, e.g. correlation scores between model hidden states (Kudugunta et al., 2019; Chiang et al., 2022), training classifiers to probe linguistic features (Liu et al., 2021a), or pruning model submodules (Kim et al., 2021). In contrast, when the model hidden states are directly associated with discrete tokens, they are directly more *interpretable*. This characteristic is especially relevant in unseen testing conditions, where it is important to pinpoint the underlying cause of model behavior.

Despite the advantages, discretizing the latent space of NMT models makes them inherently less expressive than their fully continuous counterparts. Maintaining translation performance relative to the continuous models is therefore a challenge. To strike a balance between expressiveness and discretization, we propose a *soft* discretization approach: In training, we assign each encoder hidden state to an entry in a fixed-size codebook. This step in effect clusters encoder hidden states to one of the many cluster centers in the latent space. The codebook where the cluster centers come from is then trained along with the translation model. To ensure that the decoder receives sufficient context information, we make it access both the discretized or continuous context, as illustrated in Figure 1. In our experiments on data from the Large-Scale Multilingual Translation Shared Task (Wenzek et al., 2021) from WMT21 (Akhbardeh et al., 2021), our approach is able to learn meaningful discrete codes and achieve translation performance competitive with models with continuous latent spaces. Our main contributions are:

- We propose a framework to learn discrete tokens as intermediate representations of multilingual NMT models (§3).
- On large-scale multilingual translation experiments, our approach is competitive with strong alternatives while offering more interpretable intermediate representations (§5.1).
- We use the learned discrete codes to study the role of bridging languages. Using two novel analyses, namely *code overlap* and *code translation*, we discover that using a similar bridge language facilitates knowledge-sharing in all languages covered by the model (§5.2).



Decoder sees discretized/continous context based on *p*
1-*p*

encoder
Nearest-neighbor lookup
Input tokens:
x_1 x_2 x_3 x_4 x_5

Figure 1: An illustration of our approach, which introduces a codebook for discretizing the encoder output latent space. During training, the decoder sees discretized and continuous context based on probability p. For inference, we use the continuous context, which have been well-clustered into a set of cluster centers after training.

2 Related Work

Multilingual Machine Translation Multilingual translation models are able to multitask over many language pairs. For this large-scale multi-task learning problem, training data plays a critical role. Low-resource directions often need upsampling to perform well (Arivazhagan et al., 2019b; Tang et al., 2021), which, meanwhile, brings capacity bottlenecks (Aharoni et al., 2019) to high-resource languages. This capacity bottleneck can be eliminated by dedicated language-specific capacity (Bapna and Firat, 2019; Philip et al., 2020; Shazeer et al., 2017; Zhang et al., 2021). When scaling up translation coverage (Aharoni et al., 2019; Zhang et al., 2020; Fan et al., 2021), zero-shot directions that have not seen any parallel training data is more likely to get encountered. While many dedicated models or objectives have been proposed to improve the zero-shot performance (Al-Shedivat and Parikh, 2019; Arivazhagan et al., 2019a; Pham et al., 2019; Zhu et al., 2020; Son and Lyu, 2020; Liu et al., 2021a; Yang et al., 2021b; Raganato et al., 2021), there is in general a *tradeoff* between supervised and zero-shot performance.

Robustness in Zero-Shot Conditions Zero-shot generalization is a widely-discussed direction in machine learning research (Socher et al., 2013; Norouzi et al., 2014; Romera-Paredes and Torr, 2015; Xian et al., 2017). In the context of NMT, early multilingual models already possess some capability of zero-shot translation of directions unseen in training (Ha et al., 2016; Johnson et al., 2017). However, zero-shot performance has been shown highly sensitive to, among other factors, training data diversity (Rios et al., 2020), language token strategies (Wu et al., 2021; ElNokrashy et al., 2022), and dropout configurations (Arivazhagan et al., 2019a; Liu et al., 2021b). A main cause of the degraded quality is that the zero-shot inference generates *off-target* translation (Zhang et al., 2020) into a language other than the desired one. In recent shared tasks (Anastasopoulos et al., 2021; Libovický and Fraser, 2021a), generating synthetic data by back-translation (Sennrich et al., 2016) to eliminate zero-shot conditions has been a dominant approach for improving upon pure unsupervised settings (Pham et al., 2021; Zhang and Sennrich, 2021; Liu and Niehues, 2021; Knowles and Larkin, 2021; Libovický and Fraser, 2021b). A main motivating factor for converting zero-shot conditions to semi-supervised ones is that the latter provides more robust and consistent inference-time behavior. In this light, to fully realize the potential of knowledge-sharing in multilingual NMT, improving zero-shot robustness is an essential task.

Discrete Representations Vector Quantized Variational Autoencoder (VQ-VAE; van den Oord et al. 2017) learns discrete tokens for continuous inputs such as images and audio, and showed its effectiveness in creating discrete representations for speech representations on practical tasks (Tjandra et al., 2020; Baevski et al., 2020). Kaiser et al. (2018) proposed an improvement to VQ-VAE by *slicing*, i.e. decomposing to quantization input and output into several subspaces. The sliced variant was used in auto-encoding for learning shorter sequences, which allows to accelerate the target generation in auto-regressive decoders. The most related work to ours is probably that of Escolano et al. (2021), who used sliced VQ-VAE (Kaiser et al., 2018) on translation tasks. The main difference is that our focus is fully parameter shared multilingual systems while Escolano et al. (2021) focused on auto-encoding and bilingual systems using language-specific encoders and decoders. Therefore, in Escolano et al. (2021) zero-shot translation only occurs after a subsequent training step on dedicated encoder for the new language. Moreover, our approach extends sliced VQ-VAE (Kaiser et al., 2018) by soft codes that utilizes both continuous and quantized encoder hidden states.

3 Learning Discrete Codes

As motivated in §1, we aim to learn to represent sources sentences with a sequence of discrete codes out of a codebook. To this end, alongisde the translation objective, we also train our model to partition the continuous latent space of the encoder output into discrete subspaces. Each of the discrete subspaces is represented by one of the k entries (cluster centers) from a trainable codebook, and the encoder hidden states are assigned to these entries. To learn a meaningful discretization, the learned cluster centers must fulfill some requirements: 1) avoid trivial solutions where all points are assigned to one or a few codebook entries, 2) carry sufficient context information for the decoder for the translation task, despite being less expressive than the encoder output prior to the discretization step.

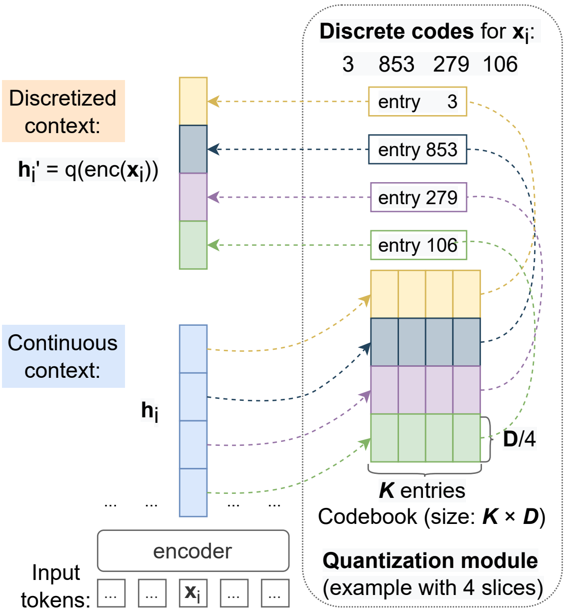

Figure 2: Illustration of the generation of the discrete codes based on a sliced (Kaiser et al., 2018) codebook.

3.1 Discretizing Encoder Latent Space

Compared to a standard Transformer (Vaswani et al., 2017), our model includes a quantization module between the encoder and decoder. We denote the quantization operation as $q(\cdot)$. Before being passed to the decoder, the encoder hidden states $\text{enc}(X)$ for input sequence X first goes through the quantization module, which runs a nearest neighbor lookup in an embedding table, i.e. the codebook. Following the notations from van den Oord et al. (2017), the codebook $e \in R^{K \times D}$ has K entries, each with dimensionality D. In our case, D is the same as the embedding dimension of the encoder, resulting in $q(\text{enc}(X))$ with the same shape as $\text{enc}(X)$.

For an input token X_i, its quantized representation is one of the K entries from the codebook $e_{k\in[1,K]}$, where k is determined by a nearest neighbor search in the embedding space, using the encoder output $\text{enc}(X_i)$ as query:

$$k = \arg\min_{j\in[k]} \|\text{enc}(X_i) - e_j\|_2, \quad (1)$$

where $\|\cdot\|_2$ indicates the Euclidean distance.

The quantization step above is vulnerable to index collapse (Kaiser et al., 2018), where only few entries from the embedding table are actively used. On auto-encoding tasks, Kaiser et al. (2018) proposed a countermeasure by breaking down the hidden dimension into multiple slices and quantizing each of them. Specifically, for input token X_i, its encoder hidden state $\text{enc}(X_i)$ is split into S slices:

$$\text{enc}(X_i)_1 \oplus \text{enc}(X_i)_2 \cdots \oplus \text{enc}(X_i)_S, \quad (2)$$

where each slice $\text{enc}(X_i)_{j\in[S]}$ is of D/S dimensions. A nearest neighbor search is conducted for each slice on the corresponding dimensions in the embedding table. The results are then concatenated and form the quantized representation:

$$q(\text{enc}(X_i)_1) \oplus q(\text{enc}(X_i)_2) \cdots \oplus q(\text{enc}(X_i)_S), \quad (3)$$

and passed to the decoder as context. Figure 2 illustrates this process.

The slicing mechanism resembles multi-head attention (Vaswani et al., 2017) in that both split the embedding dimension into subspaces for richer representation. Therefore, we will use the same number of slices as the number of attention heads.

3.2 Soft Discrete Codes

Training Compared to encoder outputs in a continuous space, the quantization module is an *information bottleneck*. In practice, limiting the amount of context information passed to the decoder will likely degrade translation quality. To strike a balance between discretization and performance, we make the discrete codes *soft*, in that the decoder can still access to the richer information prior to quantization by a probability. Specifically, during training, the encoder gives the quantized context $q(\text{enc}(X))$ by probability p, and the raw context $\text{enc}(X)$ by probability $1 - p$. This procedure is illustrated in Figure 1.

In Equation 1, the lookup of index k is a non-differentiable operation. When the encoder passes on the quantized context, in order to train the parameters below the quantization module, we use the straight-through estimator (Bengio et al., 2013) to copy gradients onto the pre-quantization encoder outputs. For the copied gradients to be useful for training, the difference between $\text{enc}(X_i)$ and $q(\text{enc}(X_i))$ should be limited. To achieve this, we use the codebook loss and commitment loss from VQ-VAE (van den Oord et al., 2017):

$$\mathcal{L}_{\text{codebook}} = \|\text{sg}[\text{enc}(X)] - q(\text{enc}(X))\|_2 \quad (4)$$

and

$$\mathcal{L}_{\text{commitment}} = \|\text{enc}(X) - \text{sg}[q(\text{enc}(X))]\|_2, \quad (5)$$

where $\text{sg}[\cdot]$ denotes the stop gradient operation. Intuitively, Equation 4 pushes the codebook entries closer to the points assigned to them, while Equation 5 limits the growth of the encoder hidden states by clipping them to the codebook entries. Each of the terms has weights α_{codebook} and $\alpha_{\text{commitment}}$ to control their importance relative to the main translation objective.

Inference After training with this mechanism, one can expect that the encoder hidden states are well-clustered around a set of codebook entries. At test time, we use the continuous context $\text{enc}(X)$ which still carries more information than the cluster centers represented by the codebook entries. We will verify this property in later experiments (§6).

4 Experimental Setup

To experiment on realistic data volumes, we use the parallel data[1] from the Large-Scale Multilingual Machine Translation Shared Task (Wenzek et al., 2021) from WMT 2021 (Akhbardeh et al., 2021). We focus on small-task-2 on Southeast Asian languages. To study model robustness in zero-shot conditions and the role of language relatedness, we select parallel data between the two high-resource languages: Indonesian (id) and English (en) and three other languages in the Austronesian family: Javanese (jv), Malay (ms), and Filipino/Tagalog (tl). This leads to two data conditions:

- Indonesian-bridge (**ID-BRIDGE**)
- English-bridge (**EN-BRIDGE**)

As pretrained initialization has been shown beneficial in many submissions last year (Yang et al.,

2021a; Liao et al., 2021; Xie et al., 2021), we initialize the models with the pretrained M2M-124 model provided in the shared task (Wenzek et al., 2021). It is worth noting that M2M-124 has seen parallel data for our *zero-shot* directions, hence zero-shot only describes the condition in our *finetuning* step. This setup is motivated by the observation that existing pretrained models are often trained on massive amounts of data, which are not always feasible to access or store. We therefore treat the pretrained M2M-124 as a given resource, without relying on all its training parallel data. We use this setup to especially study if the models can retain the pretrained knowledge on directions that are zero-shot in finetuning.

4.1 Data

The training parallel data (Wenzek et al., 2021) are compiled from the OPUS platform (Tiedemann, 2012). The specific datasets are listed in Appendix B. As parts of the training data are crawled and therefore rather noisy, we follow the filtering steps opened sourced by Fan et al. (2021), including length filtering, bitext de-duplication, and histogram filtering. An overview of the training data after filtering is in Table 2. Following the evaluation protocol of the shared task (Wenzek et al., 2021), we report spBLEU on the FLoRes-101 (Goyal et al., 2022) devtest set. We additionally report chrF++ (Popović, 2017) as another metric.

4.2 Baselines

Besides comparing to directly training on our baseline model, we also compare to two existing approaches that encourage language-independent representations, both of which have been shown effective in zero-shot translation:

Language-Independent Objective (Pham et al., 2019; Arivazhagan et al., 2019a) applies an additional loss function that enforces the representations for the source and target sentences to be similar. The loss function minimizes the difference between encoded source and target sentences after pooling. Details about the implementation are in Appendix C.1.

Adversarial Language Classifier (Arivazhagan et al., 2019a) aims to remove source language signals from the encoder hidden states, and thereby create more language-independent representations. A language classifier is trained on top of the encoder, and its classification performance is used adversarially on the encoder through a gradient reversal layer (Ganin et al., 2016). Details about the implementation are in Appendix C.2.

4.3 Training and Inference Details

As motivated in §4, we finetune from the small variant of M2M-124 with 175M parameters. This model has a vocabulary size of 256K, 6 layers in both the encoder and decoder, 16 attention heads, embedding dimension of 512 and inner dimension of 2048. As the training data for different languages are very unbalanced, we use temperature-based sampling (Arivazhagan et al., 2019b) with coefficient 5.0, which heavily upsamples low-resource directions and is recommended for unbalanced data conditions (Arivazhagan et al., 2019b; Tang et al., 2021). Additional details are in Appendix A.

For our codebook approach, we use 10K codebook entries. Initial trials with a size of 1K gave worse performance, while 40K heavily reduced training speed. We choose 16 slices[2] for the codebook, the same value as the number of attention heads. We keep these two values identical as both slicing and multi-head attention breaks the embedding dimension into multiple subspaces of lower dimensionality. The scale on the codebook loss and commitment loss (α_{codebook} and $\alpha_{\text{commitment}}$) are 1.0 and 1.001. We found the model sensitive to increasing $\alpha_{\text{commitment}}$, where higher values leads to index collapse[3]. After exponentially decreasing it to approach 1.0, we settled at 1.001. For the probability of seeing the continuous encoder context, with a search among {0.1, 0.5, 0.7 0.9}, we found 0.9 and 0.5 the best parameters for ID-BRIDGE and EN-BRIDGE respectively.

We implement our approach and the two baselines (§4.2) with FAIRSEQ (Ott et al., 2019)[4].

[2] Initial experiments on smaller datasets showed weaker translation performance with 2 and 4 slices.

[3] A potential reason is the encoder parameters are updated too aggressively by the commitment loss in these cases.

Table 3: Translation quality in spBLEU(↑) and chrF++(↑). "↪" indicates finetuning on the parallel data (Id-Bridge or En-Bridge; §4). Pivoting through the bridge language for $Y \leftrightarrow Z$ directions scores 19.7, 17.5 spBLEU and 44.9, 42.8 chrF++ for Id-Bridge and En-Bridge respectively using the systems in rows (1) and (4).

5 Main Results

We first discuss the translation performance of our multilingual systems (§5.1), and then use the learned discrete codes to investigate cross-lingual knowledge-sharing of the trained models (§5.2).

5.1 Translation Performance

Baseline Conditions To set the upcoming results in context, we first present the performance of training without additional improvements in rows (1)-(3) and (4)-(6) of Table 3. Rows (1) and (4) show the performance of training with random initialization. This corresponds to a condition where we have parallel data but no pretrained resources. On the other side of the spectrum, in row (2) and (5), we report the results of directly running inference on the pretrained `M2M-124` model. This corresponds to another extreme where we have access to pretrained models but cannot additionally train on parallel data. In rows (3) and (6), we combine the best of two worlds: initializing with pretrained model and finetuning on parallel data. For supervised directions, pretraining mainly improves →English directions: In the En-Bridge condition, initializing with `M2M-124` gains 1.1 spBLEU over random initialization, from 27.0 to 28.1 spBLEU. For other supervised directions, however, we do not observe gains from pretraining. This could be related to the pretrained model being particularly strong at decoding English. For zero-shot directions in our setup (these directions are seen in training by the pretrained model), as they are comparatively low-resource among all the directions covered in `M2M-124`, out-of-box translation quality on these directions is relatively low, with an average of 9.9 spBLEU. However, when finetuning, we see a striking difference between Id-Bridge and En-Bridge: there is a large gain from 9.9 to 17.7 spBLEU with the former, but a degradation from 9.9 to 5.1 spBLEU for the latter. We study this phenomenon next.

Impact of Bridge Languages For En-Bridge, the finetuning step causes catastrophic forgetting of the zero-shot directions (−4.8 spBLEU). On the other hand, for the Id-Bridge condition, pure finetuning leads to substantial improvements in *both* supervised and zero-shot directions. The gain from 9.9 to 17.7 spBLEU in the $Y \leftrightarrow Z$ directions is particularly noteworthy since the model has not seen parallel data for these directions in finetuning. This indicates that the growth in supervised directions brings zero-shot directions forward too. Moreover, on these directions, pretraining also gives large gain of 1.9 spBLEU over random initialization. Overall, the observations suggest that incorporating a similar language as bridge is beneficial to re-using pretrained knowledge. Furthermore, given that the amount of parallel data in the En-Bridge condition is nearly 4 times of that in the Id-Bridge condition, using a similar bridge language also appears to be more *data-efficient*. This likely related to all translation directions being similar, therefore easing the multilingual learning task.

`fairseq/tree/master/examples/quant`

Impact of Using Codebooks Compared to pure finetuning in rows (3) and (6), by incorporating the codebook we improve zero-shot translation by 0.6 and 10.1 spBLEU for ID-BRIDGE andEN-BRIDGE respectively. Compared to the two existing approaches, namely language-independent objective and adversarial language classifier in rows $(*.1)$ and $(*.2)$, our approach performs on par with them for ID-BRIDGE, achieving 18.3 spBLEU for $Y \leftrightarrow Z$ directions and 21.9 spBLEU over all directions. In the more challenging EN-BRIDGE condition, we fall behind the two other approaches by around 2.0 spBLEU on zero-shot directions. Using a language identifier[5] (Costa-jussà et al., 2022), we found that the culprit here is still off-target translation, where some test sentences were translated to an incorrect language. While our codebook approach reduces the proportion of off-target sentences from 87.4% to 13.1% compared to the pure finetuning baseline in row (6), the figure is still higher than the 4.7% achieved by the two alternative models in rows (6.1) and (6.2). Despite this gap, an advantage of our approach is easier analyses of learned representations, which we will now leverage to investigate why the two data conditions come with very distinct zero-shot behavior.

5.2 Using Discrete Codes to Interpret Learned Representations

Since our codebook approach allows easier interpretation of model hidden representations, we take advantage of this characteristic to answer the following question: *why is the* ID-BRIDGE *data condition more performant despite using less data?*

Formalization To this end, we first extract the discrete codes for all source languages on the test set[6]. Given a total of S slices, a sentence with t tokens $X_{1,\dots,t}$ is represented as S sets of discrete tokens $T^s_{1,\dots,t}$ for slice s, where $s \in [S]$. Between two sets of semantically identical sentences (e.g. multiway test sets in two different languages), we can compare the discrete codes by examining: 1) their overlap and 2) the difficulty of transforming one set to another. The results quantify the similarity between the two sets of codes, and hence the model representations for the two source languages.

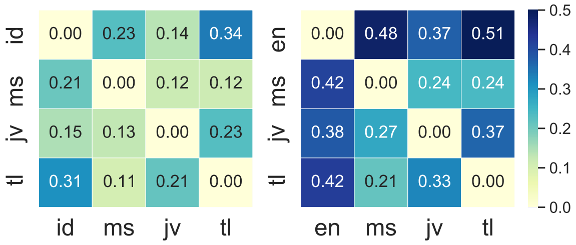

Figure 3: KL divergence(↓) of code distribution for the ID-BRIDGE (left) and EN-BRIDGE (right) setup. *Lower* values indicate a higher degree of sharing. ID-BRIDGE results in more sharing not only between itself and {ms, jv, tl} but also among {ms, jv, tl}.

Discrete Code Distribution For each slice, we normalize the code occurrences into a probability distribution. The distribution P is defined by:

$$p(c_i) = \frac{\text{frequency}(c_i)}{\sum_{c_j \in [C]} \text{frequency}(c_j)}, \qquad (6)$$

where c_i is a discrete code from the set $[C]$. For a pair of languages i and j, we then compute the KL divergence between their code distributions P_i and P_j:

$$D^{(i,j)}_{\text{KL}} = (P_i || P_j). \qquad (7)$$

Figure 3 depicts the KL divergence of code distribution averaged over all slices. A comparison of the En- and ID-BRIDGE setup exhibits several major differences. First, the clearly prominent first row and column in EN-BRIDGE shows that its bridge-language is represented very differently from all other languages ({ms, jv, tl}). For the ID-BRIDGE counterpart, the difference between the bridge language and the remaining languages is much milder. Second, but perhaps more importantly, among the languages used in zero-shot directions ({ms, jv, tl}), the amount of sharing is also higher under the ID-BRIDGE setup. This finding is crucial as the raw tokens for {ms, jv, tl} are identical between the ID-BRIDGE and EN-BRIDGE setup. Therefore, the higher degree of sharing is clearly an outcome of the model creating its representations differently. Overall, these results show that the choice of the bridge language not only impacts the knowledge-sharing mechanism between itself and the remaining languages, but also for the remaining languages in the model.

Discrete Code Translation The code distribution analysis above makes a simplified assumption by considering the discrete codes as a *bag of words*.

[5] https://github.com/facebookresearch/fairseq/tree/nllb#lid-model

[6] The FLoRes-101 test set is multiway. Therefore the semantic meanings of the sentences are the same.

To additionally assess the *structural (dis)similarity* between the code representations for different languages, we consider the task of *translating* the discrete codes of a language to another.

While a constructed language like Interlingua would create the same representations for the source sentences with identical meanings, our discrete code representation is not yet invariant to the source language. Nevertheless, we do expect them to be more abstracted from the source sentences, making the translation task easier than directly between the raw tokens. Here we train a translation model on the discrete codes and use the test performance to quantify how similarly the source languages are represented. When the representations are more different from each other, i.e. language-specific, the translation quality on the discrete is expected to be lower.

Specifically, we randomly sample 100K sentence pairs[7] for each translation direction in the experiments of Table 3 extract their discrete codes assigned by the trained models (rows (3.3) and (6.3) of Table 3), and train a new Transformer-base (Vaswani et al., 2017) to translate between the extracted codes of different languages. We flatten the slices, therefore making each source token represented by 16 discrete codes. After training for 200K steps, we report BLEU scores on the test set, which is also converted to discrete codes. The results are shown in Figure 4. First, the translation task is clearly easier on the discrete codes derived from the ID-BRIDGE system. Second, the scores differences are especially prominent when translating out of Malay (ms) and Javanese (jv), which are more related to Indonesian than Filipino/Tagalog (tl). Along with the results from the code overlap, our results show that using a similar bridge language results in higher knowledge-sharing not only syntactically but also structurally, especially between related languages.

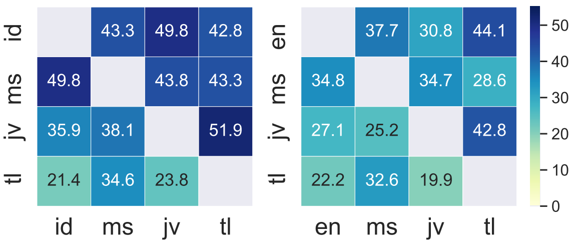

Figure 4: BLEU(↑) scores of translating between discrete codes for the ID-BRIDGE (left) and EN-BRIDGE (right) setup. *Higher* values indicate a higher degree of sharing. In general it is easier to translate the codes for the ID-BRIDGE setup, indicating more structural similarity between the representations.

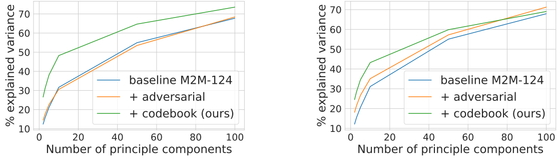

(a) ID-BRIDGE (b) EN-BRIDGE

Figure 5: Our codebook approach creates better-clustered encoder hidden states, as shown by a much higher percentage of variance explained by PCA compared to both the baseline and a strong alternative approach (adversarial language classifier).

6 Analyses on Learned Discrete Codes

Next we further investigate the discrete codes regarding its usefulness for the learned representations (§6.1) as well as the translation task (§6.2).

6.1 How well-clustered are the hidden states?

As motivated in §3, although at inference time we use the continuous encoder hidden states instead of the cluster centers, the soft discrete codes will still enforce encoder hidden states into clusters, thereby resembling a discrete structure. To verify whether the encoder latent space indeed becomes more discretized with our approach, we analyze the encoder hidden states on the test set using Principle Component Analysis (PCA). If the data points representing the encoder outputs are well-clustered, a larger percentage of their variance should be explained by the learned principle components. As shown in Figure 5, our approach (marked with green line) consistently leads to higher proportions of explained variances compared to the baseline `M2M-124`, as well as the strong alternative approach with the adversarial language classifier. These results therefore confirm the effectiveness of our soft discrete code approach in enforcing discrete structures in the encoder latent space.

6.2 Meaningfulness of Clusters Centers

Recall that at inference time our soft discrete code model uses the encoder hidden states prior to discretiztaion, although it does use both pre- and post-discretization encoder context in training. A main reason of doing so is that discretizing the encoder

[7] The training data (Table 2) allow us to use 340K sentences. We sampled 100K for faster experiment iteration.

hidden states to cluster centers creates an information bottleneck that limits model expressiveness. Despite the expected performance degradation, we are nonelessness interested in *quantifying* how much information is lost by using the cluster centers as context instead. In other words, the question is *how meaningful are the cluster centers for the translation task?* In Table 4, we report the results of using the cluster centers as context for the decoder at inference time. Compared to using the encoder hidden states, we see a degradation of 4.1 and 1.7 and spBLEU for ID-BRIDGE and EN-BRIDGE respectively. This indicates that the cluster centers are still relevant for the translation task, although much less powerful than the encoder hidden states prior to discretization. It also rules out the possibility of the learned codes being trivial repetitions, which would otherwise have been detrimental to the translation performance.

Encoder States at Inference	**Avg. spBLEU(↑)**			
	→X	**X→**	**Y↔Z**	**Avg.**
ID-BRIDGE (X=id)				
encoder states (Tab. 3 row (3.3))	27.2	23.6	18.3	21.9
cluster centers	22.8	20.0	14.3	17.8
EN-BRIDGE (X=en)				
encoder states (Tab. 3 row (6.3))	26.8	26.3	15.2	20.9
cluster centers	24.3	24.6	13.9	19.2

Table 4: At inference time, using cluster centers instead of the clustered encoder states degrades performance by 1.7-4.1 spBLEU. Despite the degradation, the scores show that translation from the clusters centers is still meaningful. This also rules out the possibility of the learned codes collapsing to trivial repetitions.

7 Analyses on Zero-Shot Translation

Our experiments so far use single-bridge languages and are evaluated in part on zero-shot directions. We now study the impact when either of the two conditions changes: 1) when parallel data is available for previously zero-shot directions; 2) when using multiple bridge languages.

7.1 When does zero-shot translation match the performance on parallel data?

Zero-shot conditions could be avoided by creating synthetic data from back-translation (Sennrich et al., 2016; Zhang et al., 2020) or mining additional parallel data (Fan et al., 2021; Freitag and Firat, 2020). Both approaches introduce additional workflows into the pipeline of building translation systems. We are therefore interested in the following question: *How much parallel data do we need to perform better than direct zero-shot translation?*

The training corpora from the shared task (§4.1) provides an oracle condition to answer this question. As shown in Table 2, the oracle parallel data amounts to 2.2M sentences in total (340K for jv-ms, 662K for jv-tl, and 1.2M sentences for ms-tl). We take 100%, 10% and 1% of the oracle parallel data and training systems together with the original data and train multilingual systems with the same configuration as rows (3) and (6) of Table 3. The results are shown in Table 5.

To our surprise, adding 1% oracle bitext (22K sentence pairs in total) of the previously zero-shot directions already results in comparable performance to the best zero-shot performance (18.4 and 17.3 spBLEU for ID-BRIDGE and EN-BRIDGE respectively). However, this comes with some degradation on supervised directions of 0.4 spBLEU for ID-BRIDGE and 0.7 for EN-BRIDGE. This is likely due to the temperature-based sampling aggressively upsampling the extremely low-resource directions, meanwhile causing the model to deprioritize other higher-resource directions. When increasing oracle bitext to 10% (220K sentence pairs in total), the system outperforms direct zero-shot performance. Lastly, the additional gain appear to diminish when going from 10% to all oracle data. For ID-BRIDGE, the performance appears saturated at 10%: adding the remaining 90% parallel data does not give additional gain. On the contrary, For EN-BRIDGE, the system appears to still improve, especially on $Y \leftrightarrow Z$ directions (+0.5 spBLEU). The performance on these directions nevertheless still falls behind the ID-BRIDGE direction by 0.8 spBLEU (18.9 vs 19.7 spBLEU). An explanation is that the EN-BRIDGE system requires more data to train as a result of the bridge language being very distant to the rest, thereby increasing the difficulty of multitasking over all the translation directions. This echos with the previous finding that using related bridge languages eases the multilingual translation task and increases knowledge-sharing (§5.1).

7.2 Do multiple bridge languages bring additional gains?

While the experiments so far are based on single bridge languages, in practice we often have access to multi-bridge parallel data. Indeed, recent

Oracle Bitext	**Avg. spBLEU(↑)**			
	→X	**X→**	**Y↔Z**	**Avg.**
Id-Bridge (X=id)				
best zero-shot (Tab. 3 row (3.2))	27.5	24.1	18.4	22.1
1%	26.9	23.9	18.4	21.9
10%	27.3	24.5	19.7	22.8
100% (2.2M bitext)	26.6	24.8	19.7	22.7
En-Bridge (X=en)				
best zero-shot (Tab. 3 row (6.1))	27.9	27.2	17.3	22.4
1%	27.0	26.8	17.1	22.0
10%	27.5	27.4	18.4	22.9
100% (2.2M bitext)	27.7	27.5	18.9	23.2

Table 5: Impact of adding oracle parallel data for the previously zero-shot directions. Adding 10% parallel data (roughly 220K sentence pairs in our case) surpasses the best performance on direct zero-shot translation.

Data Condition		**Avg. spBLEU(↑)**			
		→X	**X→**	**Y↔Z**	**Avg.**
Multi-Bridge	X= id	27.0	24.3	18.3	21.9
	X= en	27.8	27.7		23.0
Only Id-Bridge (Tab. 3 row (3))		27.1	24.2	17.7	21.7
Only En-Bridge (Tab. 3 row (6))		28.1	27.6	5.1	16.5

Table 6: Results of using multiple bridges (combining Id-Bridge and En-Bridge). Despite substantial gains over En-Bridge, the multi-bridge system only gives a mild improvement in zero-shot performance ($Y \leftrightarrow Z$) over the Id-Bridge system.

works (Freitag and Firat, 2020; Fan et al., 2021) have shown success on large-scale fully-connected models, as well as evidence of multi-bridge outperforming the English-bridge condition (Rios et al., 2020). What remains unclear is whether there is a synergy when combining the parallel data from several single-bridge conditions. We investigate this hypothesis by training a multi-bridge system, combing the data from our Id-Bridge and En-Bridge setup. As shown in Table 6, for supervised directions of $\rightarrow X$ and $X \rightarrow$, there is no clear difference between the performance of the multi-bridge system and that of the single-bridge ones. For zero-shot directions ($Y \leftrightarrow Z$), while multi-bridge gains substantially over En-Bridge (18.3 from 5.1 spBLEU), there is only a slight gain over Id-Bridge. Given that the multi-bridge model more than doubles the training time of Id-Bridge, the little performance difference to the multi-bridge system shows that choosing a bridge language related to the remaining languages is a data-efficient way to achieve strong zero-shot performance.

8 Conclusion

In this work, we focus on learning to represent source sentences of multilingual NMT models by discrete codes. On multiple large-scale experiments, we show that our approach not only increase the model robustness in zero-shot conditions, but also offers more interpretable intermediate representations. We leverage the latter property to investigate the role of bridge languages, and show that using a more related bridge language leads to increased knowledge-sharing, not only between the bridge language and remaining but also between all other languages involved in training.

A limitation is that the discrete codes only give a mechanism to compare hidden representations, but are not directly interpretable by humans. A potential improvement would be to use an existing codebook that corresponds to an actual human language. Besides this, as next steps, we plan to improve the generation process of the discrete codes. The first direction is to make the code lookup conditionally-dependent along the time dimension and learn to shrink the sequence length of the discrete codes, thereby creating a more compact representation. Another direction is to explicitly incentivize more shared codes between different, and especially related, languages during training. This would bring the discrete codes closer to a language-independent representation.

Acknowledgement We thank James Cross and Paco Guzmán for their feedback in the early stage of this work. We thank the anonymous reviewers for their detailed and insightful feedback. We also thank Ngoc Quan Pham, Tu Anh Dinh, and Sai Koneru for feedback on the paper draft.

A Additional Training and Inference Details

When training, one optimization step happens after 16384 tokens. We use the Adam optimizer with betas $(0.9, 0.98)$. The learning rate is 0.0001 with the inverse squared root schedule and 2500 warmup steps. As for regularization parameters, we use label smoothing of 0.1, dropout of 0.3, and attention dropout 0.1. The models are trained for 500K updates in total. An exception is the MULTIBRIDGE experiment with more training data, where we trained for 800K updates in total. For inference, we decode with a beam size of 5.

B Dataset Details

The training parallel data include the following corpora: bible-uedin (Christodoulopoulos and Steedman, 2015), (Multi)CCAligned (El-Kishky et al., 2020), Gnome[8], ELRC[9], KDE4[10], GlobalVoices[11], OpenSubtitles[12], QED (Abdelali et al., 2014), MultiParaCrawl[13], TED2020[14], Tanzil[15], Tatoeba[16], Ubuntu[17], WikiMatrix (Schwenk et al., 2021), wikimedia[18], and TICO-19 (Anastasopoulos et al., 2020).

C Implementation of Baselines

C.1 Language-Independent Objective

We chose meanpool and L2 distance for the similarity loss since it gave better or more consistent performance in initial experiments. As for the weight of the language-independent objective, we used 1.0 following Pham et al. (2019).

C.2 Adversarial Classifier

We extend the adversarial language classification approach from Arivazhagan et al. (2019a) for robust training. Specifically, we use a modified loss when adversarially training the encoder. Moreover, we apply the language classification on the token level to remove the need for selecting a pooling method. The classifier minimizes the cross-entropy loss when predicting the language labels:

$$\mathcal{L}_{\text{classifier}} = -\sum_{c=1}^{L} y_c \text{log}(p_c), \tag{8}$$

where L is the number of classes to predict, y_c is a binary indicator whether the true language label is c, and p_c is the predicted probability for the instance belonging to language c.

Removing source language signals from the encoder representations can be achieved by a gradient reversal layer (Ganin et al., 2016) from the language classification. An issue with the standard classification loss in Equation 8 is that, when the classifier is performing well, the loss landscape is rather flat, causing minimal gradient flow to the encoder. In fact, when the classifier predicts the source languages accurately, we instead need large gradients to update the encoder representations as they contain high amounts of language signals. Therefore, when updating the encoder parameters adversarially, we use the modified loss:

$$\mathcal{L}_{\text{adv\_classifier}} = \sum_{c=1}^{L} y_c \text{log}(1 - p_c), \tag{9}$$

which in effect mirrors Equation 8 by the horizontal axis and the vertical line defined by $x = 0.5$. With the modified loss, the optimization direction does not change, but the gradient is larger when the classifier is performing well.

The translation model is then trained with:

$$\mathcal{L}_{\text{encoder\_decoder}} = \mathcal{L}_{\text{MT}} + \mathcal{L}_{\text{adv\_classifier}}. \tag{10}$$

For training stability, we alternate the optimization of the classifier (Equation 8) and the main encoder-decoder parameters (Equation 10). Optimizing them jointly would otherwise lead to co-adaptation of the parameters of the translation and classification module and empirically causes training instability.

Don't Discard Fixed-Window Audio Segmentation in Speech-to-Text Translation

Chantal Amrhein[1] and **Barry Haddow**[2]
[1]Department of Computational Linguistics, University of Zurich
[2]School of Informatics, University of Edinburgh
amrhein@cl.uzh.ch, bhaddow@ed.ac.uk

Abstract

For real-life applications, it is crucial that end-to-end spoken language translation models perform well on continuous audio, without relying on human-supplied segmentation. For *online* spoken language translation, where models need to start translating before the full utterance is spoken, most previous work has ignored the segmentation problem. In this paper, we compare various methods for improving models' robustness towards segmentation errors and different segmentation strategies in both offline and online settings and report results on translation quality, flicker and delay. Our findings on five different language pairs show that a simple fixed-window audio segmentation can perform surprisingly well given the right conditions.[1]

1 Introduction

End-to-end spoken language translation (SLT) has seen considerable advances in recent years. To apply these findings to real online and offline SLT settings, we need to be able to process continuous audio input. However, most previous work on end-to-end SLT makes use of human-annotated, sentence-like gold segments both at training and test time which are not available in real-life settings. Unfortunately, SLT models that were trained on such gold segments often suffer a noticeable quality loss when applied to artificially split audio segments (Zhang et al., 2021; Tsiamas et al., 2022b). This also highlights that a good segmentation is more important for SLT than for automatic speech recognition (ASR) because we need to split the audio into "translatable units". For a cascade system, a segmenter/punctuator can be inserted between the ASR and machine translation (MT) model (Cho et al., 2017) in order to create suitable segments for the MT model. However for end-to-end SLT systems, it is still not clear how to best translate continuous input.

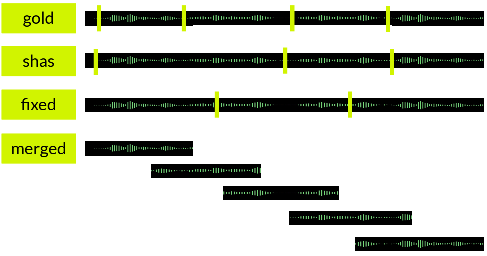

Figure 1: Visualisation of the different audio segmentation methods studied in this paper.

Solving this problem is very much an active research field that has mainly been tackled from two sides: (1) improving SLT models to be more robust towards segmentation errors (Gaido et al., 2020; Li et al., 2021; Zhang et al., 2021) and (2) developing strategies to split streaming audio into segments that resemble the training data more closely (Gaido et al., 2021; Tsiamas et al., 2022b). Both types of approaches were successfully used in recent years for the IWSLT offline SLT shared task (Ansari et al., 2020; Anastasopoulos et al., 2021, 2022) to translate audio without gold segmentations. However, they have not yet been tested systematically in the online SLT setup where translation starts before the full utterance is spoken. Recent editions of the IWSLT simultaneous speech translation shared task focused more on evaluation using the gold segmentation rather than unsegmented audio (Anastasopoulos et al., 2021, 2022). Segmenting streaming audio is especially interesting in online SLT because aside from effects on translation quality, different segmentations can also influence the delay (or latency) of the generated translation.

In this paper, we aim to fill this gap and focus on the end-to-end online SLT setup. We suspect that there is an interplay between more robust models and better segmentation strategies

[1] We publicly release our code and model outputs here: https://github.com/ZurichNLP/window_audio_segmentation

and that an isolated comparison may not be informative enough. Consequently, we explore different combinations of these two approaches for two different SLT models and present results in five language pairs. Figure 1 shows the four segmentation methods we study in this work (see also Section 3.3). Our experiments follow the popular retranslation approach (Niehues et al., 2016, 2018; Arivazhagan et al., 2020a,b) where a partial segment is retranslated every time new audio becomes available. Retranslation has the advantage of being a simple approach to online SLT, which can use a standard MT inference engine. As a side-effect, the previous translation can change in later retranslations and the resulting "flicker" (i.e. sudden translation changes in the output of previous time steps) is also considered in our evaluation of different strategies.

Our main contributions are:

- We explore various combinations of segmentation strategies and robustness-finetuning approaches for translating unsegmented audio in an online SLT setup.
- We find that the advantage of dedicated audio segmentation models over a fixed-window approach becomes much smaller if the translation model is context-aware, and merging translations of overlapping windows can perform comparatively to the gold segmentation.
- We discuss issues with the evaluation of delay in an existing evaluation toolkit for retranslation when different segmentations are used and show how these can be mitigated.

2 Related Work

In recent years, the IWSLT shared task organisers have stopped providing gold segmented test sets for the offline speech translation task which has lead to increased research focus on audio segmentation (Ansari et al., 2020; Anastasopoulos et al., 2021, 2022). One obvious strategy to segment audio is to create fixed windows of the same duration, but previous research has mostly relied on more elaborate methods. Typically, methods with voice activity detection (VAD) (Sohn et al., 1999) were employed to identify natural breaks in the speech signal. However, VAD models do not guarantee breaks that align with complete utterances and can produce segments that are too long or too short which is why hybrid approaches that also consider the length of the predicted utterance can be helpful (Potapczyk and Przybysz, 2020; Gaido et al., 2021; Shanbhogue et al., 2022). Most recently, Tsiamas et al. (2022b) finetune a wav2vec 2.0 model (Baevski et al., 2020) to predict gold segmentation-like utterance boundaries, an approach which outperforms several alternative segmentation methods and was widely adopted in the 2022 IWSLT offline SLT shared task (Tsiamas et al., 2022a; Pham et al., 2022; Gaido et al., 2022).

Apart from improving automatic audio segmentation methods, previous research has also focused on making SLT models more robust toward segmentation errors. Gaido et al. (2020) and Zhang et al. (2021) both explore context-aware end-to-end SLT models and show that context can help to better translate VAD-segmented utterances. Similarly, training on artificially truncated data can be beneficial to segmentation robustness in cascaded setups (Li et al., 2021) but also in end-to-end models (Gaido et al., 2020). While this approach can introduce misalignments between source audio and target text, such misalignments in the training data are not necessarily harmful to SLT models as Ouyang et al. (2022) recently showed in an evaluation of the MuST-C dataset (Di Gangi et al., 2019).

Both of these approaches – improving automatic segmentation and making models more robust toward segmentation errors – can be combined. For example, Papi et al. (2021) show that continued finetuning on artificial segmentation can help narrow the gap between hybrid segmentation approaches and manual segmentation. However, a combination of both methods is not always equally beneficial. Gaido et al. (2022) repeat Papi et al. (2021)'s analysis with the segmentation model proposed by Tsiamas et al. (2022b) and show that for this segmentation strategy, continued finetuning on resegmented data does not lead to an improvement in translation quality.

In our work, we aim to extend these efforts and test various combinations of segmentation and model finetuning strategies. We are especially interested in fixed-window segmentations which have largely been ignored in SLT research but are attractive from a practical point of view because they do not require an additional model to perform segmentation. To the best of our knowledge, we are the first to perform such an extensive segmentation-

focused analysis for online SLT, considering delay, flicker and translation quality for the evaluation.

3 Experiment Setup

3.1 Data

We run experiments with TED talk data in five different language pairs where the task is to translate a TED talk as an incoming stream without having any gold sentence segmentation.

For English-to-German, we use the data from the MuST-C corpus (Di Gangi et al., 2019) version 1.0[2]. This dataset is built from TED talk audio with human-annotated transcriptions and translations. For testing, we use the "tst-COMMON" test set. For Spanish-, French-, Italian- and Portuguese-to-English, we use the data from the mTEDx corpus (Salesky et al., 2021)[3]. This dataset is also based on TED talks and provides human annotated transcriptions and translations of the audio files. For testing, we use the "iwslt2021" test set from the IWSLT 2021 multilingual speech translation shared task (Anastasopoulos et al., 2021). The dataset statistics can be seen in Table 1.

3.2 Spoken Language Translation Models

We base all our experiments on the joint speech- and text-to-text model (Tang et al., 2021a,b,c) released by Meta AI. For the English-German experiments, we use the model provided by Tang et al. (2021b)[4] and for the other language pairs, we use the multilingual model provided by Tang et al. (2021a)[5]. We refer to these models as the **original** models. These models are trained on full segments that mostly comprise one sentence:

> **And like with all powerful technology, this brings huge benefits, but also some risks.**

To investigate the effects of different segmentation strategies combined with segmentation-robust models, we finetune three different variants based on each model. In each case, the finetuning data is augmented with artificially segmented data, but no segments cross the boundaries between the individual TED talks.

- **prefix:** This model is finetuned on a 50-50 mix of original segments and synthetically created prefixes (i.e. sentences where the end is arbitrarily chopped off). Finetuning on prefixes should help for translating artificially segmented audio where the segment stops in the middle of an utterance. We create prefixes of the original segments by randomly sampling a new duration for an audio segment and using the length ratio to extract the corresponding target text. An example for a prefixed version of the original segment can be seen here:

  > **And like with all**

- **context:** This model is finetuned on a mix of original segments and synthetically created longer segments. Context was already shown to help with segmentation errors by Zhang et al. (2021). This model should be able to translate segments that consist of multiple utterances. For each segment in the original training set, we randomly either use the original segment (50% of the time) or an extended segment created by prepending the previous segment (25% of the time) or the 2 previous segments (also 25% of the time). We then add context-prefixed segments for each of these (possibly-extended) segments, by truncating the last concatenated segment. An example for a context-prefixed version of the original segment can be seen here:

  > We work every day to generate those kinds of technologies, safe and useful. **And like with all powerful technology, this brings huge benefits,**

- **windows:** This model is finetuned on a 50-50 mix of original segments and windows of random duration. We split the audio into windows by starting at the beginning of the audio

[5] https://github.com/facebookresearch/fairseq/blob/main/examples/speech_text_joint_to_text/docs/iwslt2021.md

and then sampling the duration of the first window. The end of this window then becomes the start of the next window and we repeat this process until we reach the end of a TED talk. For every such window, we extract the corresponding target text from the time-aligned gold segment(s) via length ratios. This mirrors the conditions at inference time with a fixed-window segmentation where a segment can start and end anywhere in an utterance and can also comprise multiple utterances. The segment durations are sampled uniformly between 10 and 30 seconds. Note that this model will see the qualitatively poorest data out of all finetuned models because both the end of the segment and the beginning depend on length ratios which can introduce alignment errors. An example for a window version of the original segment can be seen here:

> or death diagnosis without the help of artificial intelligence. We work every day to generate those kinds of technologies, safe and useful. **And like with all powerful technology, this brings huge benefits, but also some risks.** I don't know how this debate ends, but what I'm sure of, is that the game

All models are trained from the original checkpoint for an additional 20k steps and the last two checkpoints are averaged if more than one is saved. We do this finetuning by continuing training with the config file of the original model. For the English→German MuST-C model, we train on the audio as well as the corresponding phoneme sequences based on the transcript, however, we do not use additional parallel text data during finetuning. For the multilingual mTEDx model, we only train on data for the selected language pairs and only on audio (no phoneme sequences) because this model was already finetuned on the spoken language translation task. The validation sets only contain gold segments and all models stop training due to the step limit before early stopping is triggered.

3.3 Segmentation Strategies

We consider four different inference-time segmentation strategies in our experiments, visualised in Figure 1:

- **gold:** These are human annotated segmentation boundaries that are released as part of the MuST-C and mTEDx data. This segmentation can be viewed as an oracle segmentation even though it may not necessarily be the best segmentation for all models. Using the gold segmentation in practice is unrealistic, especially in the online setting where there would be no time for a human to segment the audio before translation.

- **SHAS:** This segmentation method was recently proposed by Tsiamas et al. (2022b). The authors finetune a pretrained wav2vec 2.0 model (Baevski et al., 2020) on the gold segmentations and train it to predict probabilities for segmentation boundaries. SHAS can be used both in offline and online setups using different algorithms to determine the segmentation boundaries based on the model's probabilities. Since we perform our experiments in an online setup, we use the pSTREAM algorithm to identify segments with SHAS. We set the maximum segment length to 18 seconds which the authors reported as best-performing.

- **fixed:** This is a simple approach that splits the audio stream into independent fixed windows of a given duration. In our experiments, we use durations of 26 seconds, which performed best in experiments by Tsiamas et al. (2022b).

- **merged:** Similarly to above, we consider fixed-size windows for this segmentation strategy but here we construct overlapping windows. We use a duration of 15 seconds[6] and shift the window with a stride of 2 seconds at a time. The translations of these overlapping windows are merged before the next window is translated (see Section 3.5).

3.4 Retranslation

We employ a retranslation strategy (Niehues et al., 2016, 2018; Arivazhagan et al., 2020a,b) for our end-to-end SLT experiments. This means that we retranslate the incoming audio at fixed time intervals. In our experiments, we retranslate every 2 seconds to be consistent with the 2-second stride from the merging windows approach. Because of such retranslations of the full audio segment — from the start of the segment up to the current time step — the SLT model may correct translation mistakes from earlier time steps. This means that the

[6] We found empirically that this works better than a duration of 26 seconds as for fixed-windows, with both increased translation quality and reduced flicker (see Appendix B).

final translation of a complete segment reaches the quality of offline translation. However, if these updated partial translations are presented to users and there are changes to previously translated text, this may be hard to follow. Therefore, it is important to not only evaluate the quality of the translations and the delay but also how often previously translated words are changed which is termed "flicker". Typically, when delay improves there will be more flicker because translating sooner means a higher chance of errors that need to be corrected in the next retranslation.

3.5 Window Merging Algorithm

One reason why a fixed-window segmentation might underperform compared to other segmentations is that utterances are likely to be split up into two or multiple segments which can introduce ambiguities and result in disfluent translations. However, this problem can be reduced if the windows are overlapping which is technically very easy to do. With a retranslation approach, we can simply shift the whole window by X seconds to obtain overlapping translations.

To merge the resulting translations, we employ a merging algorithm that was previously proposed for a cascaded SLT setup (Sen et al., 2022). Their merging window algorithm also works for end-to-end SLT because it is not dependent on a transcript of the source audio. The algorithm identifies the longest common substring (LCS) between the growing translation of the output stream and the translation of the current window. The current output is formed by everything to the left of the LCS coming from the output at the previous time step, followed by the LCS and then everything to the right of the LCS from the current translation output. In this way, the translation of the input stream is continuously extended.

The merging is controlled by a threshold that defines the minimum required length of the LCS. At every time step, this threshold is computed by:

$$threshold = |T_t| * \tau$$

Where T_t is the current window translation length and τ is a ratio hyperparameter. If the LCS is shorter than this minimum length, instead of merging the current translation with the output stream, the window is backtracked to the left and a longer window is translated. We backtrack 0.1 seconds at a time for a maximum of three backtracks. Only when a sufficiently long LCS is found or the maximum number of backtracks is reached, do we perform the merging operation. In our experiments, we set the ratio τ to 0.4 which performed best in the cascaded setup (Sen et al., 2022). If there are multiple LCS (common substrings with the same length), we merge at the last-occurring one.

3.6 Evaluation

For evaluation, we use SLTev[7] (Ansari et al., 2021), a toolkit that can evaluate translation quality, delay and flicker in a retranslation SLT setup. We explain below how the evaluation is adapted for unsegmented input. Since we assume our input is segmented at the talk level, we evaluate at the talk level too.

For **translation quality**, SLTev internally resegments the translations and aligns the new segments to the reference segments such that the word error rate is minimised (Matusov et al., 2005). It is not guaranteed that the new segments follow the sentence boundaries and are perfectly aligned but, as long as the introduced alignment errors are similar for different segmentations, they can be compared.

For **flicker**, we cannot use the sentence-level measure in SLTev because this is computed as an average over all segment-level flicker scores, and with different segmentations, this measure is not comparable. However, the document-level measure is evaluated independent of the segmentation and this works well for our purpose.

For **delay**, we do not use the official implementation in SLTev because of the way it assigns timestamps to repeated tokens. To explain the problem, consider the following example:

P	13.18	O
P	14.18	O horror,
P	15.18	O horror, terror, horror
C	16.18	O horror, horror, horror.

where we retranslate the newly available audio every second and consequently get three partial translations (P) and one final, complete translation (C). In SLTev, every token is assigned the time stamp of its type's first occurrence. This results in the following time stamp assignments with the original implementation.

<table>
<tr><td>O</td><td>horror</td><td>,</td><td>horror</td><td>,</td><td>horror</td><td>.</td></tr>
<tr><td>|</td><td>|</td><td>|</td><td>|</td><td>|</td><td>|</td><td>|</td></tr>
<tr><td>13.18</td><td>14.18</td><td>14.18</td><td>14.18</td><td>14.18</td><td>14.18</td><td>16.18</td></tr>
</table>

[7] https://github.com/ELITR/SLTev

All occurrences of “horror” and “,” are assigned the timestamp 14.18 even though most of them are not yet generated by that time. If we translate longer segments that may be comprised of multiple sentences, encountering tokens that were already seen before becomes more and more likely. All of those would be assigned the timestamp of the first occurrence which favours longer segments (which we take to the extreme with our merged windows output stream). To solve this issue, we adapt the delay computation and store the individual timestamps for all repeated tokens. For this, we also need to be aware that previous content can change with each retranslation (e.g. terror → horror). We solve this following Arivazhagan et al. (2020b)’s notation of content delay and only assign timestamps once the previous context has finalised:

O	horror	,	horror	,	horror	.
|	|	|	|	|	|	|
13.18	14.18	14.18	16.18	16.18	16.18	16.18

With these new timestamps, all possible segmentations will receive the same delay if the translated text is identical and longer segments are no longer favoured in the SLTev delay calculation. However, since we wait until the context has finalised before we assign the time stamps, the new delay measure is now also affected by flicker.

4 Results

4.1 Translation Quality

We compare the different SLT models on different segmentations of the test sets and show the resulting translation quality of the complete segments in terms of BLEU in Table 2. Note that we would reach the same translation quality in an offline setting because the final retranslation is a translation of the full window, and in common with previous work, translation quality of online SLT is only measured on the final retranslation. We also evaluate with COMET (Rei et al., 2020) and report even better results with the merging windows approach but also find that COMET might be less reliable in a streaming SLT setup due to resegmentation errors (see Section D.1).

Does SHAS perform best with the original model (first column) as in previous work? When the SLT model is just trained on gold data, SHAS proves to be the best-performing segmentation out of all automatic segmentations which is in line with results by Tsiamas et al. (2022b) and Gaido et al. (2022). As in previous studies, we also find that the original model shows a considerable drop in BLEU when moving from the gold segmentation to automatically split segments.

		original	prefix	context	window
	gold	25.4	25.5	25.2	25.5
en-de	SHAS	24.5	23.9	24.9	24.8
	fixed	22.4	21.1	23.6	23.1
	merged	24.8	23.8	**25.3**	22.8
	gold	41.6	41.3	41.1	41.4
es-en	SHAS	40.2	40.3	40.7	41.0
	fixed	35.0	36.9	39.6	38.4
	merged	38.9	39.9	**42.0**	39.7
	gold	37.2	36.2	35.6	35.6
fr-en	SHAS	**36.2**	36.1	35.8	36.1
	fixed	31.0	32.0	34.5	32.9
	merged	34.6	35.2	35.8	31.9
	gold	27.0	28.7	28.8	29.0
it-en	SHAS	26.4	28.0	28.7	29.0
	fixed	22.5	25.6	27.5	26.3
	merged	25.3	27.4	**29.2**	27.6
	gold	30.6	29.5	28.7	29.1
pt-en	SHAS	**29.5**	28.9	29.2	28.6
	fixed	23.6	24.0	26.9	26.2
	merged	26.6	27.4	28.1	24.3

Table 2: BLEU scores with different SLT models (columns) and different audio segmentation methods (rows). Best result for *automatic* segmentation scenario marked in bold and green.

Is SHAS still the best-performing segmentation with the finetuned models? Finetuning with alternative segmentations can offer strong improvements for SHAS (+2.3) on it-en, with small improvements on es-en and en-de, but lower BLEU on pt-en and fr-en. Similarly, Gaido et al. (2022) found that SHAS did not benefit from finetuning on resegmented data. However, for the two segmentation approaches based on fixed windows, finetuning greatly reduces the gap to the gold segmentation.

This is especially noticeable when we finetune on context and prefixes (third column). This confirms the finding by Zhang et al. (2021) that context-aware models can better translate artificially segmented audio. When merging overlapping windows, we consistently see an improvement over the segmentation with non-overlapping fixed windows. In three language pairs, this method outperforms SHAS and in two the context-finetuned model even improves over the gold segmentation.

Do training conditions need to match the segmentation at inference time? Apart from the context-aware finetuned model, we also finetuned a model on fixed windows of random duration (last column). This matches the fixed-window audio input at inference time better because a segment can start anywhere in an utterance, unlike the context-based model where every training segment started at the beginning of an utterance. Surprisingly, we find that the model finetuned on windows of random duration generally performs worse with the merging window strategy than the context-based model. This suggests that the training data for this model contains more misalignments between speech and translation because we extract both the start and the end of the segment via length ratios. This causes more flicker (see next Section) which makes it harder to merge the translations at each time step correctly. We leave extended experiments where the alignments between speech and translation are computed via ASR or the SLT output of the windows of random durations (as opposed to a simple length ratio) to future work.

4.2 Flicker

As mentioned in the Introduction, translation quality is not the only important evaluation metric in an online SLT scenario. When using a retranslation approach, we also need to consider the flicker that is caused by the model updating its translations at every time step. We compute the flicker as described in Section 3.6. The flicker scores for the Spanish-to-English test set can be seen in Figure 2, the same figures for the other language pairs are in Appendix D. For the results shown here, we use an output mask of 0. We show in Appendix C that our findings also hold with larger output masks. We show scores with and without biased beam search.

Biased beam search (Arivazhagan et al., 2020a) is a modification to regular beam search that biases the probability distribution at the current time step towards a token in a given prefix translation at the same timestep. This can be used to stabilise retranslation – the translation of the current prefix is biased towards the translation of the previous prefix, suppressing flicker. In our experiments, we use the translation of the previous step as the prefix with a beta parameter of 0.25 and mask the 5 last tokens such that changes towards the end of the sentence are still possible[8]. Biased beam search cannot be applied directly to the merged window approach, since it depends on an alignment between the translation of the current prefix and that of the previous prefix. When translating using sliding windows, the current and previous prefixes have different start points, so their translations cannot be easily aligned. We experimented with a way to reduce flicker by merging on the last common substring rather than the longest but this causes considerable translation quality loss (see Appendix B).

Does the segmentation strategy matter for flicker? From Figure 2, we can see that there are big differences between the different segmentation strategies. Fixed windows have the highest flicker because there we translate the longest windows. If something at the beginning of the window translation is changed, this will increase the flicker score considerably. With biased beam search, the flicker can be dramatically reduced. Merging overlapping windows has a lower flicker than fixed windows without biased beam search, both because the duration of the windows is shorter and because the merging algorithm prohibits changes to the left of the longest common substring[9]. This segmentation method even has lower flicker than SHAS when no biased beam search is applied. With biased beam search, SHAS performs mostly similar to the gold segmentation which has the lowest flicker overall.

Does model finetuning help reduce flicker? Prefix finetuning helps reduce flicker both with and without biased beam search because the models see incomplete sentences at training time and are less likely to hallucinate to finish the sentence. Context finetuning helps even more and we saw in the outputs that this model has less of a tendency to connect multiple sentences into a longer sentence which can reduce flicker. The model finetuned on windows shows an even higher flicker than the original model for most segmentation strategies even though it was designed to be able to translate seg-

[8] We do not show translation quality scores with biased beam search because on average there is only a difference of -0.006 BLEU.

[9] Reducing the window length to 15 seconds for the fixed window segmentation reaches a flicker that is only slightly higher than for merged windows but the translation quality suffers considerably.

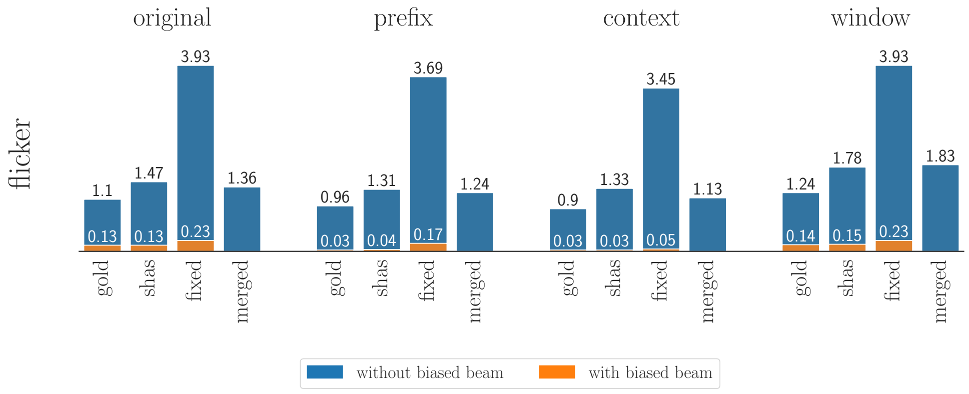

Figure 2: Flicker values for the different segmentation strategies and SLT models on the Spanish-to-English test set. The results are grouped by training strategy and each bar corresponds to a different segmentation strategy. We do not apply biased beam search to the merged segmentation.

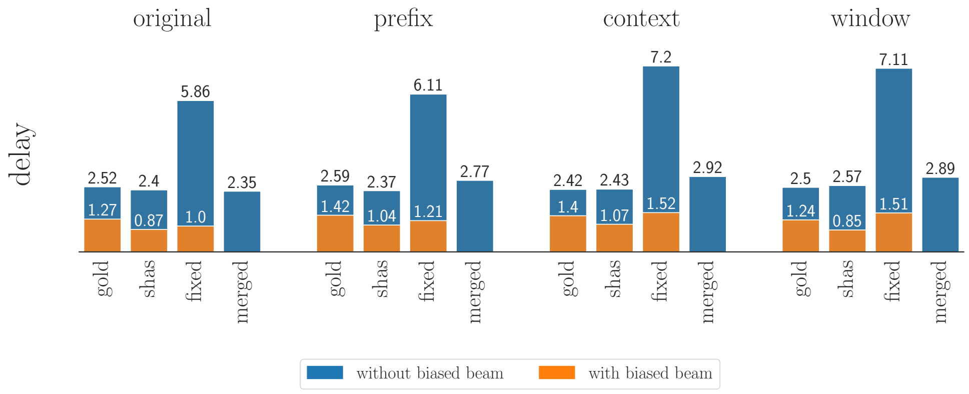

Figure 3: Delay values for the different segmentation strategies and SLT models on the Spanish-to-English test set. The results are grouped by training strategy and each bar corresponds to a different segmentation strategy.

ments that can start and end anywhere in a sentence. As discussed in the previous section, we think this increased flicker is an artefact of the automatically generated training data which can be erroneous.

4.3 Delay

The final evaluation metric we consider is delay. The results can be seen in Figure 3. Again, we show results with and without biased beam search for the gold, SHAS and fixed-window segmentation.

Does the segmentation strategy matter for delay? Because our definition of delay is affected by flicker as well (see Section 3.6), the fixed segmentation without biased beam search not only has the highest flicker but also the highest delay. In our results, we can see that the high delay is caused by the flicker because when we reduce flicker with biased beam search the fixed segmentation has comparable delay to the gold and SHAS segmentations. The merging windows approach has comparable delay to the gold and SHAS segmentations without biased beam search. Since we cannot apply biased beam search reliably to the merging windows approach without hurting translation quality, the flicker cannot be reduced and therefore, the merging windows approach has higher delay than the other segmentation methods with biased beam search. If delay could be defined independently of flicker in a way that still works for comparing different segmentations, the merging windows approach would likely have similar delay also compared to the outputs with biased beam search.

Does model finetuning help reduce delay? The results are a bit mixed. For example, the context model reduces delay for the gold segmentation but increases it slightly for SHAS and more for the fixed segmentation and the merging windows approach. In general, the choice of the model does not seem to be as important for delay as for translation quality and to a lesser extent flicker. It is possible that apparent effects only occur because our definition of delay is affected by flicker.

5 Discussion

Based on our results in Section 4, we believe that fixed-window segmentation should not be disregarded in future SLT research on unsegmented audio. Given the right setup with a context-aware model and a merging window algorithm, this segmentation can outperform current state-of-the-art automatic segmentation models and in some cases even the gold segmentation in terms of translation quality. Moreover, in an online SLT setup, a fixed-window approach brings the additional benefit that no dedicated segmentation model needs to be loaded at inference time and run every time new audio becomes available.

While there is currently no solution to bring flicker down to biased beam search levels without hurting quality (see Appendix B) or increasing delay (see Appendix C), this should not be a reason to disregard fixed-window segmentation as it opens exciting opportunities for future research.

6 Conclusion

In this paper, we explored several combinations of segmentation-robust finetuning and different automatic segmentation strategies in an online SLT setup. We focus on a retranslation-based approach to SLT and we run experiments on five different language pairs based on two different SLT models. Considering the evaluation of translation quality, flicker and delay, we discuss several issues that arise when comparing different segmentations and propose a fix to an existing toolkit for evaluating delay. Our results show that a simple fixed-window segmentation can perform surprisingly well if an algorithm is used for merging overlapping windows and a context-aware SLT model is used. In terms of translation quality, this segmentation performs comparably to SHAS — the current state-of-the-art segmentation method — and in some cases even outperforms the gold segmentation, showing potential for future application to offline SLT. In terms of flicker and delay, the results of the merging windows approach are comparable to the other segmentations if biased beam search is not enabled but future work is needed to reduce flicker in the merging windows approach to similar levels as biased beam search for other strategies without hurting translation quality.

Ethical Considerations

In our work, we only use publicly available model checkpoints, toolkits and datasets and do not collect any additional data. Our experiments also do not involve human annotators.

Limitations

While we aim to evaluate on a number of language pairs and with different automatic metrics, there are still some open questions that we could not answer in this work. First, we did not perform a human evaluation and, therefore, it remains unclear how distracting the different flicker and delay values with different setups would be for a user. However, previous work by Macháček and Bojar (2020) shows that character erasure - a metric related to flicker - correlates with usability scores in a human evaluation which suggests that this would also be true for flicker. Second, the current implementation of SHAS can be used to simulate an online setting but it still expects the full audio as input. Consequently, we could not empirically compare how long translation takes with different segmentation methods in a real online setup. Third, our experiments are limited to SLT using a retranslation strategy. We leave further experiments with simultaneous SLT models that use a policy to decide at each time step whether to wait for further input or to translate for the future.

Acknowledgements

We thank Sukanta Sen and Ioannis Tsiamas who shared their code with us for the window merging algorithm and the pSTREAM implementation of SHAS, respectively. We are also grateful to Noëmi Aepli and Amit Moryossef and the anonymous reviewers for their valuable feedback. This work has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreements (project ELITR; no. 825460 and project GoURMET; no. 825299), and from the Swiss National Science Foundation (project MUTAMUR; no. 176727). All experiments made use of the infrastructure services provided by S3IT, the Service and Support for Science IT team at the University of Zurich.

Appendix

A Further Finetuning Specifications

We finetune all models and translate with a single NVIDIA Tesla V100 GPU. For the multilingual mTEDx model, the additional parameter `load-speech-only` needs to be added to the official training script[10]. We use the `restore-file` parameter to specify the checkpoints of the original models from which continued training should be initialised.

We will release all code (training scripts, translation scripts and evaluation modifications), the finetuned model checkpoints and the outputs upon publication.

B Experiments with Last Common Subsequence

As a possible way of reducing flicker for the merging windows approach, we try merging on the last common subsequence (longer than two tokens) instead of the longest common subsequence. In this way, we can maximise the finalised part of the growing output translation and reduce flicker. Figure 4 shows how the flicker increases for both merging strategies when the window size increases. With the original implementation that merges on the longest common subsequence, the flicker increases dramatically when the window size is increased. For the modified merging algorithm that merges on the last subsequence (longer than two tokens) the flicker increases only moderately with increased window size and is in general much lower.

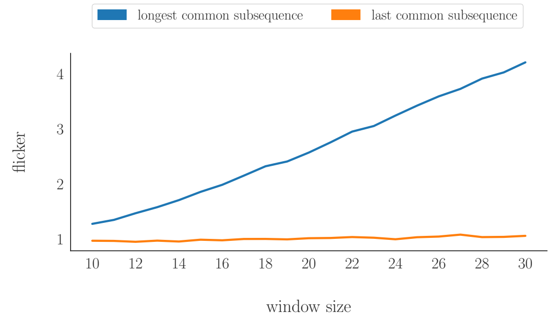

Figure 4: Flicker values with the original model on the English-to-German test set for different window sizes when merging on the longest common subsequence (blue) and the last common subsequence (orange).

Based on these results, one might choose to merge on the last sequence, however, this change also affects the translation quality. Figure 5 shows the BLEU scores of both merging methods with different window sizes. Unfortunately, merging on the last common subsequence performs continuously worse than merging on the longest common subsequence. If quality is the main focus, this merging method is not advisable. These results also show that a window size of 15 performs best for the merging windows approach.

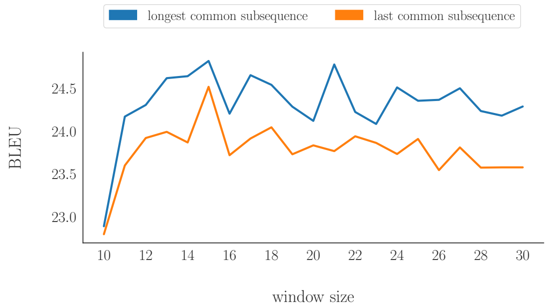

Figure 5: BLEU scores with the original model on the English-to-German test set for different window sizes when merging on the longest common subsequence (blue) and the last common subsequence (orange).

C Results with Output Mask

We also evaluate the four different segmentation methods when an output mask is applied. This means at every time step the output is truncated from the right. The number of tokens that are removed is defined by the mask size, i.e. a mask of size 0 means no tokens are removed and a mask of size 7 means seven tokens are removed. We compute these results for Spanish-to-English without biased beam search and the context-aware model which showed the lowest flicker in general.

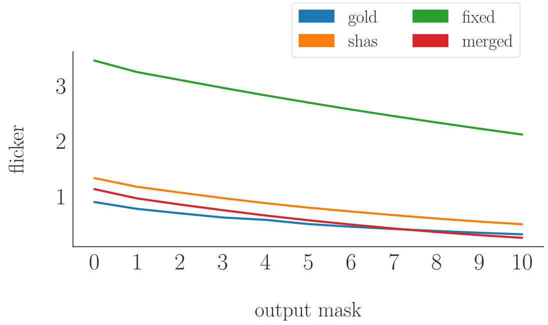

Figure 6: Flicker with different output masks on the Spanish-to-English test set. Results for all four segmentation methods with the context-finetuned model.

[10] https://github.com/facebookresearch/fairseq/blob/main/examples/speech_text_joint_to_text/docs/iwslt2021.md

Figure 6 shows the flicker at different output mask sizes. First of all, it can be noticed that the fixed window segmentation has a continuously higher flicker than all other segmentation methods and that the flicker is still rather large even with a mask of size 10. This suggests that most flicker in the fixed-window segmentation does not occur towards the end of the segments.

The merging windows approach consistently has lower flicker than SHAS and with larger mask sizes even lower flicker than the gold segmentation. With a mask of size 10, the flicker is at 0.25 which is comparable to the flicker of the original model with fixed window segmentation where biased beam search is enabled.

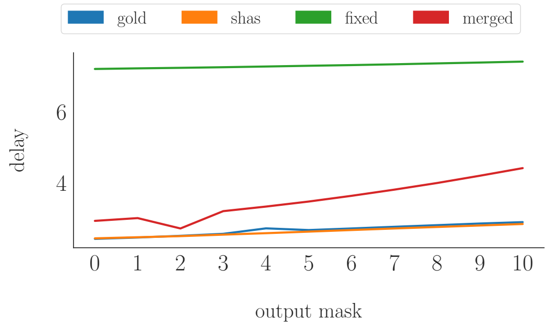

Figure 7: Delay with different output masks on the Spanish-to-English test set. Results for all four segmentation methods with the context-finetuned model.

However, this reduced flicker comes at the cost of a higher delay because the masked tokens will not be available at the time they are actually produced. This flicker-delay trade-off is well-known. Figure 7 shows the increase in delay with larger output masks. For the merging windows approach, we see that the delay increases more than for SHAS and the gold segmentation. Since our definition of the delay measure is affected by flicker, these results are hard to interpret. Nevertheless, using an output mask is a way to reduce flicker for the merging windows approach without reducing translation quality but we need to accept a higher delay.

D Additional Results

D.1 Translation Quality with COMET

For completeness, we present performance results measured with COMET (Rei et al., 2020) in Table 3. This is evaluated outside of SLTev but we use the same resegmentation tool (Matusov et al., 2005) to align the translations with the reference segments. The results show similar patterns as with BLEU and the context model paired with the merging window approach performs best among the automatic segmentation approaches on all language pairs. This approach even outperforms the gold segmentation on three language pairs. Note however that evaluating resegmented text with COMET may have some undesirable side-effects because the translated text is not always split at correct segmentation boundaries, e.g. the first token of a segment often is glued to the end of the previous segment.

Table 3: COMET scores with different SLT models (columns) and different audio segmentation methods (rows). Best result for *automatic* segmentation scenario marked in bold and green.

We tested this with 200 gold segments for en-de and manually corrected the resegmentation of the original model output. While the BLEU score does not change much with these corrections (24.70 vs. 24.73), the COMET score jumps from -0.1128 to 0.0467 which is a larger improvement than some differences in Table 3. Since it is unclear if such resegmentation errors occur equally often in all our experiment setups, we only include the results with BLEU in the main body of the paper. We hypothesise that COMET has only seen well-formed sentences at training time and consequently is less reliable on such resegmented data. In the future, document-level neural evaluation metrics could be better suited for evaluating translations of unsegmented or automatically segmented audio in SLT.

D.2 Flicker Results for Other Language Pairs

We present the same plots as in Section 4.2 for English-to-German in Figure 8, French-to-English in Figure 9, Italian-to-English in Figure 10 and Portuguese-to-English in Figure 11. The results follow the same patterns as the results for Spanish-English discussed in Section 4.2:

- Fixed windows without biased beam search have the highest flicker.
- For the language pairs into English, the merging windows approach has lower flicker than SHAS if no biased beam search is used.
- Finetuning on context reduces flicker.

D.3 Delay Results for Other Language Pairs

We present the same plots as in Section 4.3 for English-to-German in Figure 12, French-to-English in Figure 13, Italian-to-English in Figure 14 and Portuguese-to-English in Figure 15. The results follow the same patterns as the results for Spanish-English discussed in Section 4.3:

- Fixed windows without biased beam search have the highest delay.
- The merging windows approach has comparable delay to SHAS if no biased beam search is used.
- Finetuning has less of an effect on delay than on flicker.

Additive Interventions Yield Robust Multi-Domain Machine Translation Models

mattpost@microsoft.com

Abstract

Additive interventions are a recently-proposed mechanism for controlling target-side attributes in neural machine translation. In contrast to tag-based approaches which manipulate the raw source sequence, interventions work by directly modulating the encoder representation of all tokens in the sequence. We examine the role of additive interventions in a large-scale multi-domain machine translation setting and compare its performance in various inference scenarios. We find that while the performance difference is small between intervention-based systems and tag-based systems when the domain label matches the test domain, intervention-based systems are robust to label error, making them an attractive choice under label uncertainty. Further, we find that the superiority of single-domain fine-tuning comes under question when training data size is scaled, contradicting previous findings.

1 Introduction

Multi-domain machine translation (MDMT) is the paradigm in which a single model is trained to service many domains by training on multiple corpora covering disparate labeled domains. The goal of MDMT is not only to provide high quality *general* machine translation enabled by knowledge transfer across domains, but also to enable high quality *domain-specific* machine translation when a model is provided cues about the target domain, used to control the generation. Though an intuitive task, the expectations surrounding the task were only recently formalized by Pham et al. (2021) in which the authors provided both a set of functional requirements demanded of successful MDMT models and an experimental framework under which those requirements can be tested.

Pham et al. (2021) explored several mechanisms for controlling domain, ranging from simple tag-based approaches to meta-learning based mechanisms. According to the functional requirements outlined by the authors, no method meets all the expectations demanded of effective multi-domain machine translators, though the experiments were run on a relatively small dataset of only in-domain data. The primary remaining expectations, according to the authors, are the superiority of fine-tuning based methods as compared to these methods which can control the target domain, and the ability to accommodate fuzzy or uncertain domains.

This framework is useful, but the authors leave open several other questions regarding the state of MDMT. The first of these is data size. Previous experiments focused only on relatively small, in-domain data in an otherwise high-resource setting of English-French and found that most models pale in comparison to models fine-tuned on a single domain. We wonder whether this fine-tuning superiority conclusion holds under a more realistic paradigm in which models trained on large, out-of-domain datasets are fine-tuned on in-domain data. While pretraining and fine-tuning on in-domain data can yield strong in-domain performance—as observed by the authors—this is likely to be at the cost of general domain performance, calling into question the transferability under MDMT.

Next, we wonder if new methods might help with the issue of domain control in MDMT. The authors examine reasonable mechanisms for controlling the domain which were known at the time. Since then, new methods have been developed which we hope to investigate under the prescribed framework. We hypothesize that additive interventions (Schioppa et al., 2021), which learn tag embeddings separately from the encoder, may be harder to ignore, and that the learned interventions may be able to absorb target-side properties more easily, while freeing the encoder to learn strong representations purely for translation.

In this work we scale the original experimental

framework presented in Pham et al. (2021) by including a significantly larger, more realistic dataset. We also experiment with additive interventions as an alternative to domain tagging. We find that:

- additive interventions perform roughly equivalently with tag-based approaches in the ideal case where provided tags match the target domain.
- additive interventions are much more robust in the face of incorrect and uncertain domain labels.
- when the experiment is scaled, models fine-tuned targeting a single domain are strong translators, but are never unmatched by other models which can service multiple domains suggesting that MDMT models in a high-resource setting are competitive with best-in-class baselines.

2 Method

As a baseline, we inject domain metadata using the tag-based approach. In this scheme, a token representing the target-side attribute, t, is prepended to source segment x and fed to the encoder E whose hidden representation is finally exposed to decoder D in a “normal" fashion:

$$\hat{y} = D(E([t] + x))$$

where $+$ indicates sequence concatenation. In tag-based approaches, the expectation is that the domain tag as a prefix acts as a conditioning variable which encourages target-side attributes to appear as desired in the final translation.

While effective and architecturally non-invasive, this method is not without downsides. Because the target token's contribution to the encoder representation is learned, there is a chance that the attribute can be ignored. To address this and other weaknesses of tag-based approaches, Schioppa et al. (2021) present the additive interventions method which requires an encoder E, a decoder D, and a separate attribute embedding layer Emb. Given a source segment x and a sentence-level attribute token t, we have

$$V = Emb(t)$$
$$\hat{y} = D(E(x) \oplus V)$$

where $\oplus$ is defined as addition broadcasted along the token dimension. Importantly, this allows prototypically discrete attributes to be represented and controlled in a *continuous* fashion, allowing for interpolation, scaling, and positionally invariant combinations, among other useful features. We note that these are somewhat analogical to an “additive" version of “source factors" approaches (Hoang et al., 2016; Sennrich and Haddow, 2016) with one major difference: additive interventions happen *after* the encoder rather than *before* the encoder.

While the original work only introduces the interventions to the top-most decoder layers in order to allow for partially freezing pretrained networks, we simplify by applying the intervention to the top layer of the encoder, such that it affects all decoder layers. Further, the authors report that improved general performance can be promoted by randomly inducing a zero-vector intervention. As such, we can specify that t is randomly replaced by $\langle\text{PAD}\rangle$ with some probability with the same effect. We report 20% masking in this paper, though we experiment with 0% masking and find no significant differences between the two.

3 Experimental Setup

3.1 Data

We follow the supervised data settings prescribed by Pham et al. (2021) which includes splits from seven domains of varying disparity: BANK, IT, LAW, TALK, RELIG, MED, and NEWS. These domains are drawn from various sources: the European Central Bank corpus (BANK) (Tiedemann, 2012); the documentation for the KDE, Ubuntu, GNOME, and PHP projects from Opus (Tiedemann, 2009) combined to form IT; The JRC-Acquis corpus (LAW) (Steinberger et al., 2006); TED Talks (TALK) (Cettolo et al., 2012); the Tanzil translation of the Koran (RELIG); the UFAL Medi-

cal corpus v1.0 (MED)[1]; and News Commentary corpus v12 (NEWS) (Tiedemann, 2012). For sake of consistency, we rely on roughly the same splits as provided by the authors,[2], though we remove duplicates within each domain, which changes the size of each training set slightly. Additionally we include English-French ParaCrawl v9 (Bañón et al., 2020) to serve as a large out-of-domain training set for some experimental settings. The effective training set sizes are summarized in Table 1.

3.2 Models

We consider several models falling into two categories: those trained with (`control`) and without(`no control`) a method for selecting the target domain.

We use approximately the same architecture for all settings, though note that all intervention-based models have an extra embedding layer with the same embedding dimension as the encoder[3]. The basic architecture follows a 12-layer encoder, 6-layer decoder transformer with 8 attention heads each (Vaswani et al., 2017), encoder and decoder feedforward embedding dimensions of 4096, and encoder and decoder embedding dimensions of 1024.

3.2.1 `no control`

We train three models with no training-time information about the domain that the data comes from and, as a consequence, have no ability to explicitly control the target domain:

1. we have an out-of-domain baseline which is trained only on ParaCrawl: `general base`.
2. we have a model which is trained on the in-domain plus out-of-domain training sets:

[1] https://ufal.mff.cuni.cz/ufal_medical_corpus

[2] https://github.com/qmpham/experiments

[3] Adding $|D| \times 1024$ parameters, where D is the set of domain labels

combined base.

3. we have six quasi-oracle fine-tuned models which are produced by fine-tuning the general base model on each target domain's training set; we collectively refer to this set of models as single-domain fine-tuned (single-dom FT).

3.2.2 control

As mechanisms for controlling the target domain we consider:

1. prepending the domain tag to the source sequence, tags
2. additive interventions with 20% masking, ints

We apply these two methods to three settings:

1. an in-domain plus out-of-domain setting, combined
2. an in-domain-only setting, in-dom
3. a multi-domain fine-tuning setting, multi-dom FT, where general base is fine-tuned on all in-domain data with domain information available at training time.

This results in six models:

- combined ints
- in-dom ints
- multi-dom FT ints
- combined tags
- in-dom tags
- multi-dom FT tags.

3.3 Training

We train a joint unigram segmentation model (Kudo, 2018) using SentencePiece (Kudo and Richardson, 2018) with a vocabulary of size 32k for each setting in general base, combined, and in-dom (reusing general base's model for multi-dom FT and single-dom FT). We train each model by sampling 10M sentences randomly, splitting on digits and enabling byte-fallback. We add a special token for each domain for which we have splits: ⟨BANK⟩, ⟨IT⟩, ⟨LAW⟩, ⟨TALK⟩, ⟨RELIG⟩, ⟨MED⟩, and ⟨NEWS⟩. We use these models to segment the data as appropriate in each setting.

We use dropout of 0.1 but disable attention dropout and ReLU dropout. We optimize label smoothed cross-entropy loss with a label smoothing factor of 0.1 (Szegedy et al., 2016) using Adam (Kingma and Ba, 2015). All models are built and trained using fairseq (Ott et al., 2019).

For models trained with out-of-domain data, we shard the effective dataset with each shard containing approximately 1b target tokens. For models trained with in-domain data only, we consider the entire combined in-domain dataset to be a single shard. We train for 30 virtual epochs, where a virtual epoch is defined as a single pass over one shard. For models which are fine-tuned, we fine-tune for 10 additional virtual epochs.

Each in-domain training set is assigned a unique special token which is included in the vocabulary and examples drawn from these in-domain training sets are provided the associated special token at training time. Examples from ParaCrawl are assigned no special domain token (i.e., no token is prepended in tags models and ⟨PAD⟩ is always provided in ints models).

3.4 Evaluation

We evaluate in three settings to probe various aspects of MT quality:

- we evaluate in-domain performance with each model from control and no control to determine the relative effectiveness of the methods of control against methods without control.
- we evaluate on the WMT15 English-French test set (Bojar et al., 2015) with no domain label provided (i.e., as if the models were in the no control setting) to test catastrophic forgetting (Goodfellow et al., 2013) in a general setting. Importantly, while the models trained on in-domain data have been exposed to newswire data, the labels are not provided at test time in this setting.
- we evaluate the effect of providing the incorrect tag to each test set, as computed by SacreBLEU (Post, 2018) and COMET (Rei et al., 2020), to test the resilience of models to label errors

4 Results

No clear winner in ideal case We evaluate the setting in which the provided domain label matches

the target test domain, and the setting of WMT15 without a provided domain label, for each setting apart from single-dom FT. The results can be read in Table 2 and are visualized in Figure 1.

Table 2 shows that when comparing control models within a training setting using bootstrap resampling (sample sizes of 1000) (Koehn, 2004), the difference in performance of tags and ints are insignificant in the majority of cases. While there are a few cases of statistically significant differ-

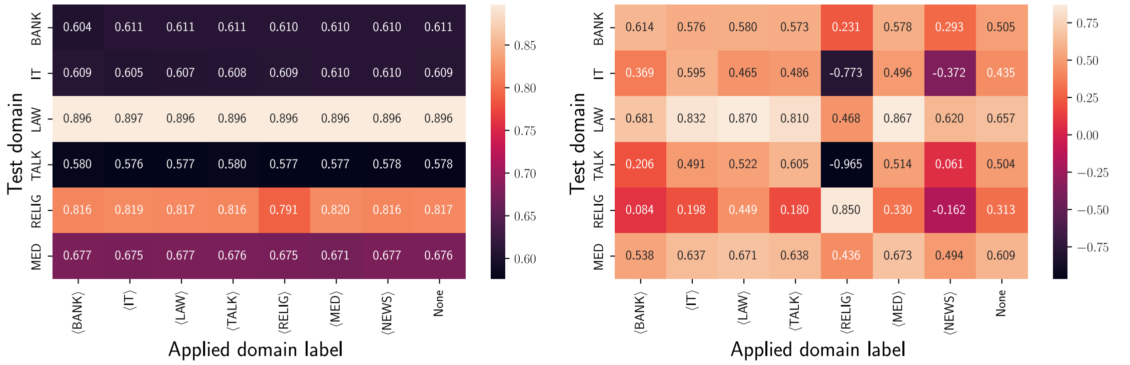

Figure 5: COMET of `multi-dom FT` models under various domain labels. `ints` left, `tags` right. `ints` maintain high quality translations under mismatching domain labels in all cases, unlike `tags`.

ences, neither `tags` nor `ints` are uniformly preferred in these cases. The opposite is observed on the out-of-domain WMT15, where `ints` performs uniformly better than `tags`, often significantly.

We observe that methods with `control` in the `combined` setting perform approximately equally to the `combined base`, showing that naive combination of in-domain and out-of-domain with a mechanism to control the domain does not improve over approaches without control, though `in-dom` and `multi-dom FT` models tend to perform better on average than any model in the `combined` setting.

`ints` are robust under domain label mismatch Next, we perform an ablation study in which we score each test across all domain label assignments (including the correct label and no label), which allows us to observe the effects of test-time labeling error. While we compute both BLEU and COMET, we include only COMET here.[4] We include the full results in Tables 3–8, but summarize the findings in Figures 2-5, which show the robustness of various models and settings to mislabeled domains.

Figures 3–5 show heatmaps resulting from this ablation, but we refer interested readers to Tables 3–8 for the long-form charts. We see that `tags` systems' performances vary dramatically, incurring severe degradation in the face of domain label error but performing strongest along the diagonal. `ints` systems, on the other hand, see only small performance changes when provided with incorrect domain labels and roughly equal performance under all possible labels, as observed in Figure 2. We see that `in-dom tags` have the highest average variation in performance, likely owing to the small amount of data which suggests that `in-dom tags` overfits to the training data. The variation in performance of `ints` systems approaches that of the `general base`, which by definition ignores the domain label and therefore has 0 variance; however, `ints` has demonstrably stronger performance than `general base` in all domains and, indeed, stronger performance than `tags` in a handful of domains and thus seems to learn strong general representations for translation which disentangles the representations of the encoder from the representations of the attribute.

Additionally, through manual analysis we find that `tags` systems are more prone to hallucinating translation artifacts from the corpus associated with the domain label being used, often causing quality degradation. We refer to Table 15 for an example of such artifacts, which includes topical and target language mismatches along with tokens which appear as a result of the HTML-encoded nature of the ⟨IT⟩ dataset.[5]

Single-domain fine-tuning is not as competitive in large-data settings We compare the performance of models trained only with in-domain data and out-of-domain data. From Table 2, we see slightly stronger in-domain performance for `in-dom` models as compared to models fine-tuned with out-of-domain data at the cost of out-of-domain performance on WMT15, suggesting that `multi-dom FT` models generalize better and may surpass `in-dom` models with more training due to the relatively little fine-tuning budget of 10 epochs afforded to them comparatively.

[4] Similar results for BLEU are listed in Appendix A.2

[5] Escaping seems to be an artifact of Moses preprocessing leakage of raw data; not germane to all domains in this work.

Finally, we see that while `single-dom FT` is typically among the highest performing systems for a given test set, it is never unmatched by an alternative system in `control`. We observe that `single-dom FT` is uniformly stronger than `general base` and `combined`, `in-dom` and `multi-dom FT` show competitive in-domain performance. We note that because there is one `single-dom FT` model per test set, the effective parameter budget is six times larger than any of the individual models, providing support for both its impracticality and untenability as compared to any other setting. This suggests that single-domain fine-tuning is not as effective as expected in high-resource settings as a strong upper-bound in MDMT.

5 Related Work

Incorporating extra-sentential information has a rich history in NMT. Aside from controlling for the domain, Sennrich et al. (2016) use a politeness tag at training and inference time to accommodate coarse politeness control in machine translation. Additionally, Kuczmarski and Johnson (2018) use tags to afford users the ability to vary binary gender in the translations of gender-neutral inputs, hoping to address gender bias in MT.

At the sub-sequence level, Hoang et al. (2016) and Sennrich and Haddow (2016) included linguistically-informed word-level "source factors", such as part-of-speech tags and dependency relations, as additional feature factors to be concatenated to form a full encoder representation with the goal of reducing ambiguity and sparseness issues.

Perhaps more relatedly, several works have explored the impacts of incorporating domain information into training using various methods. Kobus et al. (2017) explore two methods: a tag-based approach which concatenates a special token to the end of the source sequence, and a "source factors"-style approach which concatenates domain-level embeddings to each token embedding in the source. Sharaf et al. (2020) explore few-shot domain adaptation, rather than domain control, through the lens of meta-learning and show that a meta-learning based approach is generally stronger than other adaptation approaches, though we note that adaptation and control address different needs. Finally, Stojanovski and Fraser (2021) frame machine translation with document-context as an unsupervised domain adaptation problem and incorporate domain embeddings within the encoder, summed with positional and word embeddings, yielding strong improvements over competitive baseline models.

6 Conclusion

In this work we examined the relative impact of additive interventions in a large-scale MDMT setting. We find that typically there are no significant differences between additive interventions and tag-based approaches when the provided domain label matches the test set, but find that additive interventions exhibit *much more desirable degradation properties* when the domain label is unknown or incorrectly provided. In addition, we find that models first trained on a large, general corpus and then fine-tuned on a single-domain—a realistic baseline in machine translation—rarely perform significantly better than approaches which are trained or fine-tuned only on in-domain data, which is in contrast to their generally superior performance in low-resource settings.

In future work we consider developing extensions to additive interventions which can further improve their performance in MDMT settings. Additionally, studying additive interventions in other tasks where tag-based approaches are dominant, such as multi-lingual machine translation, could be an interesting avenue for exploration.

Abstract

This paper describes the Inria ALMAnaCH team submission to the WMT 2022 general translation shared task. Participating in the language directions {cs,ru,uk}→en and cs↔uk, we experiment with the use of a dedicated Latin-script transcription convention aimed at representing all Slavic languages involved in a way that maximises character- and word-level correspondences between them as well as with the English language. Our hypothesis was that bringing the source and target language closer could have a positive impact on machine translation results. We provide multiple comparisons, including bilingual and multilingual baselines, with and without transcription. Initial results indicate that the transcription strategy was not successful, resulting in lower results than baselines. We nevertheless submitted our multilingual, transcribed models as our primary systems, and in this paper provide some indications as to why we got these negative results.

1 Introduction

This paper describes the Inria ALMAnaCH team submission to the WMT 2022 general translation shared task. We chose to explore the language directions {cs,ru,uk}↔en and cs↔uk in order to concentrate on the Slavic language family. Due to some experimental problems that impacted the into-Slavic directions most heavily, we only submitted {cs,ru,uk}→en and cs↔uk language directions, but we present all results we obtained here.

A major area of interest in machine translation (MT) research is transfer between languages, particularly related ones and for lesser resourced languages (Zoph et al., 2016; Kocmi and Bojar, 2018). One way of encouraging transfer is to train multilingual models, whereby several language directions are trained simultaneously, often sharing some (Firat et al., 2016) or all model parameters (Ha et al., 2016; Johnson et al., 2017; Aharoni et al., 2019), with the hope that similarities between the languages can boost performance, particularly for the lower-resourced languages.

To encourage lexical sharing and therefore the transfer capacity of such models, joint subword segmentation models (Sennrich et al., 2016b) and MT vocabularies are often used (Sennrich et al., 2016a), and techniques such as phonetisation and transliteration/transcription can be applied to texts in a bid to overcome differences in writing systems and spelling (Nguyen and Chiang, 2017; Chakravarthi et al., 2019; Goyal et al., 2020; Muller et al., 2021).

In our submission to the WMT 2022 general translation shared task, we experimented with multilingual models and the use of customised transcription into a common writing system designed to maximise lexical sharing, similar to the one used in (Muller et al., 2021). We choose to work with the language directions involving Slavic languages, that is {cs,ru,uk}↔en and cs↔uk. We find that our transcription method unfortunately leads to degraded results, likely a consequence of errors being injected and notably the necessity to apply a learned detranscription model as a post-processing step for into-Slavic language directions. Our multilingual models achieved largely inferior results to our bilingual baseline models for the same number of parameters, showing that multilingual transfer cannot compensated for sharing the vocabulary over a larger number of languages. Transcribing the languages in the multilingual setup results narrows the gap slightly, but the results remain lower than the bilingual baselines. We nevertheless decided to submit our multilingual models with common-Slavic transcription rather than our superior baseline results in the full knowledge that these results would not achieve the best results in the shared task.[1]

[*] Contributions made whilst at Inria.

[1] We believe it was more interesting to submit these results to test our hypothesis rather than to submit more standard

2 Related Work

There has been a considerable body of work in MT dedicated to multilingual models, whereby several language directions are trained simultaneously, with different degrees of parameter sharing, ranging from separate encoders and decoders (Firat et al., 2016) to the sharing of a single encoder and a single decoder for all languages with a single shared vocabulary (Ha et al., 2016; Johnson et al., 2017; Aharoni et al., 2019). As well as being practical by providing a single MT model that can be used for multiple directions, the models have the advantage of aiding the representations of lower-resourced languages, particularly if related, higher-resourced languages are also included in training (Kudugunta et al., 2019; Aharoni et al., 2019; Tchistiakova et al., 2021).

In addition to approaches such as joint subword segmentation models (Sennrich et al., 2016b) and the use of a joint vocabulary for all languages (Johnson et al., 2017), strategies to encourage more lexical sharing have also been explored in order to overcome surface differences introduced by orthographic conventions, notably phonetisation (Liu et al., 2019; Rosales Núñez et al., 2019; Sun et al., 2022) and transliteration (Nakov and Tiedemann, 2012; Nguyen and Chiang, 2017; Goyal et al., 2020). These approaches can be particularly useful for borrowings and for proper nouns, which can be made to be identical (or near-identical) across languages once transliteration has been applied.

Transliteration is the mapping of one writing system to another, and therefore is relevant when languages are written in different scripts (e.g. Latin, Cyrillic, Devanagari, etc.). In particular for related languages, it can be interesting to apply transliteration in order to exploit the fact that many words can be made to be similar on the surface once transliteration has been applied. Much of the work that has explored transliteration for MT has focused on Indian languages, for which the mapping between scripts is relatively straightforward (Bawden et al., 2019; Goyal et al., 2020; Kunchukuttan and Bhattacharyya, 2021; Sun et al., 2022), but there has also been research on other language families (Maimaiti et al., 2019; Sun et al., 2022), including Slavic languages (Maimaiti et al., 2019). In our systems, we follow a similar approach to test whether a form of transliteration that maximises lexical overlap between Slavic languages could help translation in a multilingual setup, even in the relatively high-resource scenario provided by the shared task.

3 Multilingual Slavic models with transcription

Building on the previous work on multilingual MT and on transliteration to encourage lexical sharing, we propose multilingual models with a custom linguistically motivated transcription scheme for translation between English and the Slavic languages Czech (cs), Ukrainian (uk) and Russian (ru).

Multilingual Slavic translation models We train multilingual Slavic translation models with a single encoder-decoder architecture as in (Johnson et al., 2017) over the following language directions: {cs,uk,ru} from and into English and cs to and from uk. Given that a single shared encoder and a single shared decoder is used, the same vocabulary is used across all languages, and we also share embeddings across the encoder and decoder. To further encourage sharing, we train a joint subword segmentation model. To test the performance of this multilingual model, we compare against bilingual baselines trained uniquely on parallel data for the

baseline systems. Due to human error, these submitted models perform less well than the results presented in this paper, as described in Section 5.3.

specific language pair, which also share encoder and decoding embeddings.

Linguistically motivated transcription We experiment with the use of a customised common Slavic writing system designed with the aim of maximising lexical overlap between the Slavic languages we study. The underlying idea is that MT models, both bilingual and multilingual, should benefit from an increase in the similarity between languages including in training. Since Slavic languages share a common ancestor, Proto-Slavic, they display similarities in terms of phonetics, grammar and vocabulary. Lexical overlap, though, can be further improved in at least two ways:

- Whereas Czech uses the Latin script with a number of diacritics, Russian and Ukrainian use the Cyrillic script. Using a common script would inevitably increase the lexical overlap and make it more explicit. For instance, using a standard Latin transliteration scheme for Russian,[2] the Russian word рука 'hand' can be rendered as *ruka*, which is identical to Czech *ruka* 'hand'.

- Each Slavic language has undergone a number of changes from Proto-Slavic, including regular sound changes. Examples such as Ru. рука∼*ruka* vs. Cz. *ruka*, where transliteration alone is enough to create a perfect lexical overlap, are therefore rare. However, there are a large number of cognates (words in related languages that share a common ancestor), which, independently of the script, are still similar and only differ in partly systematic ways. For instance, Ru. корень 'root', Uk. корiнь 'id.' and Cz. *kořen* 'id.' are cognates. Using standard transliteration schemes, the Russian and Ukrainian words can be rendered as *koren'* and *korin'*, respectively. This is closer to Cz. *kořen* but is not identical. More importantly, it fails to identify the fact that Uk. i often corresponds to Cz. *e* and that Cz. *ř* often corresponds to Ru. and Uk. р.

To further increase lexical overlap and with the aim of encouraging more transfer between the languages than what is permitted by standard transliteration schemes, we developed transformation rules for all three Slavic languages based on systematic patterns, based on observations from cognate lists in the three languages and knowledge about their morphology, in order to lower the differences introduced between them by sound changes and morphological particularities, similarly to (Muller et al., 2021). For Russian and Ukrainian, this involves a script change, but Czech is also modified. We call this transformation *linguistically motivated transcription*.[3] Going back to the example above, the output of our transcription scripts for Ru. корень, Uk. корiнь and Cz. *kořen* is the same, namely *koren*. Table 1 illustrates our linguistically motivated transcription strategies on a constructed multilingual example.

Transcription and detranscription Our common Slavic transcription is applied during preprocessing to the training data. For into-English language directions, no further processing is required following translation, because we only transcribe the Slavic languages and not English. However for from-English directions and for cs↔uk, the output of the MT model will require detranscription in order to transform the outputs into the correct form for that language. We therefore also train small transcription models, which are essentially individual translation models trained to translate from the transcribed text to the original writing system. This step can be trained on large quantities of monolingual data rather than being limited to parallel data, which is important if error propagation is to be kept to a minimum.

4 Data

We developed systems for four of the several language combinations taken into account for the general translation task. They are {cs,ru,uk}↔en and cs↔uk. We took part in the challenge under its constrained track, using only a portion of the data made available for the task. The following sections describe the data we used and how we processed and filtered it. We present the data sizes and their corresponding sources in Table 8 in Appendix A.

[2] Here and elsewhere in this paper, we use the so-called "scientific transliteration" when we transliterate Russian and Ukrainian. It is a standard, slightly language-dependent, transliteration scheme.

[3] Transliteration is generally defined as a bijective script change, a constraint that is too strict to allow for a significant increase in lexical overlap. Relaxing the bijectivity constraint, on the other hand, means that some information is lost. It is no longer a transliteration *stricto sensu*. Contrarily to (Muller et al., 2021), we therefore use the term *transcription* rather than transliteration to denote a transformation process that performs non-bijective changes.

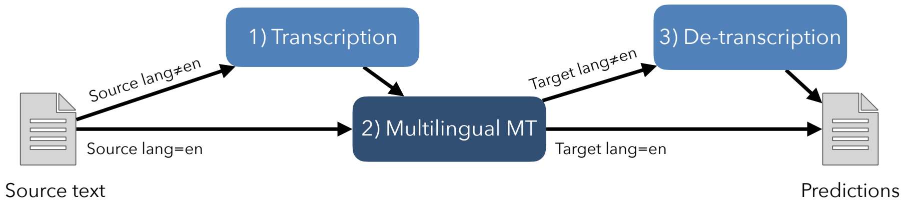

Figure 1: Illustration of our multilingual MT approach using common Slavic transcription.

4.1 Parallel Data

We used all of the parallel data provided for the language pairs we selected, with the exception of the back-translated news data, CzEng2.0 and two more datasets released at a later stage of the challenge, ELRC-EU acts, and Yakut parallel data, for the training of our NMT systems. We excluded the back-translated news data[4] and CzEng 2.0,[5] which are both back-translated data sources, after inspecting their respective content and discovering a large proportion of poorly translated sentences. To assess their quality and gauge the amount of noise present, the other parallel data were carefully examined. This was important especially for the web-mined data such as CCAligned, Wikimatrix, and CommonCrawl, which all contained a variety of quality issues identified in (Kreutzer et al., 2022).

Parallel Data Filtering: Each parallel corpus was subjected to a generic filtering pipeline involving the removal of blank lines and sentences without corresponding translations. We carried out language identification on the web-mined parallel corpora using FastText (Joulin et al., 2016a, 2017), thus removing sentence pairs where either the source or target is not in the intended language. Finally, the parallel corpora for each language pair were combined, and duplicate translation pairs were removed. Table 2 shows the original number of parallel sentences for the different language pairs and their corresponding sizes after filtering.

Language pair	Original	Filtered
cs–en	56,289,558	54,495,258
cs–uk	3,163,969	2,490,622
en–ru	31,052,852	25,584,007
en–uk	23,355,100	22,322,394

Table 2: Number of parallel sentences.

4.2 Monolingual Data

We used monolingual data to train the detranscription models. As with the parallel data, we removed empty lines, duplicated lines and also sentences that were not from the target language by doing language identification with FastText (Joulin et al., 2017, 2016b). This process was necessary since most of these sentences were web-mined text. The statistics of the monolingual data for each language are shown in Table 9 in Appendix A, along with their sizes before and after pre-processing.

For the transcription experiments, we randomly selected 20M sentences from the pre-processed monolingual texts for each of the Slavic languages.

4.3 Validation and Test Data

For each language pair, we chose 2000 and 3000 sentence pairs from the pre-processed parallel texts as our internal validation and test sets respectively, and the remaining sentences were used for training. In order to compare the various systems we developed, we also used the development set provided for the shared task (the FLORES development set and the WMT2018 test set depending on the language pair). This was also done for the systems with transcription. En↔uk and cs↔en models were only evaluated on the in-house test and the FLORES development sets because they were not in covered by the WMT2018 test sets. We also provide automatic scores on the WMT2022 test sets.

4.4 Subword Tokenisation

We tokenised all data using a joint SentencePiece (Kudo and Richardson, 2018) unigram model with a character coverage of 1.0 and a maximum sentence length of $4,096$ tokens. Specifically, for the bilingual systems, we uniformly sampled $5M$ monolingual sentences from the parallel training data of each language pair to have $10M$ sentences in total over which we trained a SentencePiece tokeniser. Similarly, for multilingual systems, we

[4] http://data.statmt.org/wmt20/translation-task/back-translation/

[5] https://ufal.mff.cuni.cz/czeng/czeng20

sampled a total of $10M$ monolingual sentences evenly from all monolingual data available for each language that the tokeniser was trained on.

5 Experiments and training

We submitted three categories of NMT systems: (i) the baseline bilingual translation models for each of the four language pairs in their original scripts, (ii) a multilingual model with common-Slavic transcription for {cs,uk,ru}→en, and (iii) a bilingual model with common-Slavic transcription for cs↔uk. Below, we provide details of these submitted systems, as well as the additional systems developed before and after the task's deadline.

5.1 NMT architecture and training

All models used the transformer-base architecture (Vaswani et al., 2017) within the Fairseq[6] toolkit (Ott et al., 2019). We use the `multilingual_translation` architecture for all models, except for those trained on a single language pair. We used batch sizes of $10,240$ tokens, a maximum sentence length of $1,024$, and a dropout of 0.3. For optimisation, we used Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.998$, a learning rate of $1 * 5e^-5$ and a warm-up of $4,000$ updates. The optimiser uses a label-smoothed cross-entropy loss function with a label-smoothing value of 0.1. For multilingual models we use temperature sampling with $T = 1.5$. All models were trained until convergence based on the BLEU score on the development set. We use BLEU (Papineni et al., 2002) to evaluate our models and to choose the best checkpoints, calculated using SacreBLEU[7] (Post, 2018).

5.2 Baseline models

We trained a bilingual translation model for each of the four language pairs we covered. We chose a vocabulary size of $64k$ for all systems after experimenting with different sizes ($16k$, $32k$, and $64k$). We then fine-tuned each bilingual model to each of the two directions in the language pair (taking the best checkpoint of the bilingual model), resulting in a baseline model for each of the 8 translation directions.

We also trained a multilingual system for all of the language pairs, i.e. a single model that can translate in every direction, which was then finetuned to each language direction. We chose to use a vocabulary size of $64k$ based on the trends we found from the bidirectional model experiments. We chose not to go bigger in order to keep the model compact and comparable to the bilingual baselines, at least in terms of the number of parameters. Our comparison therefore tests whether for a same number of parameters multilingual models (and transcription) can be beneficial, despite the fact that multilingual vocabs are likely to result in a higher degree of segmentation for the individual languages.

5.3 Common Slavic transcription

To assess the impact of transcription, we trained bilingual and multilingual models on the transcribed versions of the Slavic parallel data. We follow the same setup as for the baseline models (i.e. bilingual/multilingual training and then fine-tuning on the specific language direction), simply substituting the original Slavic text with the transcribed versions.[8] When presenting the results, we refer to the transcribed version of Russian (ru), Czech (cs) and Ukranian (uk) as rl, cl and ul respectively.

Due to human error, our submitted multilingual systems were trained with a vocabulary of 16k rather than 64k, which severely penalised them and resulted in very low official scores. We report results with the intended vocabulary size of 64k in this article.

5.4 Detranscription models

For each Slavic language, we trained a detranscription model on $20M$ parallel sentences (transcribed→original), consisting of monolingual sentences and their automatically transcribed versions. We used a joint SentencePiece model of size $16k$ and used the same architecture as before. These models were applied after translation to make sure that transcribed Slavic outputs were in their original writing system.

6 Results

6.1 Baseline models (without transcription)

We first report results for our baseline models in Table 3 (i.e. without transcription).

We provide results for our in-house test set (from the same distribution as the training data), the FLORES devtest subset and the WMT2018 test

[6] `https://github.com/facebookresearch/fairseq`

[7] With the following parameters: `case:mixed|eff:no|tok:13a|smooth:exp|version:2.3.1`

[8] SentencePiece models were also retrained on the new data, keeping a vocabulary size of 64k.

Table 4: BLEU score results for bilingual and multilingual models using transcription for all Slavic languages.

set (when available). Although the BLEU scores are not directly comparable across test sets, the baseline results are generally quite high. The highest results are seen for cs↔en and for all sets other than the WMT2022 test set, the lowest are generally seen for cs↔ul, which correspond to the highest and lowest resourced language pairs respectively. Interestingly, the en↔uk test set are comparatively tougher than the other sets we evaluate with.

When we compare bilingual and multilingual results, it is clear that the bilingual models are largely superior for all language directions, with very large differences in BLEU scores across evaluate sets. The only BLEU scores that are higher for the multilingual model is for en↔uk, for which the in-house test set gives slightly higher results. However, this does not hold for the other test sets, indicating overfitting of the models. These results are not so surprising given the relatively small vocabulary size of 64k for the four languages included in training. This is to compare with the bilingual models' 64k vocabulary sizes spread over two languages only. The obligation to share a same vocabulary size amongst more languages (and more scripts) is certainly not compensated by any gain that could possibly be had through multilingual transfer.

6.2 Results with transcription

In Table 4 we provide the results of bilingual and multilingual models with transcription (and detranscription where necessary).

Although transcription should not help the bilingual models that translate to and from English since there is only one Slavic language involved, we include these results for comparative purposes. Ideally, these results (for {cs,uk,ru}↔en) should be identical to the baseline results, showing that transcription does not introduce noise into the process. In reality, we see a systematic drop in results when transcribing for into-English directions, and a greater drop in BLEU score for into-Slavic directions, most likely due to errors introduced by the detranscription model. Interestingly, some directions suffer much more than others (e.g. en→uk and en→ru have a drop of over 2 BLEU vs. en→cs's drop of 0.20 BLEU on WMT2022). This could well be a reflection of the fact that the transcription scheme was centred around Czech, with fewer modifications being made to this language than to the others.

For the multilingual models, the scores are again much lower than the bilingual models with transliteration for all directions, although some slight improvements are seen for into-English directions, although the performance is much closer for en→uk. We do however see an improvements across the board on the results of the baseline multilingual models (i.e. without transcription), suggesting that transcribing helps to marginally make up some of the lost scores. Unfortunately, it is unclear whether this is due to the vocabulary now being spread over fewer different scripts or whether transcription does help provide better transfer in some other ways.

7 Discussion

Given these disappointing results, it is important to make a first step to understanding why transcription does not help. We therefore look at some additional results concerning the noise that the transcription step might be introducing: (i) the translation results for the detranscription step itself and (ii) comparative results for cs↔uk when transcribing the source, the target or both.

Detranscription quality We show the results for the detranscription step itself in Table 5, where we apply our detranscription models to the texts to which our transcription rules have been applied. The BLEU scores are very high, but not exactly perfect, suggesting that errors are being introduced in this step. The results are highest for Czech, therefore confirming our earlier hypothesis that this step is degrading less for this language given that fewer changes are made.

We also provide results (Table 6) of the raw output of the from-English bilingual models with transcription (i.e. before applying detranscription). We compare these to the results of the bilingual baselines (trained to produce the correct script) but with automatic transcription applied to the outputs in order to provide a point of comparison in terms of the BLEU score. The results are lower for the bilingual models with transcription for Russian and Ukrainian, suggesting that the outputs of the MT models are also far from perfect, and that transcription may be introducing ambiguities and making it harder for the models to learn. However, as can be seen in previous results, the same cannot be said for Czech, where the results are actually slightly higher for the bilingual model with transcription compared to the bilingual baseline with transcription applied.

Comparative results for cs↔uk with different combinations of transcription Table 7 shows the results for cs↔uk when transcribing the source, target or both. The best results when using the original scripts, as can be seen in previous results. However, the results suggest that in some scenarios, it could be better to transcribe just the source rather than to transcribe both source and target. The advantage of this for uk→cs is that Ukrainian is being made to look more like Czech, but without there being extra errors added by the detranscription step. (Muller et al., 2021) showed that transcribing could be useful for lower-resource languages, so a possibility here is that the languages are sufficiently high-resource for transcription not to help so much and for the errors introduced in detranscription to outweigh any potential benefits.

8 Conclusion

Setting aside the fact that multilingual models provide very inferior results to specific bilingual models for the same number of parameters, our results suggest that the answer to the question “Does transcription help cross-script machine translation?” is no. This is at least for the languages on which we experimented and given the amount of training data we had at our disposition. Our bilingual model results show that transcription harms performance, whether it is done on the source side, the target side or both sides. There are several possible explanations for this: (i) the relatively high-resource scenario we are working in, where baselines can already achieve good results and where little gain can be achieved through this type of transfer, (ii) the possibility that transcription introduced ambiguities that could harm translation, and (iii) the detranscription step itself also introducing errors.

Abstract

In this paper, we describe our NAIST-NICT-TIT submission to the WMT22 general machine translation task. We participated in this task for the English ↔ Japanese language pair. Our system is characterized as an ensemble of Transformer big models, k-nearest-neighbor machine translation (kNN-MT) (Khandelwal et al., 2021), and reranking.

In our translation system, we construct the datastore for kNN-MT from back-translated monolingual data and integrate kNN-MT into the ensemble model. We designed a reranking system to select a translation from the n-best translation candidates generated by the translation system. We also use a context-aware model to improve the document-level consistency of the translation.

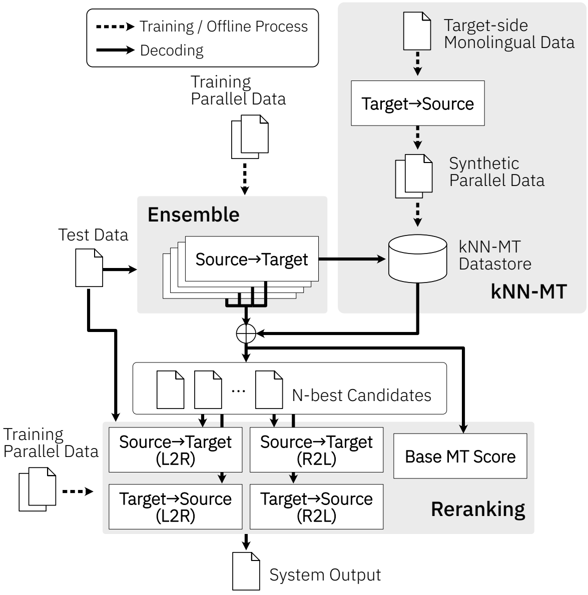

Figure 1: System overview.

1 Introduction

We participated in the WMT22 general machine translation task in two language directions, English-to-Japanese (En-Ja) and Japanese-to-English (Ja-En). We built our system on an ensemble of Transformer big models, k-nearest-neighbor machine translation (kNN-MT) (Khandelwal et al., 2021), and reranking. Figure 1 shows an overview of our system.

Our translation system is a combination of kNN-MT and an ensemble of four Transformer big models. We train each of the Transformer NMT models using a different random seed, and pick one model as kNN-MT. A notable point about our system is that we construct the datastore for kNN-MT from back-translated monolingual data rather than reusing training data. We found that using back-translated data improves translation performance compared with using a parallel training corpus for the datastore.

Our reranker is designed to select the translation from the n-best translation candidates generated by the translation system. The reranker computes the weighted sum of each translation candidate across multiple models and selects the translation candidate with the highest score. We used k-best batch MIRA (Cherry and Foster, 2012) to select the weights for the model scores that maximize the BLEU score of the development set.

2 Corpora and Preprocessing

For the training data, we used all the provided bilingual parallel data: JParaCrawl v3 (Morishita et al., 2020), News Commentary v16 (Tiedemann, 2012), Wiki Titles v3, WikiMatrix, Japanese-English Subtitle Corpus (Pryzant et al., 2018), The Kyoto Free Translation Task Corpus, and TED Talks. As the English translation of the Japanese-English Subtitle Corpus is only available in lowercase, we trained a Moses truecaser (Koehn et al., 2007) using the other corpora to add capitalization into the subtitle corpus. After truecasing, the first letter of each sentence was capitalized using detruecasing to produce sentence-cased English text

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 244 - 250
December 7-8, 2022 ©2022 Association for Computational Linguistics

to match the casing in the other corpora. We cleaned the data by removing duplicate lines and applying language filtering. As much of the training data was crawled from the internet, we used fasttext (Joulin et al., 2016a,b) to predict the language of each sentence and removed the sentences that were not predicted to be the correct language. This has the effect of reducing the noise of the dataset by removing sentences with garbage tokens. We tokenized the text into subword units using a joint vocabulary size of 64,000, a character coverage of 99.98%, and byte fallback using sentencepiece (Kudo and Richardson, 2018). After subword segmentation, all sentences shorter than 1 token or longer than 250 tokens were removed. We also removed all sentences where the number of tokens in one language was more than double the number of tokens in the translation, i.e the ratio of tokens between the source and target is >2.0. After filtering, 27,784,519 sentence pairs remained for training.

3 Translation System

3.1 Base Model

Our translation model is based on the Transformer big architecture (Vaswani et al., 2017) with an FFN size of 8,192 implemented in FAIRSEQ (Ott et al., 2019). The hyperparameters for our translation models are shown in Table 1.

Translation Model	
Architecture	Transformer big with FFN size of 8,192
Optimizer	Adam ($\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Inverse square root decay
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.3
Gradient Clipping	1.0
Label Smoothing	$\epsilon_{ls} = 0.1$
Mini-batch Size	512,000 tokens
Number of Updates	80,000 steps
Averaging	Save checkpoint for every 1,000 steps and take an average of last 10 checkpoints
Length Penalty	1.0
Beam Size	10
Reranker Model	
Architecture	Transformer big with FFN size of 8,192
Optimizer	Adam ($\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Inverse square root decay
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.3
Position Embeddings	SHAPE ($K = 512$)
Gradient Clipping	1.0
Label Smoothing	$\epsilon_{ls} = 0.1$
Mini-batch Size	512,000 tokens
Number of Updates	80,000 steps
Averaging	Save checkpoint for every 2,000 steps and take an average of last 10 checkpoints

Table 1: Hyperparameters of our translation and reranker models.

3.2 kNN-MT

kNN-MT (Khandelwal et al., 2021) extends the decoder of a trained machine translation model using the k-nearest-neighbor search algorithm, and retrieves the cached translation examples. The method consists of two steps, *datastore creation*, which creates key-value translation memory, and *generation*, which calculates an output probability distribution based on the nearest neighbors of cached translation memory.

Datastore creation The typical NMT model is composed of an encoder that encodes the source sentence X and a decoder that generates target tokens $Y = (y_1, y_2, \dots, y_I)$. Each target token y_i is generated based on its output probability $P(y_i|X, y_{<i})$. kNN-MT caches parallel text $\mathcal{D}$ in a datastore represented as key-value memory $\mathcal{M}$. The value is a token y_i that comes from a target sentence in a parallel corpus, and the key is its intermediate vector h_i of each time step computed by the decoder. The datastore is formulated as follows:

$$\mathcal{M} = \{(h_i, y_i), \forall y_i \in Y \mid (X, Y) \in \mathcal{D}\}. \quad (1)$$

In our model, we use the 1024-dimensional vector representation from the decoder before it is passed to the final feed-forward network as the key h_i.

We use FAISS (Johnson et al., 2019), which is a toolkit for kNN search, to represent the datastore and search for the nearest neighbors. We use the `OPQMatrix` vector transform, `IndexIVFPQ` index, and `IndexFlatL2` index as the coarse quantizer. The hyperparameters of our search index are shown in Table 2.

Generation During decoding, kNN-MT generates output probabilities by computing the linear interpolation between the kNN and MT probabil-

Type	Value
Shape of OPQ matrix	$\mathbb{R}^{1024\times1024}$
Number of clusters (IVF)	65,536
Number of sub-vectors (PQ)	64
Number of clusters to search	64
Number of top-k neighbors	16

Table 2: Hyperparameters of our search index.

ity distributions,

$$P(y_i|X, y_{<i}, \theta) = \lambda p_{\text{kNN}}(y_i|X, y_{<i}, \theta) + (1-\lambda)p_{\text{MT}}(y_i|X, y_{<i}, \theta), \tag{2}$$

where λ is a hyperparameter for weighting each probability and θ represents the trained weight parameters and we set $\lambda = 0.4$

The k-nearest-neighbor keys $\mathcal{N}$ are converted into a distribution over the vocabulary p_{kNN} by applying softmax function.

$$p_{\text{kNN}}(y_i|X, y_{<i}, \theta) \propto \sum_{(k_j, v_j)\in\mathcal{N}} \mathbb{1}_{y_i=v_j} \exp\left(\frac{-||k_j - h_i||_2^2}{\tau}\right), \tag{3}$$

where k_j and v_j are the top-j neighbor key and value respectively and τ is a hyperparameter that represents the temperature of softmax and we set $\tau = 100$.

3.3 Back-Translated Monolingual Datastore

Our kNN-MT system uses back-translated monolingual data for the datastore instead of bilingual corpora. This method allows us to use monolingual resources without any additional training. First, we use the bilingual corpora to train a target-to-source translation model, which is then used to back-translate the monolingual corpora. The back-translated synthetic source sentences are then passed through the source-to-target model, which generates the intermediate vectors for each decoding time step to fill the datastore.

The monolingual data for English was taken from News Commentary v16 (Tiedemann, 2012), Europarl v10, Leipzig's news corpora (2018-2020), news-typical (2016), newscrawl and newscrawl-public (2018), web and web-public (2018-2020), and the largest available size of wikipedia corpus from each year for a total of over 26 million sentences. The monolingual data for Japanese includes News Commentary v16 (Tiedemann, 2012), and all Leipzig news, newscrawl, web, web-public, and wikipedia corpora from 2014 to 2021, totaling over 15 million sentences.

	Japanese	English
# of sentences	15,051,874	26,237,110
# of tokens	396,647,042	690,734,548

Table 3: Monolingual data statistics.

We preprocessed the monolingual data much the same way as the bilingual data, removing duplicate lines and using fasttext to filter out sentences where the predicted language did not match the target language. The text was tokenized into subword units using the model trained on the bilingual corpora. In order to reduce the time for the back-translation, sentences with more than 200 tokens were removed from the monolingual data. Table 3 shows the monolingual data statistics after preprocessing. Note that the number of tokens is equal to the size of the resulting kNN datastore for each target language.

3.4 kNN-MT with Ensemble Model

We integrate kNN-MT into the ensemble model. We train Transformer big models with different random seeds, just as we would build a normal ensemble model. Because the kNN search is too computationally expensive, we randomly pick a model instance and use it for the search as follows:

$$\begin{aligned} &P(y_i|X, y_{<i}, \theta_1, \dots, \theta_M) \\ &= \lambda p_{\text{kNN}}(y_i|X, y_{<i}, \theta_1) \\ &+ \frac{1-\lambda}{M}\sum_{m=1}^{M} p_{\text{MT}}(y_i|X, y_{<i}, \theta_m), \end{aligned} \tag{4}$$

where M is the number of model instances for the ensemble, and we set $M = 4$.

4 Reranker

Our reranker selects one of the n-best translation candidates from the translation system. Similar to other rerankers, it computes the weighted sum of multiple model scores for each translation candidate and selects the candidate with the maximum score. We used the average log-likelihoods of the

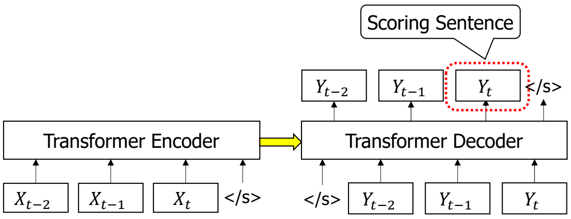

Figure 2: Context-aware model (context length $\ell = 2$).

words in each document as the model scores:

$$\hat{D} = \operatorname*{argmax}_{Y_{t=1}^{T}} \left\{ \sum_k w_k \frac{\sum_{t=1}^{T} \sum_{i=1}^{|Y_t|} \mathcal{L}_k(y_{t,i})}{\sum_t |Y_t|} \right\}, \tag{5}$$

where D denotes a set of document translations, which consists of T translations ($D = Y_{t=1}^{T}$), and Y_t is the t-th translation in the document. $y_{t,i}$ denotes the i-th token in the translation Y_t, in which the number of tokens is $|Y_t|$. $\mathcal{L}_k(y_{t,i})$ denotes the log-likelihood of the token $y_{t,i}$ scored by the k-th model, and w_k is the weight of the k-th model.

The weights of the model scores were trained to maximize the BLEU score of the development set. We used k-best batch MIRA (Cherry and Foster, 2012) to optimize the weights.

4.1 Reranking Models

A characteristic of our reranker is the use of context-aware model scores, which are the log-likelihoods calculated per document of the test (or development) set. By taking the context into consideration during scoring, we expected to improve the consistency of the translation throughout each document.

We use an N-to-N translation model of Tiedemann and Scherrer (2017) as the context-aware model, which translates multiple concatenated sentences. Figure 2 illustrates the context-aware model in which the context length is two sentences ($\ell = 2$). The model computes the log-likelihood of the target translation Y_t using preceding ℓ sentences; that is,

$$\mathcal{L}_k(y_{t,i}) = \log p_k(y_{t,i} | X_{t-\ell}^{t}, Y_{t-\ell}^{t}), \tag{6}$$

where $p_k(\cdot)$ denotes the likelihood computed by the k-th model, and $X_{t-\ell}^{t}$ and $Y_{t-\ell}^{t}$ denote the source sentences and their translations from $t - \ell$ to t, respectively.

We used five models in total: the score from our translation system, and a combination of source-to-target and target-to-source translation and left-to-right (L2R) and right-to-left (R2L) decoding directions.

We trained the R2L models by reversing the order of the target tokens. Although the order is the same during scoring, we reversed the target tokens after concatenating multiple sentences. Therefore, the sentence order of the target side becomes (Y_t, Y_{t-1}, Y_{t-2}). Note that the scoring sentence is the last sentence (Y_{t-2}), and the R2L models score sentences later than the L2R models.

4.2 Training and Reranking

We used only the parallel corpora described in Section 2 and trained Transformer big models (Vaswani et al., 2017) with an FFN size of 8,192 for reranking. However, the trained models were sentence-wise models because we did not use document information in the training corpora. To apply the sentence-wise models to the N-to-N translation, we modified it using the following techniques.

- We did not use sentence separators (e.g., '[SEP]' between sentences) because the sentence-wise models did not include such separators.

  In the reranking task, we know the target tokens in advance, and we can easily identify the tokens for the target sentence, which we are scoring, without the separators.

- In the N-to-N translation, we had to score long translations because we simply concatenated multiple sentences during inference using a sentence-wise model which was not aware of the concatenated sentences. To learn appropriate models for long translations from sentences, we used the shifted absolute position embeddings (SHAPE) (Kiyono et al., 2021) to make a model invariant to absolute positions. The maximum shift was 512.

For the hyperparameters for the reranking models, we used the same setting as Kiyono et al. (2020) (Table 1).

To search for the best translations while considering context, we applied the beam search method to search for the translations that satisfied Eq. (5). We used a beam width of 10.

	En-Ja	Ja-En

5 Results

5.1 Translation System

Ablation Study To validate the effectiveness of our translation system, we performed an ablation experiment. Table 4 shows the experimental result on newstest 2020. Note that this experiment does not use a reranker system, and we evaluated the 1-best translation. The result shows that both ensemble and kNN-MT are effective, and combining them further improves translation performance.

kNN-MT Datastore As noted in Section 3.3, our kNN-MT datastore uses different data than the training corpus. We evaluated the translation performance of kNN-MT on a single Transformer model without ensemble. Table 5 shows the comparison of the kNN-MT datastore evaluated on newstest 2020. In the table, 'No Datastore' indicates that kNN-MT is not used, and 'Training Data' and 'BT Monolingaul Data' indicate that the datastore is constructed from training data and back-translated monolingual data, respectively. As shown in the table, our 'BT Monolingual Data' datastore outperforms the datastore constructed from the training data, despite its smaller size.

5.2 Context Length at Reranking

Table 6 shows the BLEU scores according to the reranking method. 'No Reranking' indicates the best translations output from the translation system. 'Oracle' always chooses the translation with the highest sentence BLEU score from the n-best translation candidates and represents the output of a perfect reranking system. The other cases indicate the BLEU scores of our reranker of varying context lengths ℓ.

The results show that our reranker improved the BLEU scores from the 'No Reranking' case, except for the case of Ja-En in newstest2020. However, the context length did not affect the BLEU scores. (We submitted the case of $\ell = 2$.) The BLEU scores of the reranker were still lower than that of 'Oracle', and future work will include studying the context-aware models to improve it further.

5.3 Placeholders

This year, the test set for the General MT task contained a set of placeholder tags, which should be output without translation. However, the provided parallel corpora for the task did not contain these special tokens. To solve this problem, we built a training set with placeholders using the existing parallel corpora.

We focused on the WikiTitles corpus, which is a subset of the parallel corpora provided for the General MT task. Most bitexts in WikiTitles are named entities because the corpus was extracted from Wikipedia titles. We substituted the parts that matched the WikiTitles entries with the placeholders.

In detail, we only extracted WikiTitles entries of five characters or more in Japanese and 10 characters or more in English from the parallel cor-

			Translation	
Direction	Placeholder (PLH)	Source	Base	PLH
En-Ja	#NAME#	3	2	3

	#Person#	1	1	1
	#Product1#	116	79	116
	#Product2#	42	26	40
	#Product3#	7	4	7
	#Product4#	2	2	2
	#Product5#	2	2	2
	#Product6#	2	2	2
	#URL#	5	5	5
	#URL1#	1	0	1
	BLEU	-	22.7	22.7

Table 7: Results of placeholder translation.

pora using the longest match, and substituted the matched parts with the placeholders. (We used only one placeholder type: '#PLACEHOLDER#'.) Note that we excluded parallel sentences in Wiki-Titles from the parallel corpora in advance. As a result, we obtained additional 1.7 million parallel sentences that contained the placeholders and used them for training and fine-tuning.

During fine-tuning the translation system, we set an unused token in the vocabulary to the placeholder tag, and fine-tuned our translation models with a combination of data from the original training data (without placeholders) and the new data with the placeholders for two additional epochs from the averaged checkpoints.

Our placeholder corpus contained only a single placeholder tag instead of the rich variety of tags contained in the test set. We resolved this during the translation of the test set by first replacing all placeholder tags with our placeholder (#PLACEHOLDER#) before translation. After translation, we identified and replaced our #PLACEHOLDER# tag with the original tag from the source sentence. In the case of multiple placeholder tags in the same sentence, we preserved the original order when converting them back into the test placeholder tag set.

Table 7 shows the results of placeholder translation; that is, the number of placeholders and the BLEU score for the wmttest2022 test set. 'Base' and 'PLH' indicate translation using the model without/with fine-tuning on the placeholder corpus, respectively. The 'Base' model failed to translate some placeholders because it processed the placeholders as strings and translated them after subword segmentation. By contrast, the 'PLH' model translated the placeholders almost perfectly. However, the model fine-tuned on the placeholder corpus did not improve the BLEU scores, and we submitted the result of the 'Base' model.

6 Conclusions

In this paper, we described our submission of the joint team of NAIST, NICT, and TIT (NAIST-NICT-TIT) to the WMT22 general MT task. We participated in this task for the En ↔ Ja translation. Our system is built on an ensemble of Transformer big models, kNN-MT with using monolingual data, and k-best batch MIRA reranker. We would like to investigate each method and further improve translation performance.

Abstract

This paper presents the system description of Samsung R&D Institute Poland participation in WMT 2022 for General MT solution for medium and low resource languages: Russian and Croatian. Our approach combines iterative noised/tagged back-translation and iterative distillation. We investigated different monolingual resources and compared their influence on final translations. We used available BERT-like models for text classification and for extracting domains of texts. Then we prepared an ensemble of NMT models adapted to multiple domains. Finally we attempted to predict ensemble weight vectors from the BERT-based domain classifications for individual sentences. Our final trained models reached quality comparable to best online translators using only limited constrained resources during training.

1 Introduction

Samsung R&D Institute Poland (SRPOL) participated in the WMT 2022 General MT task for three translation directions: EN→RU, RU→EN and EN→HR. All our systems were built using only constrained datasets. In contrast to previous years, where the task focused on news translation, this year's task was domain-independent. However, MT models benefit a lot from domain adaptation. Therefore, we decided to prepare an ensemble of NMT models adapted to multiple domains to benefit from domain adaptation and improve generalization. We prepared a news profiled model but also a general-purpose one. Additionally, we worked on medical and legal domains; however, there was very limited in-domain data in the constraint path for this domains and we had to extract pseudo in-domain data from monolingual corpora.

Our system was implemented using Marian framework. The core of the submitted solution is iterative back-translation and iterative distillation combined with finetuning and ensembling. Besides, we used BERT models for data filtering to prepare corpora for training domain-adapted models. Finally, we created dynamic ensemble weighting to choose the best combination of single models in the final translations. All techniques combined allowed us to improve baseline models by 3-6 BLEU (Papineni et al., 2002) and reach the quality comparable with online translators (measured by BLEU).

2 System overview

2.1 MT model

Our models were trained with the Marian NMT (Junczys-Dowmunt et al., 2018) toolkit. We used Marian for training, back-translation, noise generation, language models and data filtering.

The training was performed on a *transformer-big* model (embedding dimension of 1024 and a feed-forward layer dimension of 4096) (Vaswani et al., 2017). We experimented with different sizes of models and different configurations of encoder-decoder layers, but we achieved no significant improvement over the default *transformer-big* configuration. Most models had a setup of either 7-5 or 8-4 encoder-decoder layers. Best single models were trained with FF layer dimension 6144, but the improvement was marginal – 0.1 BLEU better than the default dimension of 4096.

Our training used batches of size 256GB (8xGPU, 32GB workspace). The optimizer was Adam (Kingma and Ba, 2015) with a learning rate of 0.0003 and linear warm-up for the initial 40 000 updates with subsequent inverted squared decay. A few initial EN↔RU training were regularized with dropout 0.1, but the following did not use any dropout. All training for EN→HR had the dropout set to 0.1.

2.2 Iterative training process

Iterative back-translation (Hoang et al., 2018) is a known technique of improving performance of

[*] Work done while at Samsung R&D Institute Poland.

MT models. Iterative distillation approach applied by NiuTrans (Zhou et al., 2021) allowed them to achieve impressive results in WMT21. During our work we combined both techniques in parallel during each iteration.

First baseline models were trained using only provided parallel corpora. Further training iterations were enriched with back-translation (iterative back-translation). With each iteration we used new back-translation prepared by best ensembles translating from target to source.

After a few iterations of iterative back-translation we started iterative distillation. Training corpus was enriched with corpora distilled from best ensembles. (→ 3.3). As a result the whole corpus consisted of parallel part, back-translated part and distilled part.

After training iteration converged we finalized the iteration with additional tuning using parallel corpora or specialized tuning corpora (→ 3.4). After the tuning we selected a new best ensemble containing the new trained model. The best ensemble was chosen by selecting the best performing on Flores devtest (Goyal et al., 2022) and Newstest 2021. With this new ensemble we prepared new back-translation and a new distilled corpus for next iterations.

Algorithm 1 Iterative training process

```
procedure ITERATEDTRAININGS

        $M_{enru}$ ←getBestEns($models_{enru}$)

    end while
end procedure
```

2.3 Domain adaptation

WMT 2022, for the first time, allowed the usage of pre-trained masked language models (MLM; exclusively in BERT-based architecture). We leveraged them to extract domain-specific subsets of mono and parallel corpora to fine-tune our NMT models in two chosen domains: *legal* and *medical*. We divide our approach into three steps: 1) Rule-based seed extraction, 2) Iterative Classifier training 3) Domain corpora extraction. Domain adaptation was performed only for the EN↔RU language pair. Finally, we used corpora described in Section 2.3.4, to adapt to the competition test sets.

2.3.1 Rule-based seed extraction

Our work focuses on two non-news domains: *medical* and *law*. We prepared initial monolingual (EN) seed corpora based on handcrafted rules and manual filtering. The datasets were too small to perform fine-tuning of MLM; therefore, we added an intermediate step. We encoded the sentences using general-purpose BERT (Devlin et al., 2019) and applied a K Nearest Neighbours (KNN) classifier to filter the extended version of the initial corpora. The extended version was extracted using the same rules but without manual filtering.

2.3.2 Iterative Classifier training

We base our approach on tri-training (Zhou and Li, 2005; Ruder and Plank, 2018). Rule-based extracted seed serves as the training data, and the manually filtered examples are the test set. In contrast to the original tri-training, we enlarge our training dataset after training the three classifiers instead of continuously adding new examples during training (we call this an iteration). Due to time constraints, we performed two such iterations per domain. The classifiers are fine-tuned BERT models, yet domain-specific ones: Lee et al. (2019) for the *medical* domain and Chalkidis et al. (2020) – *legal*.

2.3.3 Domain corpora extraction

With the final ensemble of classifiers, we scored a subset of monolingual, English data (CommonCrawl) and parallel corpora, which was not used during the ensemble training. We raised a threshold for the classifiers to 0.9 and included a sentence to a domain using unanimous voting. The resulting monolingual/parallel corpora size is presented in Table 1.

	Domain	
Corpora	Medical	Legal
Monolingual	93.3	184.6
Parallel	5.1	135.5

Table 1: Size of extracted domain-specific corpora (in thousands)

2.3.4 Test set adaptation

The last step of domain adaptation was the WMT 2022 test set adaptation. Our main intention was to prepare a corpus based on sentences similar to those present in the competition test set. To achieve this goal, we used the KNN algorithm. The first step was creating a dataset consisting of sentence embeddings from the WMT 2022 test set and all constrained corpora. Embeddings were acquired using the BERT base model (cased) (Devlin et al., 2019). Afterwards, we applied the k nearest neighbours search. The parameters were selected empirically: the number of nearest neighbours was set to 20, and we chose the Euclidean distance metric. Finally, the candidates were picked by finding neighbours whose distance to a given sentence from WMT 2022 test set was lower than 1.2.

2.4 Dynamic ensemble weighting

For each given (expert-selected) collection of NMT models, two modes of ensemble translation were tested. In the standard mode, the entire test set is translated using the same "static" set of weights for ensemble components. Alternatively, we attempted to construct a regression model that would generate weights best suited to a given sentence type; we call this mode "dynamic". For this, we concatenated outputs from 3 BERT-based predictors, trained to classify sentences as belonging to legal, medical and news domain, respectively. The medical and legal predictors were as described in 2.3.2; the predictor for news domain was fine-tuned in the same way with the pretrained BERT model allenai/news-roberta-base. Because each predictor produced 6 strongly-correlated values, the resulting vectors underwent dimensionality reduction, before being passed as inputs to the weight regression model; the regression itself is a relatively simple affine transformation in the logit domain. We leveraged only English Bert models; therefore, in the RU→EN direction, we performed preliminary translation using some early ensemble and extracted the predictions from its English outputs; the Croatian task does not use weight optimization.

Because we could not perform a direct optimization of BLEU/chrF (Popović, 2015) with regard to ensemble weights (some sort of grid- or random-search would be possible, but was deemed too expensive), we settled on minimizing cross-entropy of reference translations. We experimented with two formulas for interpolation of probability distributions: in logarithmic-probability domain (more commonly found, e.g. in Marian), or in linear-probability domain.[1] However, because the minimization of cross-entropy in log-P domain will degenerate the ensemble to the single best model (it can be easily shown), we added the regularization parameter to optimization of this kind of ensembles. The regularization term penalizes the divergence from the uniform vector.

26k sentences were selected from the model training corpora as the training data, half of which was classified as news, the rest as legal, medical, or randomly sampled. Three validation sets were used: Flores, Newstest 2021 and training data held-out.

Static and dynamic weights were independently estimated using gradient-descent for a handful of different ensembles in each direction; the general observations on development sets were the following:

- for each of the directions, two different vectors/transforms seem to be optimal, depending on the development set (one for Flores, another for Newstest 2021 and held-outs)
- the impact of the interpolation model (log-P vs linear-domain) is moderate, usually with small advantage of log-P, except for EN→RU Flores where linear yields ca. +0.22 BLEU
- the impact of the dynamic weighting is minimal, giving 0.09 BLEU improvement on RU→EN direction, with 0.1–0.3 BLEU degradation on top EN→RU configurations.

For final submission, in RU→EN direction we used static ensembles as described; however, in EN→RU task we made a last-minute decision

[1] We added an in-house extension to Marian-NMT that implements this alternative ensemble interpolation (i.e. done in the linear-probability domain); a patch that facilitates running ensemble translations with a weight vector different for every sentence was also implemented.

to scrap automatically-derived weights and used expert-crafted ensembles (obviously, also static).

We conjecture that the reason for the limited benefits from the above experiments lies in the indirect optimization of BLEU through cross-entropy, as well as – in the dynamic approach – in small actual distinctiveness of domain-specific data.

3 English-Russian

All corpora were preprocessed by removing sentences of inappropriate languages, normalizing punctuation, replacing all Russian letters ё (yo) with е (ye), removing duplicate sentences.

3.1 Parallel corpora

During the training, we used all accessible English-Russian parallel data except UEDIN back-translated news corpus. This corpus was used only during the first training iteration before generating any new back-translated data. Later it was excluded from training because it was worsening the results. We filtered sentence pairs where the length ratio between source and target sentences exceeded 1.6. Paracrawl (Bañón et al., 2020) paragraphs consisting of more than one sentence were split into single sentences and appended to the original dataset.

We used our in-house rule-based filtering, but we did not detect improvement but worsened quality over not-filtered data. Similarly, inferior results were obtained by applying Cross-Entropy Filtering (Junczys-Dowmunt, 2018). Therefore, we used unfiltered data during most of the training process.

3.2 Monolingual corpora

We used the monolingual corpora in two ways: to train language models and to augment the parallel data with back-translated data. Back-translation (Sennrich et al., 2016) is a commonly used technique for improving machine translation, especially for low-resource languages (Edunov et al., 2018).

We chose three different sources of monolingual corpora and preprocessed them similarly to parallel data (with minimal preprocessing). The used corpora are:

- News crawl
- CommonCrawl
- News-CommonCrawl

All corpora were filtered by a language model trained on the same corpus leaving only sentences with a likelihood larger than 1e-5. Due to the poor quality of CommonCrawl, we used only lines/paragraphs containing three or more sentences, which we split into single sentences.

News-CommonCrawl is the same filtered CommonCrawl but additionally filtered by a fastText[2] model trained on 100k news sentences from News crawl and 100k sentences from CommonCrawl. Using this model, we selected sentences classified by fastText as news (Joulin et al., 2017).

During all training iterations, except the first, we back-translated monolingual data using the best ensembles of currently trained models. We used clean back-translation as well as noised (Edunov et al., 2018) and tagged back-translation (Caswell et al., 2019). We applied gumbel noise for noised back-translation, as implemented in Marian, changing the epsilon value from default 1e-5 to 1e-3.

3.3 Teacher-Student Knowledge Distillation

Distilled corpora were prepared by translating parallel corpora using best ensembles in the direction of training with a beam equal to eight and selecting two translations most similar to the original translation. Such corpus was added to the parallel corpus expanding it three times.

3.4 Tuning corpora - FLORES

Despite poor results of standard filtering, we experimented with modified filtering versions during further iterations. We finally found the following filtering by marian-scorer that applied to parallel corpora improved results in some of the final training iterations.

- Language model filtering - Using a language model trained on a monolingual corpus we filtered utterances for which the normalized likelihood of the target side was higher than 1e-5.
- Backward cross-entropy filtering - Using the backward translation model, we filtered only sentence pairs where target to source translation normalized likelihood was larger than 1e-2.

The filtering described above was not applied to the Wikititles corpus.

[2] https://fasttext.cc

3.5 Tuning corpora - NEWS

Models adapted for news were finetuned by two consecutive tuning iterations using the following corpora:

1. Paracrawl and News Commentary
2. News Commentary and all Newstests from WMT2012-20

3.6 Contextual corpus and decoding

The corpus used for contextual training translation was built of two parts:

- Parallel utterances from News Commentary containing 2-4 subsequent sentences.
- Sequence of 2-4 adjacent sentences from one paragraph of CommonCrawl monolingual corpus, back-translated sentence by sentence. The back-translated part was tagged.

During decoding, we translated a sentence four times:

- without a context
- with one preceding sentence
- with two preceding sentences
- with two preceding and one following sentence

From the four above translations, we chose the translation most similar to 3 others using Levenshtein distance (Levenshtein, 1965) as a similarity metric.

4 English-Croatian

We applied similar preprocessing as for Russian language. Additionally to all available EN-HR corpora from OPUS (Tiedemann, 2012) we added all available data for Serbian language to the training. We used custom validation set based on TED for first iterations and WMT22 dev set for last two iterations. We added directional tokens in front of each sentence that allowed to differentiate between Croatian and Serbian translation.

For back-translation we used news mono corpora and source language from all EN-HR parallel corpora as well. Additionally to the back-translated corpora we added EN-HR parallel data. We performed two iterations of back-translation. After training of first iteration with back-translated data we fine-tuned the model on all parallel EN-HR data. After training of the second iteration we fine-tuned the model on CCMatrix corpus (Schwenk et al., 2021). The back-translation was noised with gumbel noise.

After the above we started to apply knowledge distillation and fine-tuning the model on distilled data. We did only 2 iterations of distillation. First distillation was done on CCMatrix corpus and second on tuning corpus (created from DGT, QED, TedTalks, EuroPat, SETIMES, hrenWaC, TED2020 corpora). We experimented with different learning rates in order to find the best performing model after this step. Finally, we made an ensemble out of the best-performing models. Additionally, we found that a normalization value of 0.5 results in a better score.

5 Results

Results of training iterations for English to Russian are presented in Table 2. Table 3 presents results for the Russian to English direction. Finally, Table 4 presents results for the English to Croatian task. Abbreviations mean:

- BTN - noised back-translation
- BTT - tagged BT
- BTTN - tagged noised BT
- KD - training with distilled parallel corpus
- news / cc / ncc - back-translated corpus
  - News crawl
  - CommonCrawl
  - News-Commoncrawl

First iteration was trained using only constrained parallel corpora provided by organizers. Next iterations were trained on mixed parallel corpora combined with back-translated monolingual data (BT). Further iterations used also distilled forward translations (KD).

Tuning with domain adaptation corpora has improved slightly (0.1-0.2) some of single models but gave no noticeable improvement on final score of ensembles.

6 Conclusions

We confirmed that iterative knowledge distillation combined with iterative back-translation is sufficient to prepare high-quality translation models.

Table 4: Iterations and results of training for EN→HR direction.

This method gives excellent results on low-resource and mid-resource languages. During the WMT 2022 General MT task, we reached one of the best results among constrained systems.

In our work, we compared different methods of back-translation: clean, noised, and tagged. Mostly, the tagged back-translation achieved the best results, but for some training iterations, noised back-translation's results were on-par or better.

We compared different sources of monolingual data used for back-translation: CommonCrawl and News crawl. The comparison suggests that the choice of the monolingual corpus has a significant influence on final results.

Our exploration of different filtering methods suggests that while using pre-filtered data (as provided in WMT 2022), it is sufficient to filter only target data, leaving source data unfiltered.

We presented a simple and effective method of adding contextual data to the training corpus, which gave a noticeable improvement.

We investigated a new method of dynamic ensemble weighting, but the results show no improvement over other methods.

Limitations

In our work we touched on a few aspects but did not have time to address them in more detail.

The research showed that tagged back-translation generally gives better results than other back-translation methods, but not always. It may be worth to investigate more deeply methods of different noising, different noise level and how it synergies on various parallel and monolingual corpora.

Almost all our training iterations were performed on very similar default transformer-big configurations. We haven't tested other configurations, larger or deeper models, different training parameters, what can improve the results.

We introduced very simple contextual translation method which can be improved in many ways.

We gained best results filtering data only on target size, leaving source data unfiltered. This issue looks worth to be investigated.

Ethics Statement

During our work we followed all the rules of ACL Ethics Policy

All our efforts aimed at conducting research for the benefit of society and to human well-being. During our research we used only fair and honest methods. We didn't hide any information needed to repeat our results. We didn't use any resources out of the data provided by organizers in constrained path.

Abstract

This paper describes Tencent AI Lab - Shanghai Jiao Tong University (TAL-SJTU) Low-Resource Translation systems for the WMT22 shared task. We participate in the general translation task on English⇔Livonian. Our system is based on M2M100 (Fan et al., 2021) with novel techniques that adapt it to the target language pair. (1) Cross-model word embedding alignment: inspired by cross-lingual word embedding alignment, we successfully transfer a pre-trained word embedding to M2M100, enabling it to support Livonian. (2) Gradual adaptation strategy: we exploit Estonian and Latvian as auxiliary languages for many-to-many translation training and then adapt to English-Livonian. (3) Data augmentation: to enlarge the parallel data for English-Livonian, we construct pseudo-parallel data with Estonian and Latvian as pivot languages. (4) Fine-tuning: to make the most of all available data, we fine-tune the model with the validation set and online back-translation, further boosting the performance. In model evaluation: (1) We find that previous work (Rikters et al., 2022) underestimated the translation performance of Livonian due to inconsistent Unicode normalization, which may cause a discrepancy of up to 14.9 BLEU score. (2) In addition to the standard validation set, we also employ round-trip BLEU to evaluate the models, which we find more appropriate for this task. Finally, our unconstrained system achieves BLEU scores of 17.0 and 30.4 for English to/from Livonian.[1]

1 Introduction

This paper introduces our submissions to the WMT22 general machine translation task. Last year, Tencent AI Lab participated in two translation tasks: News (Wang et al., 2021a) and Biomedical translation (Wang et al., 2021b). This year, we participate in English⇔Livonian (En⇔Liv), a very low-resource and distant language pair. Considering the scarcity of parallel En-Liv corpus, we only participate in the unconstrained evaluation.

We use M2M100 1.2B[2] (Fan et al., 2021) as the pre-trained model which is a massive multilingual translation model that supports any pair of 100 languages[3] and shows promising performance for low-resource translation. To adapt it to En-Liv, the first thing to do is enabling it to support Liv. A common approach is to expand the vocabulary and the word embedding matrix to contain the extra tokens. However, the incoming embeddings must be randomly initialized (Garcia et al., 2021; Bapna et al., 2022), which leads to inconsistency with the original embeddings and increases training difficulty. Fortunately, Rikters et al. (2022) has released a translation model for En-Liv called Liv4ever-MT[4]. Inspired by supervised cross-lingual word embedding alignment (Lample et al., 2018b), we propose cross-model word embedding alignment (CMEA) that learns a linear transformation between the embedding matrices of two models. Therefore, the incoming embeddings can be extracted from Liv4ever-MT and transformed to M2M100's word embedding space rather than random initialization.

In terms of model training, we adopt a gradual adaptation strategy. The overall training process is shown in Figure 1. Following Rikters et al. (2022), we also use Estonian (Et) and Latvian (Lv) as auxiliary languages. Liv has been influenced by Et and Lv for centuries. There are about 800 Et loanwords and 2,000 Lv loanwords in Liv (Décsy, 1965). Therefore, we first add Et and Lv for many-to-many translation training, resulting in a 4-lingual

[*] Work was done when Zhiwei He was interning at Tencent AI Lab.

translation model. We then augment the En-Liv data with forward and backward translations using Et and Lv as the pivot languages. Finally, we combine all the authentic and synthetic data to retrain the model, followed by a few steps of fine-tuning with the validation set and online back-translation.

In terms of model evaluation, we find that the data set provided by Rikters et al. (2022) suffers from inconsistent Unicode normalization. This inconsistency is reflected in using two or more encodings for the same character, which leads to inconsistent encoding between model hypothesis and reference[5] and thus inaccurate evaluation. In our experiments, normalizing the character encoding can bring an average improvement of +2.5 BLEU on the liv4ever[6] test set (see appendix A) and up to +14.9 BLEU on a subset from a specific source. In addition to the standard validation set, we also employ round-trip BLEU to evaluate our models, which is an effective unsupervised criterion (Lample et al., 2018a) and reduces the demand for the parallel corpus. Zhuo et al. (2022) have found that in the scope of neural machine translation, round-trip translation quality correlates consistently with forward translation quality. We consider round-trip BLEU a better evaluation method for this task. The reasons for this are threefold: more data, more general domain, and the same original language as the WMT22 En-Liv test set.

This paper is structured as follows: Section 2 describes the data statistics and processing methods. Then we present our evaluation methods in Section 3. Our translation system and ablation study are detailed in Section 4, followed by the final results. Finally, we conclude the paper in Section 5.

2 Data and Processing

2.1 Overview

Statistics Table 1 lists statistics of the parallel and monolingual data we used. We collect parallel data for any pair in {En, Liv, Et, Lv} and collect monolingual data for En and Liv.

Data	Lang	# Sent.	
		Raw	Filter
Parallel Data	En-Liv	1.2K	1.1K
	En-Et	40.3M	20.7M
	En-Lv	27.2M	11.3M
	Liv-Et	14.8K	14.8K
	Liv-Lv	12.4K	12.2K
	Et-Lv	10.7M	7.0M
Monolingual Data	En	325.6M	281.3M
	Liv	138.2K	50.2K

Table 1: Statistics of parallel and monolingual data. We report the number of sentences before and after filtering.

Data Source The parallel data is mainly all available corpora from OPUS[7]. Due to the scarcity of data, we include liv4ever-dev in training data and use liv4ever-test as the validation set. For En-Et and En-Lv, we augment them with the parallel data from WMT18 and WMT17, respectively. For En-Liv, En-Lv and Liv-Lv, we collected additional parallel data from Facebook posts of the Livonian Institute and Livones.net[8]. The monolingual En is News Crawl 2007-2021. The monolingual Liv combines all Liv from parallel data and monolingual data from liv4ever[6].

2.2 Pre-processing

To obtain higher quality training data, we employ a series of data cleaning using Moses toolkit[9] and our scripts[10]. We process parallel data as follows:

- Replace Unicode punctuation, normalize punctuation and remove non-printing characters
- Language identification and filtering
- Remove instances with too much punctuation
- Remove instances with identical source and target sentences
- Remove instances containing URLs
- Remove instances appearing in evaluation data
- Remove instances with more than 175 tokens or length ratio over 1.5

The liv4ever corpus has a small amount of data, and the existing tools may not support Liv well. Therefore, for the liv4ever corpus, we don't apply punctuation processing or language and length ratio filtering. For the monolingual data, we use the same cleaning steps as parallel data except for

[5] SentencePiece does uniform normalization by default. Therefore, the character encoding in the model hypothesis is uniform but may not be consistent with the reference.

[6] https://opus.nlpl.eu/liv4ever-v1.php

[7] https://opus.nlpl.eu/

[8] The numbers of additional sentences collected from Facebook are En-Liv: 54, En-Lv: 61 and Liv-Lv: 61.

[9] https://github.com/moses-smt/mosesdecoder

[10] https://github.com/zwhe99/corpus-tools

identical source-target filtering and length ratio filtering.

After cleaning the data, we apply SentencePiece[11] encoding using the trained model from Liv4ever-MT[4]. We also reuse their vocabulary that shared by all languages.

2.3 Evaluation Data

We regard the liv4ever-test as the validation set, which is a multi-way data set for {En, Liv, Et, Lv} containing 855 unique sentences. Besides, for En⇔Liv evaluation, we collect monolingual English from the source of WMT22 English-German (En-De) test set to compute round-trip BLEU (En⇒Liv⇒En).

3 Model Evaluation

This section describes our methods for model evaluation. Specifically, we explain the Unicode inconsistency problem in the liv4ever data set and the resulting underestimation of model performance. In addition, we introduce round-trip BLEU as the more appropriate way for this competition.

3.1 Unicode inconsistency problem

Rikters et al. (2022) collected the liv4ever data set and built Liv4ever-MT, the first machine translation model for Livonian. We find that the liv4ever data set does not use consistent Unicode normalization, resulting in different encodings for the same character. This did not lead to any training problem in Rikters et al. (2022) because SentencePiece does NFKC[12] normalization by default. However, when computing SacreBLEU[13], the encoding of model output and the reference will be inconsistent, resulting in inaccurate evaluation.

We re-evaluate the performance of Liv4ever-MT before and after normalizing the encoding of references to NFKC. Table 2 shows the SacreBLEU results[14] on the entire test set and a subset from Satversme. Before normalization, our results are very close to those reported in Rikters et al. (2022), while after normalization, the BLEU score improves considerably. In particular, the difference in BLEU score is up to 14.9 on the Lv⇒Liv of the Satversme subset. Therefore, we report SacreBLEU after normalization in the following.

	En-Liv		**Et-Liv**		**Lv-Liv**	
	⇒	⇐	⇒	⇐	⇒	⇐
			All			
Liv4ever-MT (Rikters et al.)	11.0	19.0	16.5	23.1	17.7	25.2
Our Eval.	10.9	18.9	16.6	22.9	17.7	24.9
+ Norm. Ref.	**14.3**	**19.3**	**20.5**	**24.4**	**22.3**	**29.3**
			Subset (Satversme)			
Liv4ever-MT (Rikters et al.)	7.7	24.5	-	-	-	-
Our Eval.	7.6	24.7	7.2	18.7	9.2	19.4
+ Norm. Ref.	**18.2**	**25.8**	**19.9**	**23.7**	**24.2**	**33.6**

Table 2: BLEU scores of Liv4ever-MT on liv4ever-test. **Liv4ever-MT** (Rikters et al.): copied from Rikters et al. (2022). **Our Eval.**: We use the released Liv4ever-MT to generate translation outputs and re-evaluate them with the original references, which shows similar results compared with Rikters et al. (2022). **+ Norm. Ref.**: re-evaluation after normalizing the encoding of references to NFKC. See Appendix A for all language pairs.

3.2 Round-trip BLEU

We collect monolingual English from the source of WMT22 English-German (En-De) test set and conduct two steps translation: En⇒Liv⇒En. The round-trip BLEU score can be obtained by comparing the original input with the model output English. We regard it a better way to evaluate En⇔Liv performance for this task considering three aspects: (1) En-De test set has 20683 sentences, much more than the liv4ever-test. (2) It may contain more general domain data, while the liv4ever-test is relatively restricted due to the low-resource limitation. (3) The original language used in computing the round-trip BLEU is the same as the WMT22 En-Liv test set (both English-original).

4 System and Ablation Study

In this section, we describe our system in this competition and provide a comprehensive ablation study of the key components.

4.1 System Overview

We depict the overview of our system in Figure 1, which can be divided into five steps:

1. **Cross-model word embedding alignment**: transfer the word embeddings of Liv4ever-MT to M2M100, enabling it to support Livonian.

[11] https://github.com/google/sentencepiece

[12] https://unicode.org/reports/tr15/

[13] https://github.com/mjpost/sacrebleu

[14] nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.0.0

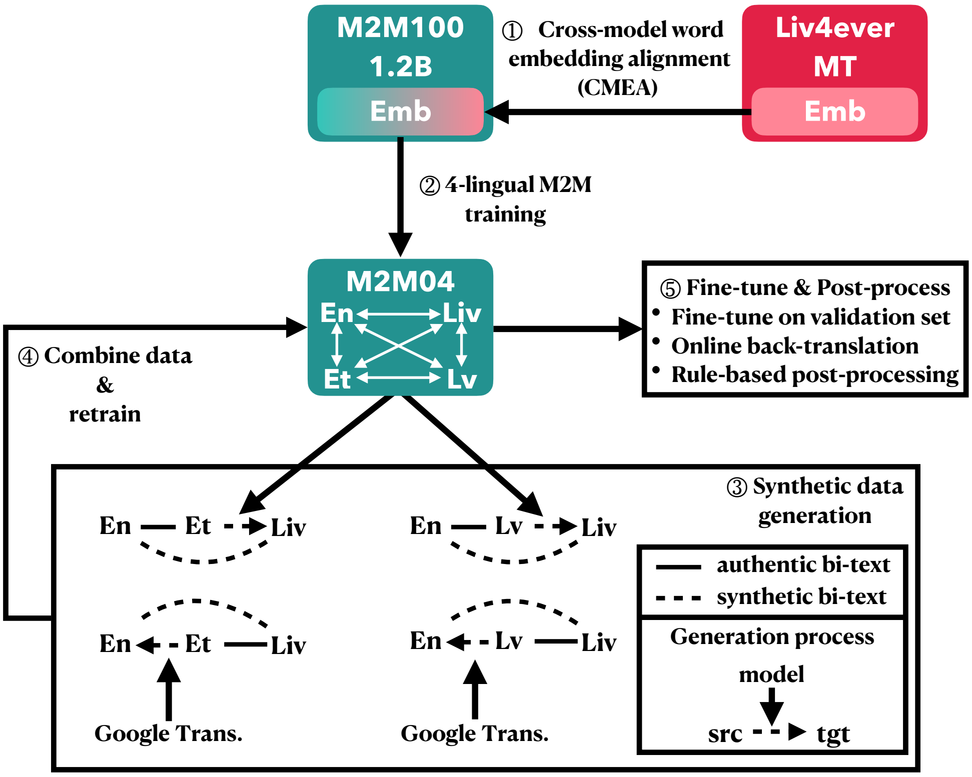

Figure 1: The training process of our translation system.

2. **4-lingual M2M training**: many-to-many translation training for all language pairs in {En, Liv, Et, Lv}, using only parallel data.
3. **Synthetic data generation**: generate synthetic bi-text for En-Liv, using Et and Lv as pivot languages.
4. **Combine data and retrain**: combine all the authentic and synthetic bi-text and retrain the model following step 2.
5. **Fine-tune & post-process**: fine-tune the model on En⇔Liv using the validation set and perform online back-translation using monolingual data. Finally, apply rule-based post-processing to the model output.

4.2 Cross-model Word Embedding Alignment

M2M100 1.2B does not support Livonian. Therefore, we used Liv4ever-MT's SentencePiece model and vocabulary to process all the data. For M2M100, the embeddings of new coming words can be randomly initialized. However, randomly initialized word embeddings and the pre-trained models may not be compatible. Inspired by supervised cross-lingual word embedding alignment (Lample et al., 2018b), we propose cross-model word embedding alignment (CMEA) to transform the trained word embeddings of Liv4ever-MT into M2M100, avoiding random initialization.

CMEA We denote Liv4ever-MT and M2M100 model by l and m. Their corresponding vocabularies and embedding matrices are d_l, d_m and $\mathbf{X}^l$, $\mathbf{X}^m$. Table 3 shows the statistics of the vocabularies. Let $\mathbf{X}^f$ be the final embedding matrix we expected. We adopt d_l as the final vocabulary, which can be divided into two parts:

$\lvert d_l \rvert$	$\lvert d_m \rvert$	$\lvert d_l \cap d_m \rvert$	$\lvert d_l \cap d_m \rvert / \lvert d_l \rvert$
47972	128108	11410	23.8%

Table 3: Statistics of Liv4ever-MT (d_l) and M2M100 (d_m) vocabularies.

$$d_l = (d_l \cap d_m) \cup (d_l - d_m). \qquad (1)$$

For the overlapped part $d_l \cap d_m$, $\mathbf{X}^f$ can reuse the embedding from $\mathbf{X}^m$:

$$\mathbf{X}^f_{d_l \cap d_m} = \mathbf{X}^m_{d_l \cap d_m}. \qquad (2)$$

For the rest part $d_l - d_m$, we first find a liner transformation $\mathbf{W}$ between two embedding spaces such that:

$$\mathbf{W}^* = \underset{\mathbf{W}}{\arg\min} \|\mathbf{W}\mathbf{X}^l_{d_l \cap d_m} - \mathbf{X}^m_{d_l \cap d_m}\|_F \qquad (3)$$
$$\text{s.t.}\ \mathbf{W}^T\mathbf{W} = \mathbf{I}.$$

According to Everson (1998),

$$\mathbf{W}^* = \mathbf{U}\mathbf{V}^T, \qquad (4)$$
$$\text{with } \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T = \text{SVD}\left(\mathbf{X}^m_{d_l \cap d_m} {\mathbf{X}^l_{d_l \cap d_m}}^T\right).$$

Then the word embeddings can be initialized as:

$$\mathbf{X}^f_{d_l - d_m} = \mathbf{W}^*\mathbf{X}^l_{d_l - d_m}. \qquad (5)$$

Experiment To investigate the effect of CMEA, we conducted **4-lingual M2M training** with different sampling temperature (Aharoni et al., 2019; Tang et al., 2021). Table 4 shows the BLEU scores on the validation set. We have the following observations:

- M2M04 outperforms Liv4ever-MT by a large margin owing to the larger model size, more training data and the pre-trained parameters.
- On most language pairs, our proposed CMEA initialization significantly improves translation performance compared to random initialization of new coming embeddings.
- Temperature set to 5 with CMEA initialization achieves the best overall results. Therefore, we used this model in **synthetic data generation**.

	En-Liv		**Et-Liv**		**Lv-Liv**	
	⇒	⇐	⇒	⇐	⇒	⇐
Liv4ever-MT Rikters et al.	14.3	19.3	20.5	24.4	22.3	29.3
M2M04 (T=5)	21.1	27.7	25.3	29.2	26.8	36.6
+ CMEA	**23.0**	**28.4**	**27.2**	**30.7**	**28.5**	**37.6**
M2M04 (T=10)	**21.3**	26.6	25.5	27.7	26.3	34.6
+ CMEA	21.1	**27.1**	**26.0**	**29.6**	**27.5**	**36.3**
M2M04 (T=20)	21.9	26.7	**26.5**	**29.8**	27.3	**36.5**
+ CMEA	**22.1**	**27.4**	25.8	27.9	**27.9**	33.8

Table 4: Experimental results of 4-lingual M2M training. We denote M2M04 as the 4-lingual translation model. 'T' represents the sampling temperature.

4.3 Synthetic Data Generation

Data agumentation (Sennrich et al., 2016; Jiao et al., 2020, 2022, 2021; He et al., 2022) is a widely used technique to boost the performance of neural machine translation. To augment the parallel data for En-Liv, we adopt both forward and backward translation to generate synthetic bi-text for En-Liv. Figure 1 (below) illustrates the process of synthetic data generation.

Considering the performances of Et/Lv⇒Liv are much better than En⇒Liv (see Table 4), we use Et and Lv as pivot languages to generate Liv instead of directly generating from En. Taking Et as the pivot language, given authentic En-Et bi-text, we use the best model in Table 4 to translate the Et into Liv, thus forming the synthetic En-Liv which is En-original. Conversely, given authentic Et-Liv, we translate Et into En using Google Translate, forming the synthetic En-Liv which is Liv-original. For Lv as the pivot language, we repeat the same steps. Table 5 lists statistics of the synthetic En-Liv data after filtering.

Data Type	**Pivot Language**	
	Et	Lv
En-original	20.5M	11.2M
Liv-original	14.2K	11.6K

Table 5: The number of sentences of generated synthetic data after filtering, which is divided into four categories based on the original language and the pivot language.

Experiment We combine the authentic and synthetic bi-text and retrain the 4-lingual model. The sampling temperature is set to 0 here to avoid downsampling for En-Liv. When using only En-original or Liv-original synthetic data, we control the sampling frequency of the different language pairs to be consistent with using the full data. Table 6 shows the BLEU scores on the multi-way validation set. We also report the round-trip BLEU on the monolingual En from the source of WMT22 En-De test set, which is En-original. Unexpectedly, original-language greatly affects the model performance and causes inconsistent results between different evaluation methods:

- En-original synthetic data remarkably degrades model performance on the validation set but significantly increases the round-trip BLEU.
- Liv-original synthetic data slightly reduces the performance on the validation set but moderately increases the round-trip BLEU.

- When using both kinds of data, the best round-trip BLEU is achieved. However, the performance on the validation set is still worse than the baseline.

	Valid (multi-way)		Round-Trip (En-original)
	En⇒Liv	Liv⇒En	
M2M04 (T=5) +CMEA	23.0	28.4	23.4
Add synthetic data and retrain			
En-original	17.2	17.5	30.7
Liv-original	21.5	27.4	25.8
Both	17.0	19.3	32.7

Table 6: Translation performance after adding the synthetic data and retraining the model.

As described in Section 3.2, we consider round-trip BLEU the more appropriate evaluation in this competition due to more data, more general domain, and the same original language as the WMT22 En-Liv test set. Therefore, we used both kinds of synthetic data in our submissions.

4.4 Fine-tuning & Post-processing

Fine-tuning To further exploit the bilingual and monolingual data, we fine-tuned the model on the En⇔Liv validation set for 500 steps jointly with online back-translation on monolingual data.

Post-processing We apply the following rule-based post-processing:

- Apply NFC normalization.
- Replace all the `httpshttp` with `https://`.
- Replace <unk> with empty string.
- When a comma appears between two digits, replace it with a decimal point (only for Liv).
- Regenerate the sentences that detected as repetition with no-repeat constraint[15] (only for Liv).

Final results Table 7 shows the test set performance and round-trip BLEU after fine-tuning and post-processing. As seen, fine-tuning significantly improves model performance on both test set and round-trip BLEU. Post-processing further boosts the performance on the test set.

	Test Set En-Liv		Round-Trip BLEU
	⇒	⇐	
Before fine-tuning	15.8	29.4	32.7
+Fine-tuning	16.3	30.1	37.1
+Post-proc.	17.0	30.4	37.1

Table 7: Translation performance after fine-tuning and post-processing.

5 Conclusion

This paper presents the Tencent AI Lab - Shanghai Jiao Tong University (TAL-SJTU) Low-Resource Translation systems for the WMT22 shared task. We start from the M2M100 1.2B model and investigate techniques to adapt it to English⇔Livonian. We propose cross-model word embedding alignment that transfer the embeddings of Liv4ever-MT to M2M100, enabling it to support Livonian. Then, Estonian and Latvian are involved in model training and synthetic data generation as auxiliary and pivot languages. We further fine-tune the model with validation set and online back-translation followed by rule-based post-processing. In model evaluation, we correct the inaccurate evaluation of Livonian due to inconsistent Unicode normalization and use round-trip BLEU as an alternative to the standard validation set.

(2022). **Our Eval.**: We use the released Liv4ever-MT to generate translation outputs and re-evaluate them with the original references, which shows similar results compared with Rikters et al. (2022). **+ Norm. Ref.**: re-evaluation after normalizing the encoding of references to NFKC.

A Re-evaluating Liv4ever-MT

Table 8 shows the results of re-evaluating Liv4ever-MT on all language pairs. Normalizing references to NFKC improves the average BLEU scores by +2.54 on the entire set and +8.26 on the Satversme subset. It is worth mentioning that liv4ever-test contains data from the following sources: Facebook, Livones.net, Dictionary, Trilium, Stalte, JEFUL and Satversme. However, there does not exist the Unicode inconsistency problem in the other sources except Satversme.

Abstract

This paper describes Lan-Bridge Translation systems for the WMT 2022 General Translation shared task. We participate in 18 language directions: English to and from Czech, German, Ukrainian, Japanese, Russian, Chinese, English to Croatian, French to German, Yakut to and from Russian, and Ukrainian to and from Czech. We mainly focus on multilingual models to develop systems covering all these directions. In general, we apply data corpus filtering, scaling model size, sparse expert model (in particular, Transformer with adapters), large-scale backtranslation, and language model reranking techniques. Our system ranks first in 6 directions based on the automatic evaluation.

1 Introduction

Our Lan-Bridge MT team participate in the WMT 2022 General Translation shared task. As machine translation expands into more and more languages, multilingual machine translation has attracted more and more attention in both academia and industry. It can not only avoid training a separate model for each language pair but also transfer knowledge from high-resource languages to low-resource ones. Many systems such as Tran et al. (2021) submitted in previous years have proved this point and achieved a state of the art results in some language directions.

For data preprocessing, knowledge-based rules, language detection, and language model are involved to clean parallel data, monolingual data, and synthetic data (mainly from large-scale data mining and backtranslation). Punctuation normalization and BPE (byte pair encoding) (Sennrich et al., 2015) with subword regularization method (Provilkov et al., 2019) are applied for all languages. As for models, we fork Fairseq (Ott et al., 2019) as our development tool and use Transformer (Vaswani et al., 2017) as the main architecture. In addition, we follow Bapna et al. (2019) to extend Transformer by adding language-specific adapters to bridge the gap between different language pairs. Finally, we ensemble dense Transformer models and sparse adapter models, and the final result are re-ranked by language models. For English to and from Chinese, we develop a separate system. In addition to optimization techniques similar to multilingual models, We also use additional private data. And for Yakut to and from Russian, due to a smaller corpus, we simply apply fine-tuning and backtranslation on our multilingual models.

We win the first place in Russian ↔ Yakut, Russian → English, English → Croatian, Czech → English and Ukrainian → English based on BLEU (Papineni et al., 2002) score. [1]

2 System Overview

2.1 Data

Here we describe our base datasets, including bitext and monolingual data sources, and the preprocessing methods we apply to prepare these initial data sets to train our baseline models.

2.1.1 Bitext Data

We use all available bitext data from the shared task for all language pairs, besides, for English to and from Chinese, we add extra data from ai-challenger. For high-resource language pairs such as English to Chinese or English to German, which provides millions of high-quality bitext, we only choose those high-quality resources, and simply apply language identification using fasttext (Joulin et al., 2017) with an ID threshold of 0.8 and knowledge-based rules shows below as data process:

- Remove empty sentences
- De-escaping HTML characters

[1] This result is based on the submission website https://ocelot-wmt22.mteval.org/, not the official final result.

- Normalization of different languages of punctuation
- Normalization of spacing
- Remove sentences with repeated tokens, including single character that repeat more than four times, two characters that repeat more than three times, and more than three characters that repeat more than twice.
- Delete the corpus with inconsistent punctuation marks at the end of the original text and the translation
- Deletion of segments where source/target token ratio exceeds 1:3 (or 3:1)
- Deletion of segments longer than 150 tokens
- Deletion of segments shorter than 5 tokens
- Transfer traditional Chinese characters to simplified Chinese characters
- Delete corpus with misaligned number of parentheses
- Delete corpus with misaligned number of Arabic numerals
- Delete corpus with a proportion of non-native language characters exceeding 0.4

The normalization of spacing and punctuation is applied using Moses (Polykovskiy et al., 2020).

For medium- and low-resource language pairs, we incorporate additional sources of data from OPUS (Tiedemann, 2012), ccAligned (El-Kishky et al., 2020), and ccMatrix (Schwenk et al., 2019). All available data sources are utilized to train our models.

Due to the low-quality issue of corpora mentioned above, we add a few filter steps to make them usable. First, we try the word alignment method using fast_align (Dyer et al., 2013) to filter low-quality sentence pairs and keep top 80% for all directions ranked by alignment score. Then we use Fairseq to train the transformer multilingual language model for all languages, similar to Bei et al. (2019), the score is calculated as follows:

$$Score_{sentence} = PPL$$

$$Score_{combine} = \lambda * Score_{src} + (1 - \lambda) * Score_{tgt}$$

Language Pair	Data
cs-en	100M
de-en	250M
fr-de	20M
hr-en	70M
sah-ru	0.1M
uk-cs	6M
uk-en	20M

cs	64M
en	72M
de	63M
fr	79M
ja	81M
sah	0.2M
ru	70M
uk	5M
zh	10M
hr	14M

Table 2: Ultimate monolingual data

Here PPL is the perplexity of a language model for sentence, λ is an empirical value between 0.2–0.8 depending on the language pair, such as the source language is English, and the target language is Croatian, then our empirical value of λ is 0.7. Finally, we consult Parallel Corpus Filtering Zhang et al. (2020) for finetuning a multilingual high-resource corpus classifier using mBERT (Gonen et al., 2020) to get our ultimate training data described in Table 1.

2.1.2 Monolingual Data

As we need a multilingual language model to filter low-quality corpus and create synthetic parallel text, we collect all high-quality monolingual corpus from News-Commentary, europarl, and news-crawl for all languages if available. For medium and low-quality resources, we use all available monolingual data from the shared task, and filter according to the above steps (where applicable). The ultimate monolingual data is described in Table 2.

Module	Big	Large
Layers	12	24
Attention Heads	16	16
Embedding Size	1024	1024
FFN Size	2048	4096
Shared Vocab	True	True

Table 3: Hyper-parameters and model sizes of different models used in our systems.

2.2 Tokenizer

We use sentencepiece (Kudo and Richardson, 2018) to train a multilingual subword tokenizer. To represent the low-resource languages better, we follow Tran et al. (2021)'s settings, sampling text with temperature 5. Especially, for Yakut, we take monolingual data into account, since it's an extremely low-resource. Finally, For bilingual models, we used a vocabulary size of 32,000, and for multilingual models, we used 100,000.

We also apply subword regularization methods (Provilkov et al., 2019; Raffel et al., 2020) when tokenizing text. For low- and medium-resource directions, we apply BPE dropout on both the source and target sides and double the corpus size. And for high-resource directions, we only use it on the source side and don't do data augmentation stuff.

2.3 Model Architectures

Similar to Tran et al. (2021), we train two separate models: Many to English, or one system encompassing every language translated into English, and Many to Many directions, or one for English into every language and other non-English directions. Due to the very late release of the Yakut to the Russian corpus, we apply simple finetuning and backtranslation in this direction. For Chinese to and from English, we train a separate model. Because we are native speakers of Chinese and good at English, we introduce about 20 million high-quality private corpus [2]

Dense Multilingual Model Our model settings are empirically designed based on Transformer (Vaswani et al., 2017). We introduce two model architectures seen in Table 3. All models are implemented on top of the open-source toolkit Fairseq (Ott et al., 2019).

We also train three bilingual models: English to/from Chinese, and French to Germany. The aim is to compare how similarities among different languages will influence multilingual model. Due to the limitation of computing resources, we do not test in other language directions.

Language Specific Adapter In brief, an adapter layer is a dense layer with residual connection and non-linear projection. The hyperparameter b is the dim size of the inner dense layers. With a large set of globally shared parameters and small interspersed task-specific layers, adapters allow us to train and adapt a single model for a huge number of languages. Bapna et al. (2019) shows translation performance improvement in multilingual models with residual adapters. So after training the dense multilingual model, we add adapters for each language direction and apply further training and finetuning on these adapter layers. In detail, for high-resource directions, we add a larger adapter (b=4096). As for medium-resource, we set b=2048 and for the low-resource, we set b=1024.

2.4 Optimization Tricks

Backtranslation As shown in previous news task submissions, such as Tran et al. (2021) and Wang et al. (2021), backtranslation can significantly improve the BLEU score in low- and medium-resource language directions. We find no significant improvement in high-resource directions. And for some "X-en" high-resource directions, like zh-en shows in Table 4, backtranslation even lower the BLEU score. For this reason, we collect monolingual data for low- and medium-resource directions. All backtranslation data are generated by our well-trained multilingual model with Transformer Big settings. We use this generated data to train models with "Large" settings.

Finetune We use in-domain finetuning to further improve the model performance, which has proven effective on previous news translation tasks. We construct different types of finetuning data with the following approaches. Li et al. (2020); Wang et al. (2021) shows that low-frequency words frequency words are mostly domain-specific nouns, etc., which may indicate the topic directly. On the other hand, this year the shared task has changed from a news domain to a general translation task. We think finetuning our model by previous in-domain news data may be harmful to our model.

[2] We have a data group and a translation review team. First, we collect public monolingual data to make it multilingual. Second, we have a cooperative corpus or terminology base with our clients. With the consent of our clients, some non-public corpora and terminology are used for training.

	Test Set	Big Model	Large Model	+BT	+Adapter	+Finetune	+LM Rerank
cs-en	wmt21	23.0	23.9	—	24.2	24.8	25.2
uk-en	flore101	35.7	35.9	36.1	37.0	37.0	37.5
ja-en	wmt21	21.5	21.8	24.0	27.2	28.0	28.0
de-en	wmt21	29.4	29.9	—	30.0	32.1	32.3
ru-en	wmt21	30.1	31.3	32.5	34.0	37.5	37.9
en-cs	wmt21	15.7	17.0	—	20.4	20.2	21.3
en-uk	flore101	24.1	24.5	27.1	28.0	28.9	29.0
en-ja	wmt21	16.9	18.0	22.5	22.8	25.0	25.1
en-de	wmt21	24.4	24.8	25.0	25.0	27.1	27.3
en-ru	wmt21	20.6	21.0	21.1	23.4	24.2	25.6
en-hr	flore101	25.8	26.4	28.9	29.3	30.0	30.3
cs-uk	flore101	19.8	21.3	25.0	25.9	26.2	26.6
uk-cs	flore101	20.8	22.0	24.1	24.3	24.3	24.5
fr-de	wmt21	35.8	36.1	37.3	39.1	39.0	39.1
zh-en	wmt21	31.4	32.0	31.7	—	34.0	34.1
en-zh	wmt21	33.0	33.4	35.1	—	35.5	35.7
Avg Incremental	—	—	0.70	2.99	2.40	4.11	4.47

Table 4: Evaluation result on dev dataset. The inside of the dividing line represents the same model. We train X-en, en-X X-X, zh-en, and en-zh models separately. All translations are generated by beam search with beam size 5. All the models are the average of the final 5 checkpoints.

So we follow Li et al. (2020); Wang et al. (2021)'s strategies to select topic-related data based on a testset. We use the selected data for further finetuning. We experimented with the 2022 news development set and apply it directly to the 2022 test set.

Language Model Reranking Following Yee et al. (2019); Tran et al. (2021), we train language models and apply noisy channel reranking to the outputs of our final system. Unlike Tran et al. (2021), which trains a separate language model for each language, we train a multilingual language model for all languages to evaluate whether the multilingual language models can also improve the quality of translations.

Model Ensemble Model ensemble is a widely used technique in previous WMT shared tasks. To deal with biases toward recent training data, it is common to average parameters across multiple checkpoints of a model. We always average the last 5 checkpoints during training. During finetuning, we tune this hyperparameters (num epoch and num average checkpoints) on the development set and use it directly on the test set of wmt22.

3 Experiment

We conduct experiments to quantify the impact of each component in our system. The evaluation conduct on newstest2021 or development set on wmt22 using SacreBLEU (Post, 2018).

3.1 Settings

Every single model is trained on 8 NVIDIA A100 GPUs, each of which has 40 GB of memory. We also employ large batching with larger learning rates (Ott et al., 2018). We set the max learning rate to 0.0005 and warmup steps to 10000. All the dropout probabilities are set to 0.1. To speed up the training process, we conduct training with a half-precision floating point (FP16). During training multilingual, we add both source-side language tags and target-side language tags to leverage the gap between different language pairs. Following Tran et al. (2021), we divide data into multiple shards and downsample data from both high-resource directions and synthetic backtranslated with each training epoch using one shard.

3.2 Multilingual Models Result

We mainly evaluate our model and method on the wmt21 test set and flore101 dataset (Goyal et al., 2021). We analyze each aspect in our final submission and the cumulative effect. The effect of each component is shown in Table 4.

According to our experimental results, increasing the model capacity, increasing the sparsity of the model (adding a specific set of Adapter Layer

	en-zh	zh-en	fr-de
Bilingual Model Big	33.0	31.4	32.6
Multilingual Model Big	31.9	30.2	35.8

Table 5: BLEU score on wmt21 test set. All result is based on Big Model without any optimization

for each speech direction), fine-tuning the training set by extracting more relevant corpus based on the original text of the test set, and using the language model for reranking is effective on all language directions and the test set. Backtranslation is particularly effective in low- and medium-resource languages. Although the improvement of BLEU value by backtranslation on high-resource languages is not obvious or even worse, the average improvement by backtranslation is as obvious in a comprehensive view, with an average improvement of 1.68 BLEU per language direction.

Because this year's task is a general-purpose machine translation, rather than the news domain machine translation task of previous years, we are not submitting translation results that validate the optimal model on the development set, but rather the results of model fine-tuning on selected domain data after the release of the test set.

3.3 Distant Language Pairs Analysis

As shown in Tran et al. (2021), the multilingual model can significantly improve the BLEU score of medium- and low-resource language directions. For high-resource language directions, there are no significant enhancements. For high-resource languages, such as en-de, the BLEU score decreases slightly, and this is even more severe for distant language directions, en-ja, and en-zh for example. To compare the influence of the distance of the language family on the multilingual model. We train bilingual models for en-zh, zh-en, and fr-de. The test result is shown in Table 5. Since most of the language directions of wmt22 are Indo-European, distant languages, Chinese and Japanese for example, cannot benefit from the knowledge transfer additive of other languages, while the parameter capacity of the multilingual model is limited. These factors lead to poor results. Overall, when training multilingual models, languages with similar language families should be trained together, instead of putting all the languages together.

Task	**BLEU**	**Task**	**BLEU**
`cs-en`	25.3⋆	`en-cs`	26.3
`de-en`	33.4	`en-de`	36.1
`ja-en`	22.8	`en-ja`	39.4
`ru-en`	45.2*	`en-ru`	32.6
`uk-en`	44.6⋆	`en-uk`	29.5
`zh-en`	28.1	`en-zh`	48.3
`fr-de`	41.8	`en-hr`	18.2⋆
`uk-cs`	36.5	`cs-uk`	38.3
`ru-sah`	15.3⋆	`sah-ru`	7.1⋆

Table 6: Our final submission results in 18 tasks. ⋆ represents the best score in the automatic evaluation. Note that the result is based on the submission website https://ocelot-wmt22.mteval.org/, not the official final result.

3.4 Submission Results

The results we finally submitted are shown in Table 6. We participate in 18 tasks this year. On the whole, all of our systems performed competitively, especially for Many-to-English directions. Yakut to/from Russian tasks is added bonus. Few teams participate in these two tasks.

4 Conclusion

In this paper, we described Lan-Bridge's submission to the WMT2022 General Translation shared task. Our main exploration was using a multilingual model to train different language pairs. It shows that the multilingual model can achieve state of art results in both high- and low-resource language directions. Meanwhile, we found that the multilingual model worked better for languages from the same or close language families than languages from distant language families. Finally, for extremely low-resource languages, even a multilingual model can boost their performance of them, but the translation is still far from usable.

5 Acknowledgments

We would like to thank our translator colleagues (Ruicheng Liu, and Qingtong Yang) for their assistance with linguistic knowledge and partners development teams (Jun Zhang et al.) for their foundational contributions to this project. We would also like to thank Yafu Li, and Yulong Chen from Westlake University for helpful discussions early on in the project.

Abstract

Manifold's English-Chinese System at WMT22 is an ensemble of 4 models trained by different configurations with scheduled sampling-based fine-tuning. The four configurations are DeepBig (XenC), DeepLarger (XenC), DeepBig-TalkingHeads (XenC) and DeepBig (LaBSE). Concretely, DeepBig extends Transformer-Big to 24 encoder layers. DeepLarger has 20 encoder layers and its feed-forward network (FFN) dimension is 8192. TalkingHeads applies the talking-heads trick. For XenC configs, we selected monolingual and parallel data that is similar to the past newstest datasets using XenC, and for LaBSE, we cleaned the officially provided parallel data using LaBSE pretrained model. According to the officially released autonomic metrics leaderboard[1], our final constrained system ranked 1st among all others when evaluated by bleu-all, chrf-all and COMET-B, 2nd by COMET-A.

1 Introduction

This report describes Manifold's machine translation system submitted to WMT 22 English→Chinese general domain translation task. The general domain translation task of WMT is a new task set up this year, replaces the time-honored news translation task. However, as the newstest datasets released previously were created by professional translators manually, they were considered to have better quality compared with the web crawled dataset. Therefore, generally our strategy is selecting data from the provided datasets according to their similarity between past WMT test sets, and training big models with different architectures or training methods based on the selected data.

2 Data Preprocessing

For officially released bilingual data, we merged ParaCrawl v9, News Commentary v16, Wiki Titles v3, UN Parallel Corpus v1.0, CCMT corpus and WikiMatrix corpus together, then applied multiple rules to preprocess and filter the officially released bilingual data, including

- Normalizing punctuation.
- Removing unprintable characters.
- Tokenizing texts. jieba[2] was applied for Chinese texts, and moses tokenizer[3] was applied for English texts.
- Removing all the sentence pairs whose source text or target text tokens count exceeds 150, and the segment pairs with a source-target token ratio lower than 2/3 or higher than 3/2.
- Removing all the sentence pairs that belong to other languages. We applied the fasttext model (Joulin et al., 2016)[4] as our language identifier.
- Deduplicating the dataset.

3 Basic models

After applying the aforementioned preprocessing and filtering rules, 30M segment pairs were kept [5]. For the kept data, we adopted two different selection strategies:

1. Following NiuTrans' system submitted to WMT21 (Zhou et al., 2021), we selected 12M segment pairs from the kept data which are

Config Item	Big	Deep	Deeper	DeepBig	DeepLarger
# Encoder Layer	6	30	40	24	20
# Attention Heads	16	8	8	16	16
Embedding Size	1024	512	512	1024	1024
FFN Size	4096	2048	2048	4096	8192
Pre-Norm	No	Yes	Yes	No	No

Table 1: Main configurations for different architectures we applied for basic models. Decoder layers numbers were fixed to 6 for all the architectures if not specially mentioned.

most similar to our validation set (i.e. newstest2020enzh data) using XenC (Rousseau, 2013). This part of data will hereinafter be referred as "XenC" for short.

2. We further cleaned the 30M segment pairs using LaBSE (Feng et al., 2022)[6], set the threshold to 0.7 according to our experience in filtering out un-aligned data. After this step, 24.3M segment pairs were kept. This part of data will hereinafter be referred as "LaBSE" for short.

Config Item	Value
dropout	0.3
learning rate	0.0005
max tokens	4096
warmup init lr	1e-7
warmup steps	4000
label smoothing	0.1
num max updates	300,000
update frequency	8

Table 2: Hyper-parameters for training models. All experiments were conducted on 4 or 8 Tesla V100 GPUs.

We applied BPE-subword (Sennrich et al., 2016)[7] to divide tokens into subwords. BPE codes were learned jointly with 32K merge operations but dictionaries for the source language and target language are generated separately.

Basic models were trained to generate synthetic, pseudo bilingual segment pairs for the next step. As is discovered by Zeng et al. (2021), sub-model diversity is a key factor to enhance the performance of ensemble model. Therefore, we trained various Transformer models (Vaswani et al., 2017) applying different architectures. For very deep Transformers, we followed the suggestion given by DLCL (Wang et al., 2019) to use Pre-Norm. Main configurations for the architectures we trained are listed in Table 1. Other hyper-parameters for training models are listed in Table 2 (same for all the experiments we took in the contest).

For each architecture X listed in Table 1, we also trained its talking-heads attention variant (Shazeer et al., 2020) to further increase model diversity. Such variants will be denoted as "X-th" in the following part of the report. All the models were developed and trained using fairseq (Ott et al., 2019) [8]

4 Data Augmentation

Previous studies show that adding synthetic data can help to boost the performance of machine translation systems (Edunov et al., 2018) (Hoang et al., 2018). We adopted four data augmentation methods during the contest, including back-translation (with sampling), forward-translation, sequence knowledge distillation and R2L translation. For R2L translation, we reversed the token sequences of inputs, e.g. converted "This is a book ." to ". book a is This", and left the target sentences unchanged.

We selected 12M sentences from officially released English and Chinese monolingual datasets respectively[9], also applying XenC algorithm on them. The selected monolingual data was preprocessed by the similar pipeline presented in section 2, with the difference on skipping the steps to filter unaligned bilingual data. The reason behind selecting 12M sentences is we expect that the data from each monolingual dataset has the same size compared with the bilingual training data, as Edunov et al. (2018) indicated.

The preprocessed Chinese monolingual data was

[6] We downloaded the pretrained model from transformers official website on October 11th., 2021. As the model was released before February 2022, the constrained system requirement is not violated.

[9] For English, we combined News Crawl, News Discussions, News Commentary and Europarl v10 corpus together; for Chinese, we combined News Crawl, News Commentary and Common Crawl corpus.

No.	Method	Data Size	Newstest 2020	Newstest 2021
1	Deep baseline model	12M	42.7	32.4
2	1 + Forward-translation (ForT)	24M	44.7 (+2.0)	33.3 (+0.9)
3	1 + Top-p back-translation (topp BT)	24M	45.8 (+3.1)	32.9 (+0.5)
4	1 + R2L KD + R2L ForT	36M	44.2 (+1.5)	33.5 (+1.1)
5	Sequence KD	12M	42.7 (-)	32.5 (+0.1)
6	5 + ForT + topp BT	36M	45.3 (+2.6)	33.7 (+1.3)
7	4 - 1 + 6	60M	45.5 (+2.8)	33.8 (+1.4)

Table 3: Model performances when applying different methods. All the models are trained by Deep architecture depicted in Table 1. Our validation dataset is from newstest2020 (Barrault et al., 2020) and test dataset is from newstest2021 (Akhbardeh et al., 2021).

No.	Method	Newstest 2020	Newstest 2021
1	Fine-tuned Deep	46.2	34.6
2	DeepBig	47 (+0.8)	35 (+0.4)
3	DeepLarger	47.5 (+1.3)	35.7 (+1.1)
4	DeepBig-th	47.6 (+1.4)	35.4 (+0.8)
5	DeepBig (LaBSE)	47.6 (+1.4)	35.5 (+0.9)
6	Ensemble of 2, 3, 4 and 5	48.1 (+1.9)	36.2 (+1.6)

Table 4: Detailed performance information of the four bigger model and the final ensemble model. All the improvements are based on the baseline model (Deep model shown in the last line of Table 3, fine-tuned using past newsdev/test datasets, by applying decoder steps based schedule sampling as regularization). All sub-models (No. 2 to 5) are also fine-tuned by the same datasets applying the same regularization method.

then back-translated into English by an ensemble model, which is composed by a Big model, a Deep model and a Big-th model, all trained with the bilingual XenC Chinese→English corpus. Inspired by some ideas of Burchell et al. (2022), we performed top-p (nucleus) sampling (Holtzman et al., 2019) in the process of back-translation to import some noises, and set topp to 0.9. In this way, 12M Pseudo English-Chinese segment pairs were constructed.

The preprocessed English monolingual data was forward-translated into Chinese, leading to another 12M English-Pseudo Chinese dataset. The ensemble model used to generate data has the same architecture with the back-translation model introduced above, the only difference is it is trained by the parallel XenC English→Chinese corpus.

We further applied sequence-level knowledge distillation (Kim and Rush, 2016) to distill this ensemble model by translating English sentences of the parallel XenC corpus into pseudo Chinese. Furthermore, we also trained a Deep model with the reversed parallel XenC data to get a right-to-left (R2L) model, and generated forward-translation and the results of knowledge distillation using reversed monolingual and parallel English corpora. After having acquired these different synthetic datasets, we trained Deep models by various combinations of them. The concrete model performance is shown in Table 3.

5 Fine-tuning and Bigger Models

After having acquired extra data by back/forward-translation, knowledge distillation, and R2L data augmentation, we experimented on several other methods to further improve our system.

Fine-tuning. We fine-tuned our Deep model using the combination of newsdev2017, newstest2017, newstest2018, and newstest2019 datasets. As the dataset used for fine-tuning is quite small, we applied decoder steps based scheduled sampling (Liu et al., 2021) as a means of regularization. We set k to 0.99. With this step, a 0.7 BLEU gain has been brought on the validation set and 0.8 BLEU gain on the test set.

Ensemble of bigger models. We trained three bigger models on the 60M XenC Dataset (configuration No. 7 in Table 3), including a DeepBig model, a DeepLarger model and a DeepBig-th model. Furthermore, we replaced the distilled data in the XenC Dataset (12M) with the LaBSE data (24M), and got a dataset containing 72M segment pairs which is used to train another DeepBig model. We fine-tuned these four models using past newsdev/test datasets and applied decoder steps based schedule sampling, then made an ensemble model comprised of them. Table 4 lists the detailed performance of the bigger models and their ensemble model.

Post-processing. We converted punctuation from half-width symbols to full-width symbols for the generated results.

6 Conclusion

In this report, we describe our Manifold English→Chinese system submitted to WMT 22 general translation task. The core idea of our system is to train various big Transformer models utilizing in-domain (actually news domain) data, based on which an ensemble model is created. Although most training data belongs to a special domain, we still achieved compelling results in the final submission, i.e. our final system ranked first among the constrained systems, evaluated by BLEU score based on the two references.

CUNI Submission in WMT22 General Task

Josef Jon
Charles University
surname@mail.ufal.mff.cuni.cz

Abstract

We present CUNI-Bergamot submission for WMT22 General translation task. We compete in English → Czech direction. Our submission further explores block backtranslation techniques. In addition to the previous work, we measure performance in terms of COMET score and named entities translation accuracy. We evaluate performance of MBR decoding compared to traditional mixed backtranslation training and we show possible synergy when using both of the techniques simultaneously. The results show that both approaches are effective means of improving translation quality and they yield even better results when combined.

1 Introduction

This work focuses on exploring of two methods used in NMT in order to improve translation quality: backtranslation and Minimum Bayes Risk decoding using neural-based evaluation metric as a utility function. The methods used and related work are presented in the following section. In next section we describe our experimental setting and results.

2 Methods

We describe methods we used to build our system in this section.

2.1 Block backtranslation

The translation quality of NMT depends heavily on the amount of parallel training data. It has been shown that the authentic bilingual data can be partially supplemented by synthetically parallel, machine translated monolingual text (Bojar and Tamchyna, 2011; Sennrich et al., 2016; Xie et al., 2018; Edunov et al., 2018). Often the synthetic and authentic parallel data are mixed in the training dataset, but previous research shows that simply mixing the two types of text does not yield optimal translation quality. We are using block backtranslation (*block-BT*) in similar configuration to Popel et al. (2020). This method creates blocks of parallel and synthetic data and presents them to the neural network separately, switching between the two types during the training. Since in last year's WMT, the submission using block-BT by Gebauer et al. (2021) did not find any improvements, presumably due to improperly chosen block size, we decided to verify effectiveness of this method once again.

Averaging type Previous work on *block-BT* shows the importance of averaging the checkpoints to combine information from different blocks of training data in order to obtain good performance. We compare checkpoint averaging with another method of combining older sets of model's parameters with the current one – *exponential smoothing*. After each update u, the current parameters Θ_u are averaged (with smoothing factor α) with parameters after the previous update Θ_{u-1}:

$$\Theta_u = \alpha\Theta_u + (1-\alpha)\Theta_{u-1}$$

Previous work by Popel (2018) contains experiments with exponential averaging, but only on the level of already saved checkpoints, not online during the training after each update as for our work.

Minimum Bayes Risk Decoding NMT models predict conditional probability distribution over translation hypotheses given a source sentence. To select the most probable translation under the model (mode of the model's distribution), an approximation of MAP (*maximum-a-posteriori*) decoding is used, most commonly the beam search (Graves, 2012). However, beam search and MAP decoding in general has many shortcomings described in recent work (Stahlberg and Byrne, 2019; Meister et al., 2020) and other approaches have

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 280 - 289
December 7-8, 2022 ©2022 Association for Computational Linguistics

been proposed to generate a high-quality hypothesis from the model.

One of them, MBR (Minimum Bayes Risk) decoding (Goel and Byrne, 2000; Kumar and Byrne, 2004), has been proposed as an alternative to MAP. MBR does not produce a translation with the highest probability, rather a translation with the best value of utility function. This utility function is usually an automatic machine translation evaluation metric. However, to optimize towards best utility function value, it would necessary to know the ideal selection of hypothesis. In case of MT, that would mean a perfect, best possible translation, which of course is not known during the translation process. For this reason, an approximation of the ideal translation is used, based on the model's probability distribution (Bryan and Wilker, 2021). This can be implemented as generating a list of hypotheses (e.g. using sampling or beam search) and then computing utility function of each hypothesis using all the other hypotheses as the ideal translation approximation (i.e. as references). This approximation of MBR decoding can be seen as consensus decoding – the hypothesis that is the most similar to all the others is chosen.

Even though MBR is able to optimize towards many metrics and increase the scores, these gains did not translate into better human evaluation of the final translations, when using traditional metrics based on surface similarities like BLEU. Recent successes in development of novel metrics for machine translation has renewed interest in this method. (Amrhein and Sennrich, 2022a; Freitag et al., 2021; Müller and Sennrich, 2021).

3 Experiments

In this section we present our experimental setup and results.

3.1 Tools

We tokenize the text into subwords using FactoredSegmenter[1] and SentencePiece (Kudo and Richardson, 2018). We use MarianNMT (Junczys-Dowmunt et al., 2018) to train the models. BLEU scores are computed using SacreBLEU (Post, 2018), for COMET scores (Rei et al., 2020) we use the original implementation[2].

3.2 Datasets

We train English-Czech NMT models for our experiments. We train our models on CzEng 2.0 (Kocmi et al., 2020). We use all 3 subsets of CzEng corpus: the originally parallel part, which we call *auth*, Czech monolingual data translated into English using MT (*csmono*) and English monolingual data translated into Czech using MT (*enmono*). We use `newstest2020` (Barrault et al., 2020) as our dev set and `newstest2021` (Akhbardeh et al., 2021) as our test set.

For experiments concerning translation of named entities, we used a test set originally designed for Czech NLG in restaurant industry domain[3](Dušek and Jurčíček, 2019). It contains sentences which include names of restaurants and addresses in Czech and their translations in English. We will call this test set the `restaurant` test set.

3.3 Models

We train Transformer-base (which we denote *base*) and Transformer-big (*big 6-6*) models with standard parameters (Vaswani et al., 2017) as preconfigured in MarianNMT. For the largest model (*big 12-6*), we use Transformer-big with 12 encoder layers and depth scaled initialization (Junczys-Dowmunt, 2019; Zhang et al., 2019)[4]. We also used learning rate of $1e{-}4$ for the 12 layer model instead of $3e{-}4$, which was used for other models. We trained all models for at least 1.4M updates. After that, we computed validation BLEU scores every 5k updates and we stopped if the score did not improve for 30 consecutive validations. We trained the models on heterogenous grid server, which includes combinations of Quadro RTX 5000, GeForce GTX 1080 Ti, RTX A4000 and GeForce RTX 3090 cards. Typical training time on 4 108Ti of the base models for 1.4M updates was 7 days.

3.4 Block-BT settings

For all our experiments, we create a checkpoint each 5k updates and we vary only the size of the blocks during which the training data have the same type (20k, 40k, 80k and 160k updates). The size is the same for all block types. We circle through the block types in the following order: *auth*→*csmono*→*auth*→*enmono*.

[1] `https://github.com/microsoft/factored-segmenter`

[2] `https://github.com/Unbabel/COMET`

[3] `https://github.com/UFAL-DSG/cs_restaurant_dataset`

[4] Training scripts available at: `https://github.com/cepin19/wmt22_general`

For checkpoint averaging, we average 8 checkpoints. For exponential smoothing, we use default Marian configuration ($\alpha = 0.001$, but there are some slight modifications based on number of updates since start of the training and batch size).

We also look at the effects of using only back-translation, or both back- and forward-translation.

3.5 Block-BT results

Training regime and averaging method First, we compare different training regimes: *mixed-BT*, where all the training datasets are concatenated and shuffled together and *block-BT* with 40k updates long blocks and two possible averaging types – exponential smoothing (*exp*) or checkpoint averaging (*avg8*).

Figure 1 shows behavior of BLEU and COMET scores on `newstest2020` during the training for these configurations. We opt to present the interval between 480k and 1280k updates. We chose the lower bound because the behavior is more stabilized than in the beginning of the training and the upper bound because all the models were trained for at least 1400k updates and 1280k is the nearest lower multiplicative for the largest block size. *40k block* curve represents a model without any averaging, *40k block avg8* is a model trained without exponential smoothing, but each checkpoint was averaged with 7 previous checkpoints for the evaluation, *40k block exp* model was trained with continuous exponential smoothing. Finally, we also experimented with combination of both - trained with exponential smoothing and averaged after the training. The combination does not improve over the separate averaging techniques and we omitted the curve from the figure to make it more readable.

In both metrics, *block-BT* with either form of averaging outperforms *mixed-BT* training. Without any averaging, the advantage of *block-BT* over *mixed-BT* is smaller. Type of averaging does not seem to play a large role – checkpoint averaging, exponential smoothing and their combination yield very similar best scores. The best scores on `newstest2020` for each combination of parameters are presented in Table 1.

The curves for checkpoint averaging and exponential smoothing behave similarly, with exponential averaging reacting faster to change of the block. Additionally, the *avg8* models have higher peaks in *enmono* (red) blocks, especially for BLEU scores. The shape of the curves could be tuned by changing frequency of saving checkpoints and number of checkpoints to be averaged for checkpoint averaging method, or by changing the α factor for exponential smoothing.

There are differences in behaviour between BLEU and COMET score curves. Most notably, COMET is less sensitive to transition from *auth* (green) to *csmono* (blue) blocks. We hypothesize this is caused by lower sensitivity of COMET score to wrong translation of named entities and rare words (Amrhein and Sennrich, 2022a). We present further experiments in this direction later.

Block size We asses influence of block size for both of the two averaging methods. We compare block sizes of 20k, 40k, 80k and 160k updates. Behaviour of COMET and BLEU scores is presented in Figures 2 and 3 for exponential smoothing and checkpoint averaging, respectively. The best scores are again shown in Table 1.

We see that 20k block size yields noticeably worse results when using checkpoint averaging that the other sizes. The negative effect of the small block size is less pronounced when using exponential smoothing, yet still present. Other block sizes perform similarly in both metrics. This results is expected, since for 8-checkpoint averaging with 5k updates checkpointing interval, it is necessary to have a block size of at least 40k updates to fit all the 8 checkpoints and thus explore all possible ratios of *auth* and *mono* data.

Reverse direction For the reverse direction, Czech to English, we performed less extensive evaluation. We only compare *mixed*, *block-BT* with 40k blocks and either exponential smoothing or checkpoint averaging. Behavior of the metrics is shown in Figure 4 and final best scores on `newstest2020` are presented in Table 2. *Block-BT* still outperforms *mixed* training, but by a smaller margin than in the other direction.

Backtranslation direction We also evaluate influence of using only backtranslations as additional synthetic data (monolingual data in target language to automatically translated to source language) or adding also forward translations (from source language to target target) and we present the results in Table 3. Interestingly the results show large gains in both BLEU and COMET when using forward translation. We hypothesize this is caused by the good quality of the model used to perform the forward translation. In such case, the translation

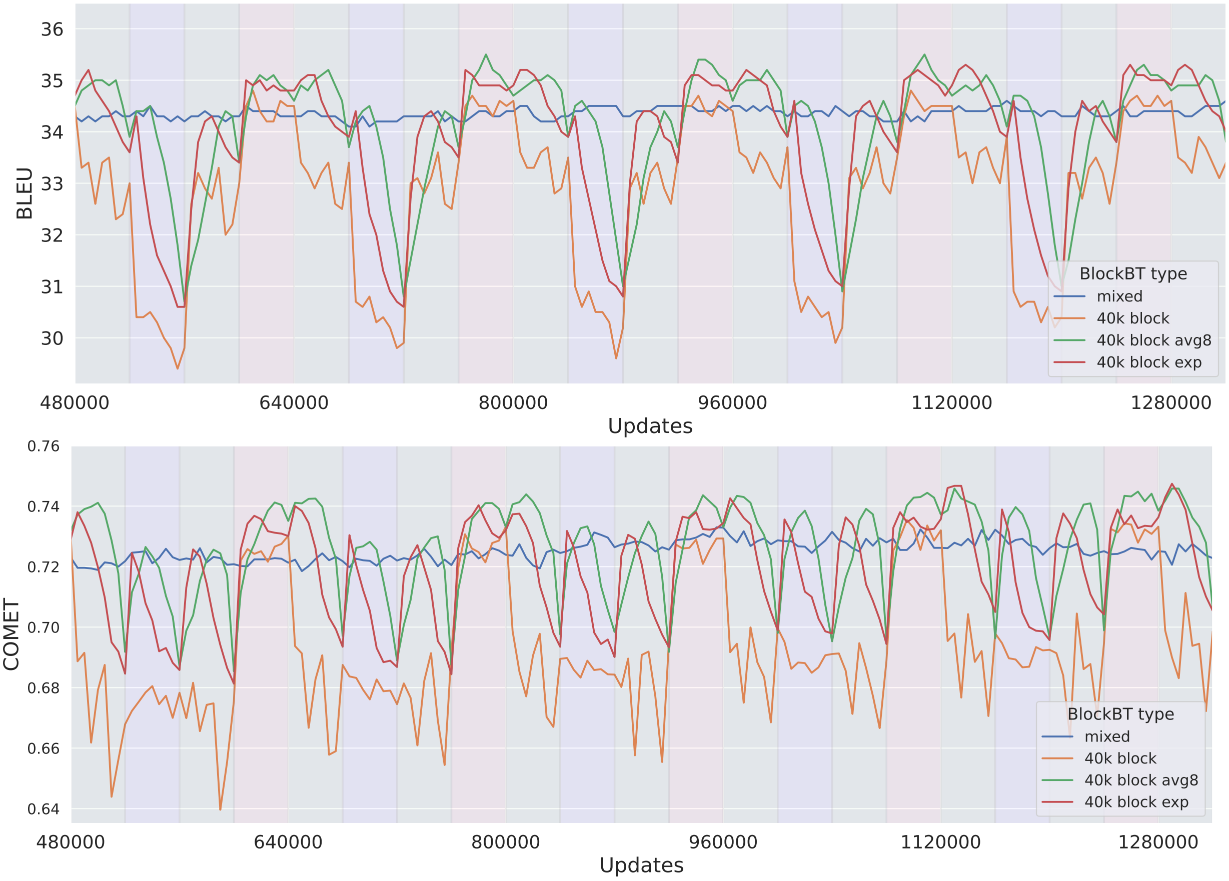

Figure 1: Comparison of different training regimes for EN-CS translation on newstest20 in terms of BLEU (top) and COMET (bottom). Background colors for block-BT regime show which part of training data was used for given part of the training. Green means authentic parallel data, blue is CS->EN backtranslation and red is EN->CS forward translation.

model assumes the role of the teacher in teacher->student training and might lead to a good quality results.

Named entities test sets From anecdotal evidence, we have seen that checkpoints with large influence of backtranslated data perform worse on named entities translation and COMET and BLEU scores might not reflect this drop of accuracy. We evaluate the models in terms of accuraccy of named entitiy translation on the `restaurant` test set. We selected Czech to English direction, since the evaluation is easier given lower morphological richness of target language. Figure 5 shows comparison of behavior of named entities translation accuracy on the restaurant test set and COMET and BLEU scores on `newstest2020` for exponential smoothing and checkpoint averaging. NE accuracy peaks towards the end of *auth* regions (green). Both COMET and BLEU scores peak also during the *auth* part of the training, but, especially for COMET, the peak occurs in earlier stages after the switch to *auth*. Overall, BLEU curve correlates better with the NE accuracy curve. We hypothesize this might be related to the fact that COMET was found to be insensitive to named entities errors by Amrhein and Sennrich (2022b).

However, it seems that the shift between the accuracy and the other two metrics is not too large in our settings and choosing the best performing model in terms of either COMET or BLEU should not hurt NE translation by a large amount. We further investigate that in Table 4 – we chose the checkpoint with best COMET (first row) and best BLEU (second row) on the `newstest2020` and the checkpoint with best NE translation accuracy on the restaurant test set (third row). We compute all three metrics for these three models. The best COMET checkpoint obtains accuracy of 60.7% on the restaurant test set, the best BLEU checkpoint reaches accuracy of 62.9%, while the best accuracy reached by any checkpoint is 63.6%.

3.6 MBR decoding

We used MBR decoding to rerank concatenation of n-best lists produced by various checkpoints. In total, we used 6-best lists from 12 checkpoints. We divided the checkpoints based on which block of the training data they were saved in and sorted them by COMET score on newstest2020. Using different strategies we selected the best performing checkpoints to provide the n-best lists. We present the results in Table 5. The first row shows results for mixed-BT regime, i.e. we concatenated n-best lists produced by the 12 best performing mixed-BT

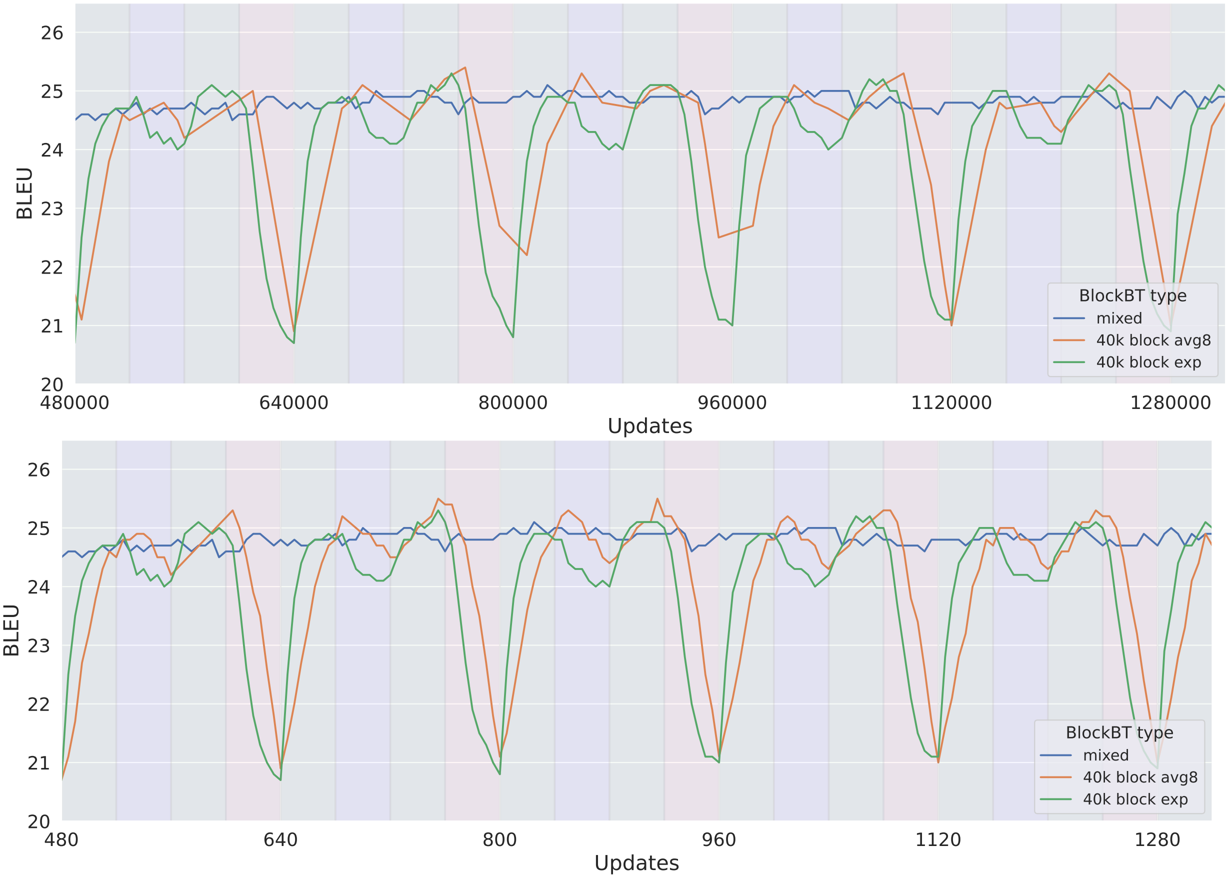

Figure 4: Comparison of different training regimes for CS-EN translation on `newstest2020` in terms of BLEU (top) and COMET (bottom). Background colors for block-BT regime show which part of training data was used for given part of the training. Green means authentic parallel data, blue is CS->EN forward translation and red is EN->CS backtranslation.

Table 5: Results of MBR decoding on `newstest2020` for different selection of the hypotheses n-best lists produced by checkpoints from different training blocks. In total, 12 n-best lists produced by transformer-base models are concatenated and the first three columns show how many n-best lists are used from each block (the checkpoints for each block are sorted by COMET (wmt20-da model), so these are produced by the best performing checkpoints). The *AVG COMET20* shows the average wmt20-da COMET scores for the first hypotheses of each n-best list that was used, *MBR COMET20* shows wmt20-da score of the final sentences after MBR decoding, COMET21 shows results of the same sentences from wmt21-da model.

checkpoints. In the second row, the block-BT training checkpoints were used to create n-best lists, selected only based on their COMET scores, without any regard on the block type they were saved in. In third row, we combine n-best lists from 4 best performing checkpoints from each type of block. In rows 4-6, we use best performing checkpoints from each type of block separately. In the final row, we show the optimal selection which yielded the highest score. The results suggest that larger diversity in terms of block type of the checkpoints improves MBR results: the combination of n-best lists produced by checkpoints from diverse block types provides a better pool of hypotheses for MBR, even though the average COMET score of these checkpoints is lower than for the less diverse selection. This can be observed in rows 2 and 3.

3.7 Submission

Our primary submission is based on the *big 12-6* model and MBR decoding. We explored all the possible combinations of 18 checkpoints from dif-

Abstract

We here describe our neural machine translation system for the general machine translation shared task in WMT 2022. Our systems are based on the Transformer (Vaswani et al., 2017) with base settings. We explore the high-efficiency model training strategies, aimed to train a model with high-accuracy by using a small model and a reasonable amount of data. We performed fine-tuning and ensembling with N-best ranking in English to/from Japanese directions. We found that fine-tuning by filtered JParaCrawl data set leads to better translations for both directions in English to/from Japanese models. In the English to Japanese direction model, ensembling and N-best ranking of 10 different checkpoints improved translations. By comparing with another online translation service, we found that our model achieved a great translation quality.

1 Introduction

We participated in the Japanese to/from English translation for the general machine translation shared task of WMT 2022. Japanese ←→English is one of the challenging language pairs for machine translation since their differences are large in both vocabulary and grammatical structure. Recent advances in neural machine translation models have greatly promoted the development of the community. The transformer is the current key model and most recent participants are using a big-setting transformer model to improve the quality of translations. However, developing a more efficient model is also important. We here use a smaller model and limited computation resources to pursue high-quality translation models.

Our systems are based on the Transformer model with base settings, and the models are trained on the parallel corpus of Japanese and English (Morishita et al., 2019). We compared the quality of translations by using fine-tuning with several datasets. Also, we tested several different hyperparameters of the training to find suitable values for the task. After the fine-tuning, we tried to perform ensembling of multiple results from the model to earn a better-quality translation in the English to/from Japanese model. Here we describe the details of our systems.

2 Data selection and preprocessing

We select a suitable parallel corpus for model fine-tuning. We compare WMT provided dataset (which contained 7 different sources including the JParaCrawl dataset), KFTT (Kyoto Free Translation Task data set, Neubig, 2011), the JParaCrawl dataset (ver 2) and so on. We performed fine-tuning for these datasets and found that the model trained on the JParaCrawl dataset achieved better performance. We used a test data set made from WMT provided data and compare model performances by BLEU score. The score of the no fine-tuned model was 37.21, KFTT fine-tuned model was 14.87 and JParaCrawl fine-tuned model was 44.09. Therefore, we decided to use JParaCrawl as our fine-tuning dataset finally. We also consider that JParaCrawl has a reasonable amount of data for our high-efficiency training strategies.

Before we use the dataset, we check the corpus data to clean up. The JParaCrawl dataset contains over 10 million sentence pairs which were constructed by broadly crawling the web and automatically aligning. Therefore, there were noise and low-quality translations. We filtered low quality translation pairs and made a better translation dataset for fine-tuning. We also find that there were some contaminations of non-Japanese languages (e.g., Korean, Chinese) in the Japanese data. We also remove these pairs from the dataset.

3 Tokenization

We perform the tokenization procedure using the SentencePiece toolkit[1] which provides us with a segmented sentence as tokens. In Japanese and some other languages like Chinese, words were not separated by spaces, therefore, tokenization needs to detect divided positions to separate each token. For Japanese, tokenization can be performed by a lattice-based tokenizer like MeCab[2]. A lattice-based tokenizer performs tokenization based on a dictionary and if the contents of the dictionary cover whole words in data, it provides highly accurate tokenization. However, in the development of machine translation using Neural Network mechanisms, more efficient tokenization methods like Byte-Pair-Encoding (BPE) were proposed (Sennrich et al. 2016c). SentencePiece was developed based on these methods and provides more efficient tokenization for the NMT (Kudo and Richardson, 2018).

SentencePiece is especially effective for languages not using spaces to separate words, has agglutinating morphology, and contains many compound words. Using SentencePiece helps extract subwords within compound words and create a more robust tokenizer. SentencePiece was used again to detokenize by removing the meta symbols from the output translation. For preprocessing the data, we have used the SentencePiece model, in which the vocabulary size is set to 32,000, and sentences whose length exceeded 250 subwords are removed from the training data.

4 Model Training

We train our NMT models with the fairseq[3] toolkit. The models are based on Transformer (Vaswani et al., 2017) with base settings. We use an encoder/decoder with six layers. We set their embedding size to 512, and their feed-forward embedding size to 2048. We use eight attention heads for both the encoder and the decoder. We used dropout with a probability of 0.3. As an optimizer, we used Adam with $\alpha = 0.001$, $\beta1 = 0.9$, and $\beta2 = 0.98$. We used a root-square decay learning rate schedule with a linear warmup of 4000 steps. We clipped gradients to avoid exceeding their norm 1.0 to stabilize the training. For the base settings, each mini-batch contained about 5,000 tokens (subwords), and we accumulated the gradients of 64 mini-batches for updates. We trained the model with 24,000 iterations, saved the model parameters every 200 iterations, and averaged the last eight models. To achieve maximum performance with the latest GPUs, we use mixed-precision training. When decoding, we used a beam search with a size of six as the default condition and length normalization by dividing the scores by their lengths. We test other parameters of a beam search in the model of Japanese → English translations (size = 2, 3, 4, and 10) and found that size = 2 provide the best BLEU score for this task. We also compared models output by scaraBLEU (Post, 2018).

Our models are trained on the Google Cloud Platform's compute engine with 2-T4 GPUs. Model training generally took approximately 3.5 hours. We train our models in mixed precision to save costs without compromising on the accuracy.

Model condition	JParaCrawl data
Pretrained Model	39.4
Finetuned Model	45.1
Finetuned with ensemble	46.9*[1]

Table 1: BLEU Scores of English → Japanese direction, each column uses the same test dataset for three conditions.

*1 This result was not submitted due to our system's trouble.

5 Model Ensembling and N-Best Reranking for English → Japanese direction

After we fine-tuned our base model, we performed model ensembling with N-Best Reranking (Le et. al., 2021). For n-best reranking, we have created a script by referring to a script by Xu Song[4], bert-as-

Models	BLEU
Our model	43.9
DeepL	26.6

Table 2 Test result of our model and DeepL

a-language-model. We performed some changes in the scripts for its application to Japanese. For measuring the likelihood of the Japanese sentences produced by the NMT model, we have used the bert-Japanese model released by Yohei Kikuta[5].

For ensembling, the basic idea is to calculate the probability of tokens and perplexity of sentences produced by 10 different checkpoint files of a finetuned model. These 10 checkpoints will create 10 different translations for a given English sentence. Later, we are using bert-as-language-model to calculate the best sentence (the one with the lowest perplexity) score. We have used this sentence output for the submission. This method ensures the selected sentence has maximized fluency compared to other candidates.

6 Results and discussions

6.1 English → Japanese direction

We performed an experiment to compare ensembling effect (Table 1). In the experiment, we prepare training data from the JParaCrawl dataset to fine-tune our model and compare translations with/without ensembling. Based on the same training conditions, the score of the ensembling model is higher than the result of the model without ensembling.

To evaluate our translation quality, we compare the result with the online translation service (DeepL) by using a test dataset which created by the JParaCrawl dataset. The test data contains 1000 sentences that were not contained in the train data. The BLEU score of our model was higher than DeepL this means our fine-tuning procedure leads to better translation for the JParaCrawl dataset (Table 2).

We also check the translation result of the test set released by WMT2022. The dataset consists of 2037 English sentences and there were no reference sentences of Japanese. Therefore, we cannot calculate BLEU score here. Alternatively, we calculate perplexity[6] (PPL), by using bert-japanese model[5], which is explained in the model ensembling section. PPL is a metric of a language model and lower values mean better. We also check the translation quality by the human evaluation of a Japanese native speaker.

The average of the PPL of our model was lower than DeepL (Table 3). The result suggested that our small model established a high-fluently prediction rather than DeepL. In detail, for 941 cases in the test set with 2037 sentences, our PPL was lower than DeepL. We presented several examples of these cases in appendix examples 1 to 4. In these examples, the quality of translations for our model is also better than DeepL based on the confirmation of a native speaker. As a bad case, we list example-5 in the appendix. Although the translation of DeepL has better quality, however, the PPL score was higher than our model's output.

The results above (Table 2 and Table 3) suggested that we can establish a high-quality NMT model by small model and a reasonable amount of data, by using high-efficiency training strategies.

6.2 Japanese → English direction

For the Japanese to English direction, we perform finetuning with the Transformer model base setting on the JParaCrawl dataset. Table 4 shows our training results. For the final submission, we also performed post-processing to delete some extra punctuations that appeared in the translation results. We found that post-processing improved our results by 0.1 BLEU score.

Model condition	Our_PPL	DeepL_PPL	No. of cases
Average	41.59	51.75	2037
Average (our < DeepL)	21.86	90.61	941
Average (our > DeepL)	59.84	15.79	1096

7 Conclusions

We explored the high-efficiency model training strategies with a small model and a reasonable amount of data. Our systems are based on the transformer with a base setting. In our experiments, we found that data cleaning, model averaging, model ensembling, beam search, finetuning, parameter-tuning, and post-processing are useful techniques to train a high-quality model. Finally, we compared the translation results between our model and the online translation service, we found that our model achieved better translation quality. Our experiments suggested that exploring more efficient training strategies with a smaller model, a reasonable amount of data, and limited computational resources is promising to achieve a high-quality translation model.

Abstract

Customer feedback can be an important signal for improving commercial machine translation systems. One solution for fixing specific translation errors is to remove the related erroneous training instances followed by re-training of the machine translation system, which we refer to as instance-specific data filtering. Influence functions (IF) have been shown to be effective in finding such relevant training examples for classification tasks such as image classification, toxic speech detection and entailment task. Given a probing instance, IF find influential training examples by measuring the similarity of the probing instance with a set of training examples in gradient space. In this work, we examine the use of influence functions for Neural Machine Translation (NMT). We propose two effective extensions to a state of the art influence function and demonstrate on the sub-problem of copied training examples that IF can be applied more generally than handcrafted regular expressions.

1 Introduction

Neural Machine Translation (NMT) is the de facto standard for recent high-quality machine translation systems. NMT, however, requires abundant amount of bi-text for supervised training. One common approach to increase the amount of bi-text is via data augmentation (Sennrich et al., 2015; Edunov et al., 2018; He et al., 2019, *inter alia*). Another approach is the use of web-crawled data (Bañón et al., 2020) but since crawled data is known to be notoriously noisy (Khayrallah and Koehn, 2018; Caswell et al., 2020), a plethora of data filtering techniques (Junczys-Dowmunt, 2018; Wang et al., 2018; Ramírez-Sánchez et al., 2020, *inter alia*) have been proposed for retaining a cleaner portion of the bi-text for training.

While standard data filtering techniques aim to improve the quality of the overall training data without targeting the translation quality of specific instances, *instance-specific data filtering* focuses on the improvement of translation quality toward a specific set of input sentences via removal of the related training data. In commercial MT, this selected set of sentences can be the problematic translations reported by customers. One simple approach of instance-specific data filtering in NMT is manual filtering. In manual filtering, human annotators identify translation errors on sentences reported by customer and designs filtering scheme, e.g., regular expressions to search related training examples for removal from the training set.

In this work, we attempt to apply a more automatable technique called influence functions (IF) which is shown to be effective on image classification (Koh and Liang, 2017), and certain NLP tasks such as sentiment analysis, entailment and toxic speech detection (Han et al., 2020; Guo et al., 2020). Given a probing example, influence functions (IF) search for the influential training examples by measuring the similarity of the probing example with a set of training examples in gradient space. Schioppa et al. (2021) use a low-rank approximation of the Hessian to speed up the computation of IF and apply the idea of self-influence to NMT. However, self-influence measures if a training instance is an outlier rather than its similarity with another instance. Akyürek et al. (2022) question the back-tracing ability of IF on the fact-tracing task. They compare IF with heuristics used in Information Retrieval and attribute the worse performance of IF to a problem called *saturation*. Compared to fact-tracing, the target sides of machine translation can be more diverse which complicates the application of IF.

We apply an effective type of IF called *TracIn* (Pruthi et al., 2020) to NMT for instance-specific data filtering and analyze its behaviour by constructing synthetic training examples containing simulated translation errors. In particular, we find

that

- the gradient similarity, also called the influence[1], is highly sensitive to the network component.
- vanilla IF may not be sufficient to achieve good retrieval performance. We proposed two contrastive methods to further improve the performance.
- training examples consisting of copied source sentences have similar gradients even when they are lexically different. This indicates that the use of influence functions can go beyond what can be achieved with regular expressions.
- an effective automation of the instance-specific data filtering remains challenging.

To the best of our knowledge, we are the first to investigate applying IF for instance-specific data filtering to NMT.

2 Method

Influence functions IF is a technique from robust statistics (Hampel, 1974; Cook and Weisberg, 1982, *inter alia*). It aims to trace a model's predictions back to the most responsible training examples without repeated re-training of the model, aka Leave-One-Out. Koh and Liang (2017) extend this idea from robust statistics to deep neural network that requires only the gradient of the loss functions L and Hessian-vector products so that the influence $\mathcal{I}(z, z')$ of two examples z and z' is approximated as

$$\mathcal{I}(z, z') \approx \nabla_\theta L(z')^T H_{\hat{\theta}}^{-1} \nabla_\theta L(z) \quad (1)$$

where $\hat{\theta}$ is the model parameters at optimum and $H_{\hat{\theta}} = \frac{1}{n}\sum_{i=1}^{n} \nabla_\theta^2 L(\theta)$ is the Hessian of the model parameters at $\hat{\theta}$. Given n number of training instances and p number of model parameters, the inverse of Hessian has a complexity of $\mathcal{O}(np^2 + p^3)$ which is expensive to compute for deep neural network. There are several proposed methods to speed up the computation of IF, e.g., by computing on a training subset selected by KNN-search (Guo et al., 2020), by approximating the Hessian with LISSA (Agarwal et al., 2017), by computing on a subset of model parameters (Koh and Liang, 2017), or by replacing the Hessian with some other procedures (Pruthi et al., 2020). In this work, we focus on TracIn which is shown to be better than some other variations (Han and Tsvetkov, 2020; Schioppa et al., 2021) in terms of retrieval performance.

TracIn, denoted by $\mathcal{I}_{\text{TracIn}}(z, z')$, replaces the computationally costly Hessian matrix with an identity matrix. The remained gradient dot product, or called the gradient similarity, is instead computed over C number of checkpoints, followed by averaging:

$$\mathcal{I}_{\text{TracIn}}(z, z') = \frac{1}{C}\sum_{i=1}^{C} \nabla_\theta L(z')^T \nabla_\theta L(z) \quad (2)$$

In NMT, given the same source sentence, the magnitude of the gradient in general is positively correlated to the length of the target sentence. In order to reduce the effect of the target length, we normalize equation 2 by the product of $\|\nabla_\theta L(z')\|$ and $\|\nabla_\theta L(z)\|$, or equivalently, we compute the cosine similarity of $\nabla_\theta L(z')$ and $\nabla_\theta L(z)$.

Given a probing instance z' and its probing gradient $\nabla_\theta L(z')$, instances in the training set that yield a positive value of $\mathcal{I}_{\text{TracIn}}(z, z')$ are called the positively influential training instances (+IFTrain) whereas those that yield a negative value of $\mathcal{I}_{\text{TracIn}}(z, z')$ are called the negatively influential training instances (-IFTrain). Taking a gradient step on +IFTrain reduces the loss on the probing example while taking a gradient step on -IFTrain increases it. IF can be used for data filtering by removing the +IFTrain examples of low quality probing samples since their gradients have similar direction. Conversely, if the probing sample is of high quality, removing -IFTrain examples from the training data would be expected to increase translation quality w.r.t. the probing sample.

3 Experimental Setting

Model configuration and training We use Transformer BASE configuration as described in Vaswani et al. (2017) with default setting and implementation in FAIRSEQ. We use a sentence-piece model to create subword units of size 32k. Unless otherwise specified, we pre-trained our NMT on Europarl-v7 data and News Commentary-v12 data in German-English direction from WMT17 for 100 epochs, about 112K updates, using Adam

[1] In this work, we use gradient similarity or influence interchangeably to denote the result of IF. Be aware that TracIn is also one type of IF.

Table 1: Example showing the changes of influence by network components. Segments that are marked in red are perturbed from the probing example. ∇_X indicates the network components used in computing the influence, ∇_{concat} indicates the concatenation of ∇_{srcEmb}, ∇_{trgEmb} and ∇_{output}.

optimizerion training of 16-bit[2]. The effective mini-batch size is 4096 x 16 tokens and it takes a p3.16xlarge[3] machine on AWS 6 hours for training. We evaluate the MT model on the newstest2017 test set with a checkpoint averaged over the 10-best checkpoints, measured by the validation loss on the newstest2014-2016 dev set. On the test set, our NMT model with non-shared parameters with the two word embeddings and the output layer scores 29.99 BLEU whereas the one with shared parameters scores 29.78 BLEU. We use beam search with beam size of 5 in decoding.

TracIn We select 5 checkpoints, i.e., at epoch 5, 8, 15, 30 and 100 for computing TracIn[4]. We select checkpoints which have relatively large changes in the validation loss, i.e., usually in the earlier phrase of training, and include the last one to cover information at the end of the training. We compute the per-sample gradient with a batch size of 1 parallelized over multiple processes with several g4dn.2x[3] machines on AWS.

4 Experimental results

This section describes our findings on the properties of applying IF on NMT for instance-specific data filtering.

4.1 Sensitivity of gradient similarity to the network components

In previous works, the influence, or called the gradient similarity, is usually computed with respect to a small part of the network parameters, especially the last or the last few layers (Han et al. (2020);Barshan et al. (2020); *inter alia*). In NMT, we found that the resulting influence is highly sensitive to the network components used in computing the gradients (or gradient component). For illustration, we construct a set of perturbed instances, compute its influence by different gradient components and observe their changes. The perturbed instances are not included during the NMT training. This independence between the NMT and the perturbed instances provides a simpler setting for checking how gradient components and the perturbed examples affect the influence.

[2] We use 32-bit precision to compute the gradient similarity once the training is done.

[3] See https://aws.amazon.com/ec2/instance-types/ for details.

[4] It is tempting to just use the deployed checkpoint to compute the influence. As shown by Liang et al. 2017, however, the Hessian term in equation 1 captures more accurately the effect of model training than the dot product of the optimal checkpoint. In TracIn, the Hessian is approximated by the average over a set of checkpoints, and we follow their guidelines for checkpoints selection.

Table 1 shows the gradient similarities of a probing example from newstest2017 with six artificially created instances. We use two NMT models, 1) trained with shared parameters between the two word embeddings and the output layer and 2) trained without parameter sharing, to compute the similarities.

We notice that gradient similarity for the model with shared parameters is more strongly influenced by lexical matches on the target side, as shown by the larger magnitude of influence values for probing examples 1 and 2 with random source sides compared to probing examples 3 and 4 with random target sides. For non-shared parameters, we observe that the gradient w.r.t. the output layer (∇_{output}) has stronger response (0.437 and 0.401) to the probing instances with random source side whereas the gradient w.r.t. source embedding (∇_{srcEmb}) has stronger response (-0.149 and -0.120) to the instances with random target sides. On the same probing example, we repeat this random sampling of source and target sentences by using the other 3003 instances in the newstest2017 set. We find that the mean magnitude of ∇_{srcEmb} is 0.04 for random target whereas it is 0.004 for random source. In the case of ∇_{output}, the mean magnitude for random target is 0.021 whereas it is 0.428 for random source. This indicates that ∇_{output} has a tendency of scoring sentence pairs higher when their target side overlaps with the target side of the probing instance and is less influenced by source-side overlap. This may be suboptimal for retrieving problematic training examples that are relevant to a given probing instance.

When using a gradient vector ∇_{concat} which is the concatenation of ∇_{srcEmb}, ∇_{trgEmb} and ∇_{output}, its similarity is dominated by ∇_{output} rather than equally shared between the three given that they have the same number of parameters. This may explain why, in the case of shared parameters, instances with random source side have higher similarities than those with random target side.

Instance 5 and 6 are minor edits of the probing instance with changes to punctuation. For instance 5, it is not easy to interpret the results for the model with shared parameters. However, in the non-shared parameter setting, we observe a higher similarity for ∇_{srcEmb} than for ∇_{trgEmb} and ∇_{output}. This is more interpretable because the punctuation change is on the target side. For instance 6, the punctuation change is on the source side and we see a higher TracIn value for ∇_{output} than for ∇_{srcEmb} and ∇_{trgEmb}. As before, the value of ∇_{concat} is more similar to the value of ∇_{output}. Further examples can be found in Table A1 in the Appendix.

These qualitative results show that the choice of network component is crucial in computing the gradient similarity. As shown in the next experiment, this affects the retrieval of training examples.

4.2 Contrastive signal is crucial for better retrieval performance

In this section, we try to illustrate how different gradient components affect the retrieval of the noisy instances with TracIn. We add control to the retrieval outcome by adding synthetic noisy training instances to the training data. In addition, we show that vanilla IF may not be sufficient to achieve good performance because the gradients are aggregated over all tokens in the target sentence. We thus propose two contrastive methods to sharpen the gradient signal.

Synthetic noisy examples We use the error template *X → Y* which stands for *X is translated to Y* to construct synthetic noise examples for the training set . We created four simple error patterns: 1) *August → January*, 2) *Deutschland → Italy*, 3) *Oktober → December* and 4) *Türkei → New Zealand.*

Error pattern	Number of instances		
	train	synthetic noisy	probing
August → January	8,017	925	9
Deutschland → Italy	15,360	4,891	30
Oktober → December	11,927	2,422	8
Türkei → New Zealand	14,963	7,417	22

Table 2: Number of instances per error pattern

In the training set, we replace the translation of the sentences containing the source pattern by the erroneous translation with a probability of 60% so that the total number of training data is unchanged. We select these error patterns because translation errors of months and country names can easily result from noisy training examples and are therefore suitable to simulate real customer issues. In addition, there are related source sentences in the test set, i.e., newstest2017, which can be used as probing examples. In order to speed up the computation of IF, we extract a subset of training data containing the original pattern, the perturbed pattern and some randomly sampled training sentences. For example, in the error pattern *Oktober* → *December*, the training subset contains sentences with *Oktober*, *Dezember*, *October* and *December* on either the source or target side together with some randomly sampled sentences. Table 2 gives the exact number of instances for each case. We follow the same training procedure as section 3 to pre-train a NMT model on the training corpus perturbed by the synthetic noises.

Contrastive-IF The gradient of a source-target pair in NMT involves complicated mapping between the source tokens and the target tokens. That is, the gradient vector does not just contain the information of the error pattern but also other context. In order to isolate the gradient of the error pattern from the aggregated signal, we propose two methods: 1) gradient masking and 2) gradient difference. Both methods leverage a cleaner translation either in the form of a gold-reference translation or a corrected hypothesis, i.e. the hypothesis with the error pattern corrected. We refer to them as *Contrastive Influence Functions* (Contrastive-IF).

The idea of gradient masking (*Mask*) is to apply a 0/1 token-level mask to the loss function so as to remove the contribution of irrelevant tokens from the gradient computation. We assign the mask based on which tokens differ between hypothesis and reference. If the 0-mask is applied everywhere except for the location of the error according to a corrected translation, we refer to it as *MaskExact*.

We can use the difference between two hypotheses in a continuous fashion by simply subtracting their gradients. Specifically, we compute the difference of the gradient of a sentence A and the gradient of a sentence B as the probing gradient: $GD(A, B) = \nabla(A) - \nabla(B)$. In this work, we use the hypothesis as A and a cleaner translation as B (either the reference or the corrected hypothesis) so that positively influential training instances w.r.t. to $GD(A, B)$ are the synthetic noisy training instances.

Results Table 3 shows the retrieval performance of vanilla IF, gradient masking and gradient difference where the gradient is computed w.r.t. to either the source embedding, output layer or the full model. We evaluate the performance with precision over the top-X% influential training instances, i.e. the number of synthetic training instances successfully retrieved given top-X% of the influential training samples. We combine results of the four error patterns by (macro) averaging their precision.

The first three rows show results for vanilla IF (TracIn) when either the hypothesis, the reference or a corrected hypothesis is used for probing the training data. Using ∇_{srcEmb} or ∇_{output} obtain substantially higher precision for each variant than using ∇_{Full}, i.e., the gradient w.r.t. the entire model, which demonstrates the importance of the choice of gradient component(s) in vanilla-IF for retrieval performance. Using the corrected hypotheses to retrieve negatively-influential examples yields the best precision for both top-1% and top-10% of retrieved training examples.

We qualitatively examine the influential instances retrieved. By using the source-hypothesis pair as the probing instance, we find that instances retrieved via ∇_{output} have less similarity on the source side. In the first probing example, *Januar* → *January* occurs more frequently in the ranking than *August* →*January*. In the second example, *Italien* → *Italy* appears as the third influential training instance when using ∇_{output} whereas all top-3 influential instances obtained by ∇_{srcEmb} contain the desired error pattern of *Deutschland* → *Italy*, see Table A2 in the Appendix.

We find that both gradient masking, ∇(HYP$_{\text{Mask}}$), and gradient difference, ∇(HYP) − ∇(REF), perform better than the vanilla IF given the same gradient component. ∇(HYP$_{\text{Mask}}$) always outperforms the comparable vanilla IF variants ∇(HYP) and ∇(REF). If we can identify the exact location of the error pattern, with the probing gradient ∇(HYP$_{\text{MaskExact}}$) or ∇(CorrHYP$_{\text{MaskExact}}$), the precision can be further boosted and this is consistent for gradients ∇_{srcEmb}, ∇_{output} and ∇_{Full}. While the gradient difference variants do not always outperform the comparable masking variants for all ∇_X, ∇(HYP) − ∇(CorrHYP) yields the overall best result using ∇_{srcEmb}.

An interesting finding is the improvement brought by the corrected hypothesis (CorrHYP). Applying vanilla-IF on it already achieves a precision of 0.930 under ∇_{srcEmb} considering the top-1% influential instances. By applying *MaskExact* or gradient difference on it, we achieve very high precisions of 0.989 and 1.0 under ∇_{srcEmb} considering the top-1% influential training instances. One notable gain brought by the proposed approaches is that for ∇_{Full}, the precision increases from 0.531 to around 0.987 for the ∇(HYP) − ∇(CorrHYP) variant, bringing it on-par to the performance of

∇(Probing)	+/-	Precision		
		∇_{srcEmb}	∇_{output}	∇_{Full}
∇(HYP)	+	0.846	0.720	0.503

	10%		0.746	0.463
∇(HYP) - ∇(CorrHYP)	1%	+	0.891	0.691
	10%		0.808	0.607

Table 4: Retrieval performance measured in average precision across all error patterns for an NMT model with shared parameters between the word embeddings and the output layer.

We also conducted a side experiment with a NMT model with shared parameters between the embeddings and the output layer. Similar to the case of a NMT model with non-shared parameters, gradient difference improves over the vanilla-IF when averaging precisions over all error patterns as shown in Table 4.

To summarize, both our contrastive-IF variants improve retrieval performance regardless of the network component used in computing gradients and whether the NMT model has shared parameters.

4.3 Copied source sentences have similar gradient signature

Our initial motivation for applying influence functions to NMT was to arrive at a more automatable way of retrieving relevant training examples for reported translation problems. We were also hoping to generalize over what can be achieved by applying manually composed regular expressions which are limited to detecting lexical overlap. In this section, we focus on the latter and investigate whether Influence Functions can retrieve training examples that cause an undesired copy behaviour in the decoder.

Experimental settings On top-of the Europarl-v7 and News Commentary-v12 data, we append a set of 176,004 copied source sentences provided by Khayrallah and Koehn (2018) to the training set. Following the training recipe in section 3, our NMT with non-shared parameters has a degradation of translation quality from 29.99 BLEU to

∇(Probing)	+/-	Precision		
		∇_{srcEmb}	$\nabla_{encoder}$	∇_{Full}
∇(HYP)	+	0.930	0.972	0.994
∇(REF)	-	0.525	0.452	0.548
∇(HYP) - ∇(REF)	+	0.708	0.712	0.949

(a) Retrieval performance for top-10% influential training examples

∇(Probing)	+/-	Precision		
		∇_{srcEmb}	$\nabla_{encoder}$	∇_{Full}
∇(HYP)	+	0.888	0.932	0.986
∇(REF)	-	0.508	0.449	0.504
∇(HYP) - ∇(REF)	+	0.670	0.647	0.895

(b) Retrieval performance for top-20% influential training examples

Table 5: Retrieval performance measured in averaged precision over the probing instances, on copied training instances. $\nabla(Probing)$ refers to the gradient with input 'source-Probing'. HYP, REF stands for hypothesis, reference. "+" ("-") indicates that positively (negatively) influential training instances were retrieved. ∇_X indicates the network components used in computing the gradient.

17.64 BLEU on the newstest2017 data, showing the detrimental effect of the untranslated target sides.

We select 40 probing instances from the newstest2017 data where their translation by the above NMT model is a copy of the source sentence. We again reduce the computation time by running TracIn over a training subset which contains the newly added noisy data, i.e., 176,004 instances and a set of randomly sampled training instances. This creates a training subset of 476,004 instances.

Results Table 5 shows the retrieval performance on copied source sentences in the training subset with probing gradients of $\nabla(HYP)$, $\nabla(REF)$ and $\nabla(HYP)$ - $\nabla(REF)$ computed over source embedding (∇_{srcEmb}), the encoder ($\nabla_{encoder}$), or the entire model (∇_{Full}). We skip the masking strategy in this case since it would mask all target tokens, resulting in a loss of 0. Different from our results so far, the vanilla IF using only the hypothesis preforms better than using the reference for retrieval and better than the gradient difference variant for all network components. For example, when considering only the top-10% influential training instances, the precision is 0.930 for $\nabla(HYP)$ with ∇_{srcEmb} and only 0.525 for $\nabla(REF)$. This may indicate that instances of copied source sentence have similar gradient signature despite their lexical difference (see Table A4 for some examples) and that the reference translation is less useful in this setting because it cannot provide a specific contrastive signal.

A surprising finding in this setting is that using gradients computed over the entire network is better than the source embedding or the entire encoder. This is in contrast to the previous findings in the synthetic training instances. This possibly indicates that the copy mechanism is spread over the entire model or parts beyond the source embedding or the encoder.

4.4 An effective IF-based instance-specific data filtering is hard to automate

Many data filtering algorithms require a threshold to decide which instances are to be filtered. This threshold can be a model score in an offline filtering algorithm (Junczys-Dowmunt, 2018) or a dynamic formula that is changed according to the learning state of the model (Wang et al., 2018). In both cases, a desirable threshold should be effective as measured in the downstream model performance and be easily computed and generalized to other situations. In the case of IF-based instance-specific data filtering, we observe two properties in the ranking of the influence which makes the automation of the data filtering algorithm challenging.

1: The range of influence varies across probing examples Although the influence is bounded between $[-1, 1]$ because of the cosine similarity, the maximum magnitude of the influence for each probing example can still be very different. Table 6 shows the mean and standard deviation of the maximum influence value of positively influential training instances computed over probing examples of the same configuration. Firstly, the mean value is quite diverse across different gradient components, and across different probing gradients of the same error pattern. For example, the mean value of the error pattern *August* → *January* computed with ∇_{srcEmb} is 0.399 or 0.059 depending on which probing gradient is used. Secondly, the standard deviation within each configuration is relatively large when compared to the corresponding mean value. For example, it is about 26%, 36%, 22% and 19% in the case of ∇_{srcEmb} using gradient difference as the probing gradient. This large standard deviation indicates the difficulty of setting an effective threshold for filtering even for probing examples with the same type of error pattern.

Error pattern	∇(HYP) - ∇(CorrHYP)		∇(HYP)	
	∇_{srcEmb}	∇_{Full}	∇_{srcEmb}	∇_{Full}
August → January	0.399 ± 0.104	0.199 ± 0.041	0.059 ± 0.023	0.119 ± 0.042
Oktober → December	0.524 ± 0.192	0.397 ± 0.123	0.056 ± 0.028	0.143 ± 0.043
Deutschland → Italy	0.576 ± 0.126	0.428 ± 0.047	0.097 ± 0.061	0.135 ± 0.046
Türkei → New Zealand	0.527 ± 0.100	0.540 ± 0.118	0.080 ± 0.044	0.165 ± 0.051

Table 6: Statistics showing the mean and standard deviation of the largest influence per configuration. The large standard deviation of the maximum influence value for probing examples of the same error pattern shows the difficulty of defining a comparable filtering threshold across probing instances.

Error pattern	∇(HYP) - ∇(CorrHYP)		∇(HYP)	
	∇_{srcEmb}	∇_{Full}	∇_{srcEmb}	∇_{Full}
August → January	1.44 ± 0.50	3.33 ± 1.76	1.78 ± 1.55	1.44 ± 0.69
Oktober → December	2.25 ± 0.43	2.00 ± 0.00	2.88 ± 1.76	2.00 ± 1.58
Deutschland → Italy	1.00 ± 0.00	1.77 ± 0.62	1.67 ± 1.22	2.70 ± 2.62
Turkei → New Zealand	3.05 ± 1.46	1.32 ± 1.26	2.27 ± 2.09	2.32 ± 1.66

Table 7: Mean and standard deviation of the number of influential training instances to be removed per configuration, using the largest consecutive difference found in the ranking as clustering criterion.

2: The influence value drops abruptly at the top-of the ranking Apart from a fixed threshold across different probing example, we also examine the possibility of automatically setting a threshold for each probing example.

We first examine a simple clustering strategy by searching for the position where the consecutive difference is the largest in the ranking of influence. Table 7 shows the result of the mean and standard deviation of the number of most influential training instances to be removed per configuration. By considering only the largest consecutive difference, less than 5 training instances would be removed which is far less than the number of synthetic training instances.

We examine further by investigating the shape of the influence of the positively influential training instances in the ranking. Figure 1 shows the influences, computed via TracIn, of the top-500 positively influential training instances per error pattern. For each error pattern, we randomly select a probing example to examine its influence under different gradient conditions. In all these cases, the influence drops sharply in the first few instances, especially in the case of vanilla IF, denoted by “GradHYP” in the figures. After the sharp drop, the influence becomes quite steady for the remaining instances. This steady behaviour holds even for instances of much lower rank, see Figure A1 in the Appendix. The “elbow” occurs before the first 50 influential training instances, which includes only a tiny portion of the synthetic noisy training instances.

How about Top-K filtering? In previous work, the authors use either Top-K or Top-X% as the filtering threshold which is not realistic in the case of NMT where 1) there can be billions of training instances, and 2) the error types are more diverse than the prediction of wrong classes. In spite of the good retrieval performance demonstrated in the previous section, our results here show that an effective automation of the IF-based instance-specific data filtering for NMT remains a challenge.

5 Conclusion

We have analyzed the use of Influence Functions for NMT as instance-specific data filtering. By constructing synthetic instances, we found that 1) the gradient similarity is very sensitive to the selected network components, 2) vanilla Influence Functions are not sufficient for good retrieval performance, 3) our proposed contrastive-IF can boost the retrieval performance regardless of the gradient component or parameter sharing, 4) finding an effective automation of IF for instance-specific data filtering is difficult. This is because the proper choice of gradient component with respect to the type of error in the probing example is crucial for the effectiveness of Influence Functions. Despite the reported effectiveness for certain classification tasks in previous literature, our results show that applying IF to NMT poses some practical difficulties that we have not yet been able to solve.

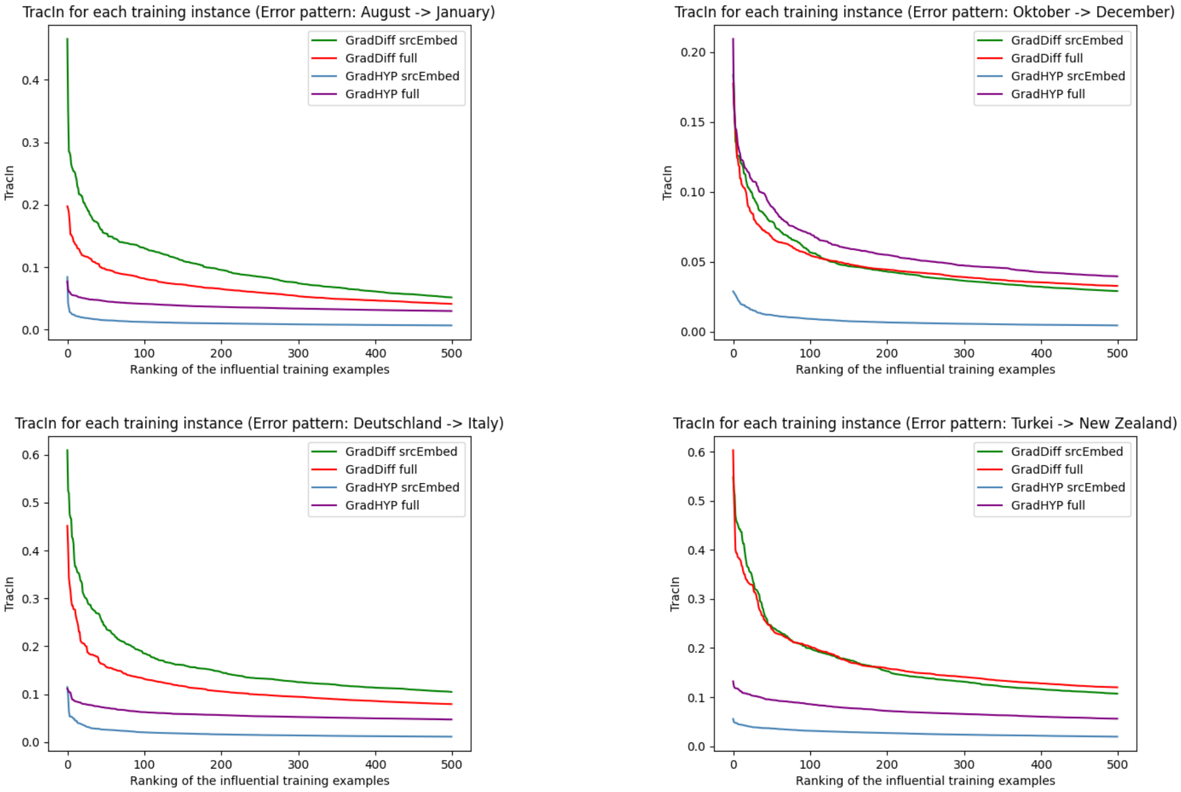

Figure 1: TracIn of the top-500 positively influential training examples. In each subfigure, we randomly select a probing example from each error pattern to compute its influence using gradient difference w.r.t. 1) source embedding (GradDiff srcEmbed), 2) entire model (GradDiff full) and using vanilla-IF with source-hypothesis as input w.r.t. 1) source embedding (GradHYP srcEmbed), 2) entire model (GradHYP full).

6 Limitations

In this work, we provided an analysis of using Influence Functions for Neural Machine Translation as instance-specific data filtering for the purpose of cost saving and finding a more generally applicable solution. Despite the reported success of some previous works in NLP/Vision-related classification tasks, we faced several challenges in applying Influence Functions to NMT. We are aware of the following limitations to our analysis:

- Our analysis focuses on TracIn rather than other influence functions because TracIn is reported to be very effective.
- Our analysis is based on a fixed set of checkpoints, following the practice of previous works. The selection and the number of checkpoints used in TracIn are computationally costly hyper-parameters.
- Our analysis focuses on major network components such as embeddings, encoder and the output layer, excluding other possible combinations.
- The scale of our experiments is limited, e.g., only the De-En language direction with 3M training instances and the synthetic examples are relatively simple. However, given such simple setting, we can already see the challenges of applying IF on NMT as instance-specific data filtering or as an attribution/interpretable method.
- The proposed contrastive IF requires a corrected translation, e.g., reference translation.

We hope that our analysis can inspire further evaluation and modification of the technique.

Abstract

This paper describes AISP-SJTU's participation in WMT 2022 shared general MT task. In this shared task, we participated in four translation directions: English→Chinese, Chinese→English, English→Japanese and Japanese→English. Our systems are based on the Transformer architecture with several novel and effective variants, including network depth and internal structure. In our experiments, we employ data filtering, large-scale back-translation, knowledge distillation, forward-translation, iterative in-domain knowledge finetune and model ensemble. The constrained systems achieve 48.8, 29.7, 39.3 and 22.0 case-sensitive BLEU scores on EN→ZH, ZH→EN, EN→JA and JA→EN, respectively.

1 Introduction

We participate in the WMT 2022 shared general MT task, including English↔Chinese(EN↔ZH) and English↔Japanese(EN↔JA). All of our systems are built with constrained data sets.

For model architectures, we exploit several Transformer variants including transformer-DLCL (Wang et al., 2019), transformer-ODE (Bei Li, 2021), transformer-RPR (Shaw et al., 2018), transformer-Coda (Zheng et al., 2021).

In this year's translation tasks, we mainly employ data filtering (Zhou et al., 2021; Zeng et al., 2021), large-scale back-translation (Sennrich et al., 2015; Lample et al., 2017), knowledge distillation, forward-translation, in-domain knowledge finetune and model ensemble to improve the final model's performance.

For the synthetic data generation, we first exploit large-scale back-translation (Sennrich et al., 2015) method to leverage the target-side monolingual data and the knowledge distillation (Kim and Rush, 2016) to leverage the source-side of bilingual data. To use the source-side monolingual data, we explore forward-translation by ensemble models to get general domain synthetic data.Furthermore, several data augmentation methods are applied to improve the model robustness, including different token-level noise and different sampling methods.

We mainly use three training strategies in the training phase, including the warmup strategy (He et al., 2016) to adjust the learning rate in training, different sampling methods (Holtzman et al., 2019) and the Graduated Label Smoothing (Wang et al., 2020).

In the fine-tuning stage, the test set is clustered into seven categories, and then use the TFIDF-Ngram algorithm (Ramos et al., 2003) to search for similar bilingual and monolingual data in all data according to these seven domains. The monolingual data is then generated using forward translation to generate pseudo-data, and finally fine-tuned together with the searched bilingual data.

We pay more attention to the differences between different models in this year. We compute Self-BLEU (Zhu et al., 2018) from the translations of the models on the valid set to quantify the diversity among different models. To be precise, we use the translation of one model as the hypothesis and the translations of other models as references to calculate an average BLEU score. A lower Self-BLEU means this model is more different from other models.

For ensemble method in every category, the self-BLEU scores of the models are calculated to represent their differences from other models, and according to the self-BLEU scores of the model, the distribution weight when they perform ensemble is calculated through the Softmax-Temperature (Zhu et al., 2018; Cheng et al., 2017). Now seven domain ensemble models are obtained, then use the model for each domain to predict the test set of the corresponding domain separately.

This paper is structured as follows: Sec. 2 describes the novel model architectures. We introduce our system and training strategy in detail in Sec. 3. Experimental settings and results are shown in Sec. 4. We conduct analytical experiments in Sec. 5. Finally, we conclude our work in Sec. 6.

2 Model Architectures

2.1 Model Configurations

As the number of model parameters increases, the model's performance is better, so deeper and wider architectures are used in our system. However, the training of the deep model is unstable, and the loss is not easy to converge. Recent studies (Liu et al., 2020a; Huang et al., 2020) show that the unstable training problem of Post-Norm Transformer can be mitigated by modifying initialization of the network and the successfully converged Post-Norm models generally outperform Pre-Norm counterparts. We adopt the Admin initialization method (Liu et al., 2020b) in our training flows to stabilize the training of deep Post-Norm Transformer. Our experiments have shown that the Post-Norm model has a good diversity compared to the Pre-Norm model and slightly outperform the Pre-Norm model.

In our experiments, we use multiple model configurations with 24/30-layer encoders to build deeper models, and the decoder layers are all 6, and the hidden layer size of all models is 4096. Note that all model configurations above apply to the following variant models.

In addition, We use Transformer-ODE as the baseline model.

2.2 Transformer-RPR

According to the research of (Shaw et al., 2018), adding relative position representation to the self-attention mechanism is used to characterize the distance relationship of elements in the sequence, which can further improve the performance of the machine translation performance. So we incorporate relative position representation (RPR) into the self-attention mechanism on both the Transformer encoder and decoder side. Preliminary experiments demonstrate that only relative key information is enough, and we set the relative window size to 8.

2.3 Transformer-Coda

At the heart of the Transformer architecture is the Multi-Head Attention (MHA) mechanism which models pairwise interactions between the elements of the sequence. Despite its massive success, the current framework ignores interactions among different heads, leading to the problem that many of the heads are redundant in practice, which underutilizes the capacity of the model. To improve parameter efficiency, according to the research of (Zheng et al., 2021), we adopt cascaded head-colliding attention (CODA) which explicitly models the interactions between attention heads through a hierarchical variational distribution.

2.4 Transformer-DLCL

From the perspective of improving the residual network structure, we introduce the DLCL(Dynamic Linear Combination of Layers) method to solve the problem of gradient disappearance or explosion in deep model training. According to the research of (Wang et al., 2019), this DLCL method can effectively improve the performance of deep models.

2.5 Transformer-ODE

According to the research of (Bei Li, 2021), residual networks are an Euler discretization of solutions to Ordinary Differential Equations (ODE), and a residual block of layers in Transformer can be described as a higher-order solution to ODE. Inspired by this work, we adopt ODE to relieve the problem of gradient disappearance or explosion in deep model training.

3 System Overview

3.1 Data Filtering

For ZH-EN and JA-EN language pairs, the filtering rules are as follows:

- Filter out sentences which are longer than 120 words or contain a long word with over 40 characters.
- The word ratio between the source and the target sentence must not exceed 1:3 or 3:1.
- Filter out the sentences that have invalid Unicode characters or HTML tags.
- Filter out the duplicated sentence pairs.
- The number of punctuation difference between the source and the target sentence must not exceed 5.
- The number of digit difference between the source and the target sentence must not exceed 3.

* Filter out sentence pairs in which English sentence has Chinese or Japanese characters.

Besides these rules, several models are trained with constrained corpus for filtering corpus:

* Filter the bilingual corpus with semantic matching models.

* Filter the bilingual corpus with word align models (Dyer et al., 2013) .

* Filter out incomplete English sentences by a discriminative model.

* Filter out incomplete Japanese sentences by a discriminative model.

* Filter out classical Chinese and ancient poetry sentences by a discriminative model.

The monolingual corpus is also filtered with the above rules and models which are suitable for monolingual data. All the above rules and models are applied to synthetic parallel corpus as well.

3.2 Data Augmentation

In the field of NLP text classification, (Wei and Zou, 2019) proposed EDA technology, which can further improve the performance of the model. Inspired by this work, we introduce three operations of synonym replacement, random swap, and random deletion to generate new data. Here we call it **Aug**. Specifically, we choose 15% of sentence pairs to add noise and keep the remaining 85% of sentence pairs unchanged. For a chosen pair, we keep the target sentence unchanged, and perform the following three operations on the source sentence:

* 30% probability of synonym replacement.

* 50% probability of random swap.

* 20% probability of random deletion.

3.3 General Domain Synthetic Data Generation

In this section, we describe our methods for constructing general domain synthetic data. The general domain synthetic data is generated via large-scale back-translation, forward-translation and knowledge distillation to enhance the models' performance for all domains. In the following sections, we elaborate the above techniques in detail.

3.3.1 Back-Translation

Back-translation is the most commonly used data augmentation technique to make good use of the target side monolingual data in NMT (Hoang et al., 2018). Previous work (Edunov et al., 2018) has shown that Different generation strategies have different effects on the quality of generated pseudo-data. After these efforts, we employ the following three generation strategies.

* Sampling Top-K: At each time step, the model generates the probability that each word in the dictionary is likely to be the next word, which we randomly draw from a sample of k = 10 most likely candidates in this distribution. Afterwards, words are generated at the next time step based on the previously selected words.

* Sampling Top-P: Top-P Sampling (Nucleus sampling) is to preset a probability limit p-value, and then arrange all possible words from high to low according to the probability, and select words in turn. Stop when the cumulative probability of a word is greater than or equal to the p-value, and then sample from the already selected words to generate the next word. In our experiments, p is set to 0.9.

* Beam Search: Generate target translation by beam search with beam size 5.

Besides, we also use Tagged Back-Translation (Caswell et al., 2019) in En→Zh, Zh→En, En→Ja and Ja→En.

3.3.2 Forward-Translation

Forward translation refers to the generation of pseudo-data using source-side monolingual data (Sennrich et al., 2015). We use the ensemble model to generate high-quality forward translation data, which can greatly improve the robustness and performance of the model. Forward translation provides steady improvements on all four tracks we competed.

3.3.3 Knowledge Distillation

Knowledge Distillation (KD) has been proven to be a powerful technique for NMT (Kim and Rush, 2016; Wang et al., 2020) to transfer knowledge from the teacher model to student model. Specifically, we use an integrated teacher model to generate target-side pseudo-data from the source side

Domains	Zh	EN	JA
CLIENT	345	364	0
conversational	0	0	502
ecommerce	518	515	453
medicals	277	1454	0
news	505	1910	505
social	503	0	0
t1	0	279	191
t3	0	14343	305
voa	0	19	0

Table 1: The distribution of the blind test sentences in different domains.

of bilingual data. Likewise, Knowledge Distillation has steadily improved on all four tracks we participated in.

3.4 In-domain Finetune

Domain adaption (Luong and Manning, 2015) plays an important role in improving the translation performance. Different from the single domain (news) in previous years, the blind test of this year has shifted to a multi-domain. Firstly, we extract the domain information of every sentence from the "doc" tag in the XML files. The distribution of the blind test sentences in different domains is shown in Table 1. Secondly, we build 1-gram, 2-gram, 3-gram, 4-gram vocab for every domain and adopt the TF-IDF algorithm to extract fine-tuning data for each domain from the whole training set. Thirdly, we finetune the models for each domain using the corresponding domain data, 90% of which is used for training and 10% for validation. Finally, the models of each domain are ensembled and generate translation results of the test sentence in the corresponding domain.

3.5 Softmax-T Self-BLEU based Ensemble

After we get numerous fine-tuned models, we need to integrate them for better results. We improve on the traditional Self-BLEU method (Zhu et al., 2018). First, we calculate the Self-BLEU score of each model in each domain, and then obtain the weight score assigned to each model in each domain through the Softmax-Temperature (Zhu et al., 2018; Cheng et al., 2017). Finally, we use the models of the respective domains to integrate according to the assigned weight scores to generate data for the respective domains.

4 Experiments and Results

4.1 Settings

All our models are implemented based on fairseq 1.0.0. All the models are carried out on 8 NVIDIA V100 GPUs, each of which has 32 GB memory. We use the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$. We use an initial learning rate of 0.001 and use a warm-up strategy during the training phase. We use warm-up step = 4000. The max token is set to 3500 tokens per GPU and we set the "update-freq" parameter in Fairseq to 8. The value of the parameter Dropout is set to 0.3, and the value of Relu-Dropout is set to 0.1. We use the officially required sacreBleu to calculate all our models.

4.2 Dataset

The statistics of all training data is shown in Table 2. For each language pair, the bilingual data is the combination of all parallel data released by WMT22. For monolingual data, we select data from News Crawl, Common Crawl and Extended Common Crawl, and the amount of data after processing is shown in Table 2.

For generating pseudo-data, we use all source monolingual to generate forward translation data and all target monolingual to generate back-translation data. Finally we use the source side of bilingual data to generate knowledge distillation data. We use the methods described in Sec. 3.1 to filter bilingual and monolingual data.

4.3 Pre-processing and Post-processing

Before model training, we pre-process the training data uniformly and customize the processing according to the requirements of each model. Chinese sentences are segmented by Jieba [1], and English, we use Moses [2] for segmentation, and Japanese, we use Mecab [3]. Punctuation normalization is applied in Chinese, English and Japanese data. Truecasing is also applied for all the languages. For all the languages, we use byte pair encoding (BPE) with 40K operations to do subword segmentation (Sennrich et al., 2016).

For the post-processing, we apply de-tokenizing and de-trucaseing on the translation results with the scripts provided in Moses. And we use punctuation normalization for the Chinese and Japanese translations.

BASELINE-MODEL	**En→Zh**	**Zh→En**	**En→Ja**	**Ja→En**
Transformer#	44.3	30.7	37.9	22.6
Transformer-SourceAug#	44.8	31.1	38.2	23.0
Transformer-TargetAug#	44.6	30.6	37.9	22.5
Transformer-BothAug#	44.2	30.5	37.7	22.4

Table 5: Case-sensitive BLEU scores (%) on the four translation directions *newstest2020* for different **data augmentation methods** in the **baseline** stage.

4.4 English→Chinese

The results of En→Zh on *newstest2020* are shown in Table 3. For the En→Zh task, there is a significant improvement in the valid set after adopting our data filtering method. Our baseline score is 45.0. After applying large-scale Back-Translation, we obtain +1.5 BLEU score on the baseline. We further gain +0.5 BLEU score after applying knowledge distillation and +0.4 BLEU from forward-translation.

In preliminary experiments, we select all models distilled from knowledge as our ensemble combinations obtaining +0.6 BLEU score. On top of that, We tried various combinations but couldn't get better results. After using our proposed ensemble strategy, the BLEU score continue to improve by 0.1, which saves a lot of manpower to select models.

4.5 Chinese→English

The Zh→En task follows the same training procedure as En→Zh. As shown in Table 3, we can observe that Back-Translation can improve 2.6 BLEU from baseline. After this, knowledge distillation brings a big improvement, which can increase the BLEU scores from 33.6 to 34.7. Forward translation further boosts the BLEU score to 35.0. Likewise, our ensemble strategy saves a lot of manpower while delivering a small BLEU boost, from 35.7 to 35.9.

4.6 English→Japanese

The results of En→Ja on *newstest2020* are shown in Table 3. The bilingual training data is 31M in total, and we filter it down to 26M sentence pairs through the filtering rules and models described earlier. Because *newstest2020* has detailed results of each step as a reference, we regard the *newstest2021* as the valid set and the *newstest2020* as the test set during training. The 26 million bilingual training data brings the baseline model to 38.5 BLEU score on *newstest2020*.

For the back translation, our training data consists of three parts: 1) 26 million bilingual target data, 2) Japanese monolingual data, 3) Bilingual augmented data. In addition to the 26 million bilingual target sentences, we sample 20 million Japanese monolingual data from the combination of News Crawl and Common Crawl. Then we used the JA-EN ensemble model to generate the hypotheses as the pseudo data set via the Top-k, Top-p and beam search strategy. We randomly extract 2 million from the bilingual data, and add noise to the source sentences as described in Sec 3.2. We improve BLEU by 1.0 with the synthetic back translation training data.

And then, we merge knowledge distillation and forward translation together. We extract 26 million bilingual source sentences and 10 million source monolingual data, and generate pseudo data using the ensemble model of the back translation models. We also use 2 million noised data like used in back translation. We improve the BLEU score from 39.5 to 40.2.

In the ensemble stage, we observe that both of the normal ensemble and our ensemble strategy have only a very slight improvement.

4.7 Japanese→English

The Ja→En task follows the same training procedure as En→Ja. From Table 3, we can observe that back translation can improve the BLEU score from 23.2 to 27.9. The knowledge distillation and forward translation further improve 0.3 BLEU score. In this task, we verify the effectiveness of our in-domain fine tuning method in the News domain. It is worth mentioning that out in-domain fine tuning method brings 0.7 BLEU after forward-translation. For the comparability of the experiment, we still ensemble models which are on the base of forward-translation. We observe that both ensemble methods make results worse.

5 Analysis

To verify the effectiveness of our approach, we conduct analytical experiments on model variants, data augmentation methods, and ensemble strategies in this section.

5.1 Effects of Model Architecture

We conduct several experiments to validate the effectiveness of Transformer (Vaswani et al., 2017) variants we used in the baseline stage and list results in Table 4. Here we take the En→Zh and En→Ja models as examples to conduct the experiments. The results in the Zh→En direction are similar to En→Zh, and the results for the Ja→En direction are similar to En→Ja.

As shown in Table 4, Transformer-DLCL achieves the best performance in En→Zh direction, and Transformer-ODE achieves the best performance in En→Ja direction. For Admin (Liu et al., 2020b) initialization, Transformer#'s BLEU is 0.2 higher than Transformer in En→Zh and En→Ja directions, so this verifies the effectiveness of Admin initialization in deep models.

5.2 Effects of Data Augmentation

For data augmentation, we conduct several experiments based on the Transformer# baseline model in four directions. Specifically, we adopt three methods detailed in Section 3.2:

* **SourceAug** Aug on the source text of the sentence pair.

* **TargetAug** Aug on the target text of the sentence pair.

* **BothAug** Aug on the source text and target text of the sentence pair.

The experimental results are shown in Table 5. Taking En→Zh direction as an example, the SourceAug achieves a BLEU score of 44.8, TargetAug achieves a BLEU score of 44.6, and BothAug achieves 44.2. Results in other directions show the same trend. Therefore, we operate on the source text of sentence pairs in the data augmentation process.

6 Conclusion

This paper summarizes the results of the shared general MT task in the WMT 2022 produced by the AISP-SJTU team. In this shared task, we participated in four translation directions: English→Chinese, Chinese→English, English→Japanese and Japanese→English. We investigate various novel Transformer based architectures to build MT systems. Our systems are also built on several popular data augmentation methods such as back-translation, knowledge distillation, forward-translation and in-domain finetune. In the future, we hope to explore more efficient model architectures and data augmentation techniques in MT systems. We hope that our practice can facilitate research work and industrial applications.

Abstract

This paper describes the NTT-Tohoku-TokyoTech-RIKEN (NT5) team's submission system for the WMT'22 general translation task. This year, we focused on the English-to-Japanese and Japanese-to-English translation tracks. Our submission system consists of an ensemble of Transformer models with several extensions. We also applied data augmentation and selection techniques to obtain potentially effective training data for training individual Transformer models in the pre-training and fine-tuning scheme. Additionally, we report our trial of incorporating a reranking module and the reevaluated results of several techniques that have been recently developed and published.

1 Introduction

This paper describes an overview of our submission systems for participating in the WMT 2022 general machine translation tasks. Our team, named NT5, is comprised of individuals from four organizations: NTT, Tohoku University, Tokyo Institute of Technology, and RIKEN. This year, we focused on bi-directional translation in a single language pair: English-to-Japanese (En→Ja) and Japanese-to-English (Ja→En) translation tracks.

Our submission system consists of an ensemble of Transformer models (Vaswani et al., 2017) with several recent extensions. We also applied data augmentation and selection techniques to obtain potentially effective training data for training individual Transformer models in the pre-training/fine-tuning scheme. The models were first trained with a large but possibly noisy parallel corpus for pre-training and then with a small but clean parallel corpus for fine-tuning. Additionally, we report our trial of incorporating a reranking module that rescores the n-best lists based on source-to-target, target-to-source, and masked language models.

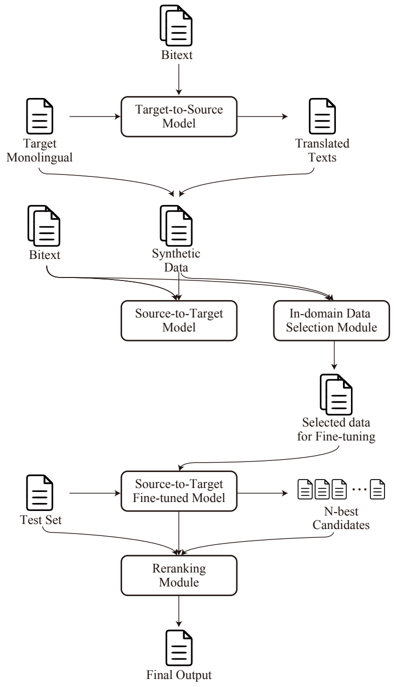

Figure 1: System overview

The following section briefly provides an overview of our entire system and each module in more depth.

2 System Overview

Figure 1 shows an overview of our system. Our submissions are for the **constrained track**, which only uses parallel and monolingual data that are provided by the WMT shared-task organizers.

*: Equal contributions. Morishita trained the initial translation model and created a synthetic corpus. Morishita and Kudo tuned the model's hyper-parameters. Oka implemented the relative positional embeddings. Chousa worked on the data filtering and the reranking module. Kiyono and Takase implemented the B2T connections and helped with the experiments. Morishita and Oka implemented the in-domain data selection methods for fine-tuning. Morishita, Kudo, and Suzuki developed an effective fine-tuning strategy. Morishita, Kudo, and Suzuki trained the main translation models. Suzuki organized the team. Everyone contributed to writing this paper.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 318 - 325
December 7-8, 2022 ©2022 Association for Computational Linguistics

We selected Transformer models (Vaswani et al., 2017) as our base translation model and chose a two-step training strategy: pre-training and fine-tuning schemes. We first constructed datasets for the pre-training and fine-tuning.

The pre-training dataset must be as large as possible, even if the data are noisy (Bansal et al., 2022). We first trained the Transformer models using only the provided bitext datasets for both translation directions: En→Ja and Ja→En. We refer to these first trained models as **initial models**. We then generated synthetic datasets for both directions through back-translation (Sennrich et al., 2016), i.e., translating target-side monolingual data using the initial model in the reverse translation direction.

The fine-tuning dataset must be as clean as possible, even if it is relatively small. Indeed, in our previous year's submission (Kiyono et al., 2020), we adapted the models to a news domain in the fine-tuning phase and drastically improved the translation quality. However, this year's task focused on a general domain, i.e., a test set that consisted of sentences from multiple domains. Thus, adaptation by fine-tuning is much more challenging. We tested and combined data selection methods based on sentence embeddings and language models for obtaining fine-tuning data. This process can be viewed as selecting domain adaptation data.

By using these datasets, we pre-trained the Transformers with pre-training configurations and fine-tuned the pre-trained models with the fine-tuning configurations described in Table 2. Finally, we conducted an ensemble of fine-tuned models. A notable characteristic of our system is that we combined the Transformer models with heterogeneous model configurations for the ensembling. Each model configuration primarily differs in its depth and width. Moreover, we applied recent advances in the extensions of Transformer models, such as bottom-to-top connection (Takase et al., 2022) and relative position embedding (Shaw et al., 2018).

Our system also uses a reranking module. We generated the ten best translation lists as reranking candidates using an ensemble of Transformer models. Then we selected the best translations based on the weighted sum of the likelihoods obtained from the source-to-target and target-to-source translation models and the masked language models.

Corpus	w/o Filtering	w/Filtering
JParaCrawl v3.0	25.7 M	25.0 M
WikiMatrix	3.89 M	3.64 M
JESC	2.80 M	2.57 M
Wiki Titles v3	757 K	327 K
KFTT	440 K	371 K
TED Talks	242 K	224 K
NewsCommentary v16	1.9 K	1.8 K

Table 1: Number of sentence pairs in bitext corpus

3 Dataset Construction

3.1 Provided Data

Bitext Corpus We used all the provided bitext corpora: JParaCrawl v3.0, News Commentary v16, Wiki Titles v3, WikiMatrix, Japanese-English Subtitle Corpus (JESC), The Kyoto Free Translation Task (KFTT) Corpus, and TED Talks. We filtered out the potentially noisy pairs using the straightforward parallel corpus filtering methods, as described in Section 3.2. Table 1 shows the size of each dataset without/with filtering.

Monolingual Corpus We also used the following provided monolingual data: News Crawl, News Commentary, and Common Crawl. We back-translated the monolingual sentences with a target-to-source model trained only with the provided parallel data, as described in Section 3.2, and used them as synthetic data (Sennrich et al., 2016).

3.2 Building Pre-training Data

Synthetic Data Construction To augment the training data, we constructed synthetic data by applying the initial translation model trained with bitext to the monolingual data. As a preprocessing step, we truecased[1] both the bitext and monolingual data. We then tokenized the data into subwords using the `Sentencepiece` tool (Kudo and Richardson, 2018) with the unigram language model option. We set the vocabulary size to 32,000 for the initial translation model, which is used for creating synthetic data. For the final submission model, we increased the vocabulary size to 64,000. Our hypothesis argues that a bigger vocabulary is crucial for completely exploiting large synthetic data. In fact, this 64,000-vocabulary model outperformed the 32,000-vocabulary model in our preliminary experiment.

Initial Translation Model	
Subword Size	32,000
Architecture	Transformer (big) with FFN size of 4,096
Optimizer	Adam ($\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Inverse square root decay
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.3
Gradient Clip	1.0
Batch Size	1,280,000 tokens
Number of Updates	50,000 steps
Averaging	Save a checkpoint every 200 steps and average the last eight
Implementation	`fairseq` (Ott et al., 2019)
Pre-training Configuration	
Subword Size	64,000
Architecture	(See Table 4)
Optimizer	Adam ($\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Inverse square root decay
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.1
Gradient Clip	0.1
Batch Size	1,024,000 tokens
Maximum Number of Updates	100,000 steps
Averaging	Save a checkpoint every 2,000 steps and average the last ten
Implementation	`fairseq` (Ott et al., 2019)
Fine-tuning Configuration	
Subword Size	Identical to Pre-training Configuration
Architecture	(See Table 4)
Optimizer	Adam ($\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 1 \times 10^{-8}$)
Learning Rate Schedule	Fixed
Warmup Steps	N/A
Max Learning Rate	0.00001
Dropout	0.2
Gradient Clip	1.0
Batch Size	14,400 tokens
Number of Updates	Tuned for each model (See Secsion 4.3)
Averaging	Save a checkpoint every ten steps and average the last ten
Implementation	`fairseq` (Ott et al., 2019)

Table 2: List of hyper-parameters: We used initial translation model for creating synthetic data, pre-training configuration to construct pre-training models described in Section 4.2, and fine-tuning configuration to construct models for submission. We used several different model configurations for ensembling. See Table 4 for more details.

	#sent. pairs	#subwords (JA)	#subwords (EN)
En→Ja	579 M	11.6 B	13.1 B
Ja→En	724 M	15.5 B	16.7 B

Table 3: Statistics of synthetic data used for pre-training

As the initial translation data, we trained the Transformer-big model defined in the original Transformer paper (Vaswani et al., 2017) for both language directions (English-to-Japanese and Japanese-to-English translations) only with the provided bitext data. The detailed hyper-parameters are described in the initial translation model section of Table 2. Finally, we respectively translated 1.4B and 1.2B monolingual sentences for English and Japanese.

Data Cleaning For both the provided bitext and synthetic data, we carried out cleaning based on a combination of sentence embeddings and handcrafted rules.

For both the bitext and synthetic data, we removed the too-long sentences whose length exceeded 500 characters. We also removed the sentences that were identified as not being written in English or Japanese with the `langid`[2] toolkit.

For the synthetic data, we further applied a sentence embedding-based filtering approach. We took advantage of LaBSE (Feng et al., 2022) to embed the Japanese and English sentences into the same embedding space. We then scored and ranked the parallel sentence pairs based on the cosine similarity of their sentence embeddings. Subsequently, we filtered out the following items from the synthetic data:

- duplicated sentence pairs
- sentences over 150 words[3] or single words with over 40 characters
- sentences whose ratio between word and character count is greater than 12
- sentences that contain invalid Unicode characters
- sentence pairs whose source/target word ratio exceeds 4
- sentence pairs whose source/target length ratio exceeds 6
- sentence pairs whose source and target sentences are identical
- sentence pairs whose cosine similarity is greater than 0.96[4]

[2] `https://github.com/saffsd/langid.py`

[3] We tokenized the Japanese sentences by MeCab (Kudo, 2006) with the IPA dictionary. Note that this tokenization is for cleaning purpose only.

[4] We found that sentence pairs with high cosine similarities might be noisy; for example, the source and target sentences

Finally, we respectively selected approximately the top 579 M and 724 M sentences from the translated 1.2B and 1.4B monolingual sentences as the synthetic data of En→Ja and Ja→En in the rank orders. Table 3 shows the statistics of synthetic data used for our pre-training.

3.3 Building Fine-tuning Data

As for the fine-tuning data, we prepared two types of data: *news* and *general*. The news data consist of the dev and test sets of the WMT'20 news translation task, which has 3,991 sentences. General data were created by selecting parallel sentences in the target domain. We used the n-gram language model-based method proposed by Moore and Lewis (2010) and selected the top 20,000 scored sentences from the synthetic corpus. We also used sentence embeddings to select the general domain data. We used an unsupervised SimSCE (Gao et al., 2021) as the English sentence embedding and SentenceTransformers (Reimers and Gurevych, 2019) as the Japanese sentence embedding[5]. We searched for the nearest 4,000 sentences to the target domain using `faiss` (Johnson et al., 2019) and combined the sentences selected by both the language model-based and sentence embeddings. As a result, our general domain data contained 24,000 sentences.

4 Primary Translation Module

4.1 Model Configuration

We trained several Transformer models for the model ensembling in the decoding phase. We independently trained models with different sizes due to the restrictions on computational resources at hand. We pre-trained and fine-tuned each model with the configurations shown in Table 2. The details of the model configurations are summarized in Table 4.

Our configuration has three notable characteristics: a bottom-to-top (B2T) connection (Takase et al., 2022), relative position embedding, and a larger batch size.

B2T Connection Transformer architectures can be categorized into two types based on the position of the layer normalizations: Post-LN and Pre-LN. Previous studies (Xiong et al., 2020; Liu et al., 2020; Takase et al., 2022) indicated that training a deep Post-LN Transformer[6] is unstable due to the vanishing gradient problem. However, Takase et al. (2022) argued that Post-LN Transformers outperform Pre-LN Transformers if their trainings are successful. Thus, we want to exploit the advantage of Post-LN Transformers. In addition, we want to make our Transformers as deep (and wide) as possible to make a full use of large synthetic data.

Several studies proposed techniques that stabilize the trainings of Post-LN Transformers while retaining their performance advantages (Liu et al., 2020; Takase et al., 2022). In this study, we used the B2T connection proposed by Takase et al. (2022), which has an additional residual connection from an input to an output in each layer. The B2T connection is easy to implement and can be incorporated with a tiny amount of extra computational cost.

Relative Position Embedding A Transformer model was originally equipped with Absolute Position Embedding (APE) (Gehring et al., 2017) for position representation. However, several recent studies (Raffel et al., 2020; Narang et al., 2021) report that Relative Position Embedding (RPE) (Shaw et al., 2018) outperforms APE, especially for sentences whose lengths are unseen during the training (Kiyono et al., 2021). Thus, for the Transformer encoder, we replaced APE with RPE. Following Shaw et al. (2018), we set clipping distance k to 16.

Larger Batch Size Ott et al. (2019) demonstrated that a large batch size improves performance. The recent development of large language models also indicates this tendency (Hoffmann et al., 2022). Given this knowledge, we followed the setting of T5 (Raffel et al., 2020) and selected a token batch size of approximately 1M. Note that this is much larger than the batch size used by Ott et al. (2019).

4.2 Pre-training

We trained each model described in Table 4 with the filtered bitext and synthetic data described in Section 3.2. We set the maximum number of updates to 100,000 and used early stopping based on the validation set performance. In this phase, we used the Pre-training configuration of Table 2. Since the synthetic data is extremely larger than the

are sometimes identical. Thus we removed them from the training data.

[5] We used `stsb-xlm-r-multilingual`.

[6] When we used the dimension sizes described in Table 4, the trainings of nine or more layers of Post-LN Transformers diverged.

Configuration	#Models	#Params.	Encoder				Decoder			
			Layer	d_{model}	d_{ffn}	Attention Heads	Layer	d_{model}	d_{ffn}	Attention Heads
`NTT-Base`	2	547M	9	1024	8192	16	9	1024	8192	16
`ABCI-Base`	2	622M	9	1024	16384	16	9	1024	4096	16
`ABCI-EncBig`	1	2.0B	12	1024	65536	16	9	1024	8192	16
`ABCI-EncDeep`	1	736M	18	1024	8192	16	9	1024	8192	16
`Failab-EncBig`	1	1.7B	9	1024	61440	16	9	1024	16384	16
`Failab-DecBig`	1	1.7B	9	1024	16384	16	9	1024	61440	16

Table 4: List of model configurations used in final system: d_{model} and d_{ffn} respectively denote sizes of embedding and feedforward layers. In En→Ja, `Failab-EncBig` and `Failab-DecBig` did not fit in the GPU memory. Therefore, we set d_{ffn} to 58368 instead of 61440, which is the largest value that successfully worked.

bitext, we upsampled the bitext until it reaches to a 1:1 ratio to the synthetic data. In addition, we used the tagged back-translation technique (Caswell et al., 2019). In detail, we attached a special token ⟨`BT`⟩ to the beginning of source sentences in synthetic data.

To improve the performance, we tried using several perturbation methods described in Takase and Kiyono (2021) in this training phase. However, they did not positively affect the performance. Since the number of sentences in our training data is far greater than in their study, regularization by perturbations might be ineffective.

4.3 Fine-tuning

We fine-tuned the pre-trained translation models with the fine-tuning dataset described in Section 3.3 and used the configurations described in Table 2. We set the maximum number of updates to 600, and used early-stopping according to the performance on the test data of WMT'21 (wmt21test).

4.4 Ensemble

We ensembled the fine-tuned models described in Table 4[7]. How we ensembled the Transformer models trained in different model configurations is another unique characteristic of our system compared with the standard configurations used in the WMT submission systems.

5 Post-processing

5.1 Reranking

We tried to apply a reranking method to select the most likely candidate from a set of candidates and input. We scored the candidate with several models and unified these scores with Minimum Error Rate Training (MERT) (Och, 2003), which is often used in Statistical Machine Translation (SMT).

Suppose we have set of candidate output sentences C_i for each source sentence s_i, where $i \in \{1, \dots, I\}$. In our case, we generated n-best candidates using the submission model with the beam-search algorithm.

Hereafter, $P_j(s_i, e) \in [0, 1]$ denotes candidate score $e \in C_i$ for i-th input s_i from the j-th model, where $j \in \{1, \dots, J\}$, and $\boldsymbol{w} = (w_1, \dots, w_j)$ denotes the vector representation of the model weights. Given weights $\boldsymbol{w}$, the most likely candidate $\hat{e}_i^{\boldsymbol{w}}$ from C_i is obtained by maximizing the weighted sum of P_j:

$$\hat{e}_i^{\boldsymbol{w}} = \underset{e \in C_i}{\operatorname{argmax}} \left\{ \sum_{j=1}^{J} w_j P_j(s_i, e) \right\}. \quad (1)$$

Finally, we explored $\hat{\boldsymbol{w}}$ for the parameter estimation of $\boldsymbol{w}$ by solving the following optimization problem:

$$\hat{\boldsymbol{w}} = \underset{\boldsymbol{w} \in [0,1]^J}{\operatorname{argmax}} \left\{ \texttt{corpus\_bleu}(\hat{\mathcal{E}}^{\boldsymbol{w}}) \right\}, \quad (2)$$

where $\hat{\mathcal{E}}^{\boldsymbol{w}} = \left(\hat{e}^i_{\boldsymbol{w}}\right)_{i=1}^{I}$.

For the candidate's score, we used the following models to compute $P_j(s_i, e)$.

L2R Forward and Backward Translation Models The left-to-right (L2R) forward and backward translation models are identical as those used for the candidate generation of En→Ja and Ja→En. For each direction, we trained two models with two different training data; these four models computed the score by force-decoding a candidate from their input.

R2L Forward and Backward Translation Models The right-to-left (R2L) forward and backward translation models generate a translation in reverse

[7] We trained two models with both the `NTT-base` and `ABCI-base` configurations with different random seeds.

ID	Model	En→Ja			Ja→En		
		wmt20dev	wmt21test	wmt22test	wmt20dev	wmt21test	wmt22test

(o)	(n) + reranking	-	-	25.7	-	-	25.0

Table 5: Performance comparison of models trained for submission: Models (b)-(i) are pre-trained models (details in Section 4.2). Models (j)-(o) do not contain wmt20dev result because the dataset is in news fine-tuning dataset. We chose model (l) for the final submission. Note that the wmt22test results were computed as the post-evaluation after the wmt22 test data was released.

word order. We trained the model of both directions with all the provided bitext datasets and computed the scores with the same procedure as was used for the L2R models.

Masked Language Models We also used the masked language models to compute the likelihood of the decoded target sentences. Specifically, we used the pre-trained models of DeBERTa (He et al., 2021)[8] for English and RoBERTa (Liu et al., 2019)[9] for Japanese. To score the candidate, we adopted *pseudo-log-likelihood scores* (PLLs), computed by masking tokens one by one, as proposed by Salazar et al. (2020) Finally, we normalized the PLLs by dividing them by token length.

5.2 Rule-base Formatting

We also applied language-specific post-processing.

Ja→En We detokenized and detruecased the sentences and removed all the unknown tokens from the outputs. Since some placeholders were tokenized into two or more tokens, we fixed them to a single token.

En→Ja We removed the spaces in the English proper nouns of two characters or fewer, the spaces before and after such special symbols as "/", "-" or "#PRS/ORG#". We replaced English style commas "," and periods "." with the Japanese styles: "，" and "。".

6 Results

Table 5 shows the performance of both the intermediate models and the final model for our submission. Our result highlights the effectiveness of the

[8] `https://huggingface.co/microsoft/deberta-v2-xxlarge`

[9] `https://huggingface.co/nlp-waseda/roberta-large-japanese-seq512`

techniques incorporated in our system.

Effectivenss of Fine-tuning Data We expected model (m), which was fine-tuned on the general domain, to achieve the best result. However, the model (l), which was fine-tuned on the news domain, achieved the higher BLEU score on both wmt21test and wmt22test. We suspect this is because the data used for the news fine-tuning are cleaner than those of the general domain. Since the fine-tuning data for the news domain consists of the previous years' dev/test sets that were translated by professionals, the news domain data are clean while the general domain data were chosen mainly from synthetic data. We will analyze the relationship between the translation accuracy and the cleanliness of the fine-tuned data in the future.

Negative Result on Reranking In Table 5, the performance of model (n) and (o) demonstrate that the reranking technique (Section 5.1) did not improve the performance over the ensemble models on wmt22test. We suspect that this performance degradation comes from the domain difference between the datasets used for MERT and the evaluation. For MERT, We used wmt21test, whose domain is news, to optimize the model weights; however, this year's test set, wmt22test, contains sentences from multiple domains. Thus, we chose model (l), which is the model without reranking, for our final submission.

7 Conclusion

We described the submission of our joint team (NTT, Tohoku, TokyoTech, and RIKEN) to the WMT'22 general translation task. We participated in the En↔Ja translation. Our system mainly consists of an ensemble of Transformer models with several recent extensions. We also applied data augmentation and selection techniques to train individual Transformer models in our pre-training/fine-tuning training scheme.

Abstract

This paper presents Adam Mickiewicz University's (AMU) submissions to the constrained track of the WMT 2022 General MT Task. We participated in the Ukrainian ↔ Czech translation directions. The systems are a weighted ensemble of four models based on the Transformer (big) architecture. The models use source factors to utilize the information about named entities present in the input. Each of the models in the ensemble was trained using only the data provided by the shared task organizers. A noisy back-translation technique was used to augment the training corpora. One of the models in the ensemble is a document-level model, trained on parallel and synthetic longer sequences. During the sentence-level decoding process, the ensemble generated the n-best list. The n-best list was merged with the n-best list generated by a single document-level model which translated multiple sentences at a time. Finally, existing quality estimation models and minimum Bayes risk decoding were used to rerank the n-best list so that the best hypothesis was chosen according to the COMET evaluation metric. According to the automatic evaluation results, our systems rank first in both translation directions.

1 Introduction

We describe Adam Mickiewicz University's submissions to the constrained track of the WMT 2022 General MT Task. We participated in the Ukrainian ↔ Czech translation directions – a low-resource translation scenario between closely related languages.

The data provided by the shared task organizers was thoroughly cleaned and filtered, as described in section 2.

The approach described in section 3 is based on combining various MT enhancement methods, including transfer learning from a high-resource language pair (Aji et al., 2020; Zoph et al., 2016), noisy back-translation (Edunov et al., 2018), NER-assisted translation (Modrzejewski et al., 2020), document-level translation, model ensembling, quality-aware decoding (Fernandes et al., 2022), and on-the-fly domain adaptation (Farajian et al., 2017).

The results leading to the final submissions are presented in section 4. Additionally, we performed a statistical significance test with paired bootstrap resampling (Koehn, 2004), comparing the baseline solution with the final submission on the test set reference translations released by the shared task organizers. According to the automatic evaluation results based on COMET (Rei et al., 2020) scores, our systems rank first in both translation directions.

2 Data

In the initial stage of system preparation, the sentence-level data was cleaned and filtered using the OpusFilter (Aulamo et al., 2020) toolkit. With the use of the toolkit, language detection filtering based on fastText (Joulin et al., 2016) was performed, duplicates were removed, and heuristics based on sentence length were applied. In particular, we removed sentence pairs with a length ratio over 3 and long sentences (> 200 words). Then, using Moses (Koehn et al., 2007) pre-processing scripts, punctuation was normalized and non-printing characters removed. Finally, the text was tokenized into subword units using SentencePiece (Kudo and Richardson, 2018) with the unigram language model algorithm (Kudo, 2018). For Ukrainian→Czech and Czech→Ukrainian models trained from scratch, we used separate vocabularies for the source and the target language. Each vocabulary consisted of 32,000 units.

We used concatenated data from the Flores-101 (Goyal et al., 2022) benchmark (flores101-dev, flores101-devtest) for our development set, as pro-

Table 1: Statistics of the total available corpora and the corpora used for system training after filtering.

vided by the task organizers.

Table 1 shows statistics for the total available corpora in the constrained track and the corpora used for system training after filtering.

3 Approach

We used the Marian (Junczys-Dowmunt et al., 2018) toolkit for all of our experiments. Our model architecture follows the Transformer (big) (Vaswani et al., 2017) settings. For all model training, we used 4x NVIDIA A100 80GB GPUs.

3.1 Transfer Learning

For our initial experiments, we used transfer learning (Aji et al., 2020; Zoph et al., 2016) from the high-resource Czech→English language pair. We used only the parallel data provided by the organizers to train the model in this direction. In this case, we created a single joint vocabulary for three languages (Czech, English, Ukrainian), consisting of 32,000 units. The Czech→English model was fine-tuned for the Ukrainian→Czech and Czech→Ukrainian language directions. Our later experiments showed that there were no gains in translation quality compared with models trained from scratch using separate vocabularies for source and target languages – the upside was that the models took less time to converge during training.

3.2 Noisy Back-Translation

We used models created by the transfer learning approach to produce synthetic training data through noisy back-translation (Edunov et al., 2018). Specifically, we applied Gumbel noise to the output layer and sampled from the full model distribution. We used monolingual data available in the constrained track, which included all ~59M Ukrainian sentences after filtering and ~60M randomly selected Czech sentences.

After training the model with concatenated parallel and back-translated corpora, we replaced the training data with filtered parallel data and further fine-tuned the model. We kept the same settings as in the first training pass, training the model until it converged on the development set.

3.3 NER-Assisted Translation

Translation in domains such as news, social or conversational texts, and e-commerce is a specialized task, involving such challenges as localization, product names, and mentions of people or events in the content of documents. In such a case, it proved helpful to use off-the-shelf solutions for recognizing named entities. For Czech, the Slavic BERT model (Arkhipov et al., 2019) was used, with which entities such as persons (PER), locations (LOC), organizations (ORG), products (PRO), and events (EVT) were tagged. Due to the lack of support for the Ukrainian language in the Slavic BERT model, the Stanza Named Entity Recognition module (Qi et al., 2020) was used to detect entities in the Ukrainian text, recognizing persons (PER), locations (LOC), organizations (ORG), and miscellaneous items (MISC). With these ready-made solutions, the parallel and back-translated corpora were tagged. The named entity categories were then numbered to assign appropriate source factors to words in the text, supporting the translation process. The source factors were later transferred to subwords in a trivial way.

Source factors (Sennrich and Haddow, 2016) have previously been used to take into account various characteristics of words during the translation process. For example, morphological information, part-of-speech tags, and syntactic dependencies have been added as input to neural machine translation systems to improve the translation quality.

In the same way, it is possible to add information about named entities found in the text (Modrzejewski et al., 2020), making it easier for the model to translate them correctly. However, the AMU machine translation system does not dis-

Table 2: The number of recognized named entity categories in the training, development and test data. The training data statistics are split into *train-bt*, which was created by noisy back-translation, and *train-parallel*, which is the filtered parallel training data.

tinguish between inside-outside-beginning (IOB) tags (Ramshaw and Marcus, 1995), treating the named entity tag names as a whole. Specifically, we introduce the following source factors:

- p0: source factor denoting a normal token,
- p1: source factor denoting the PER category,
- p2: source factor denoting the LOC category,
- p3: source factor denoting the ORG category,
- p4: source factor denoting the MISC category,
- p5: source factor denoting the PRO category,
- p6: source factor denoting the EVT category.

An example of a tagged sentence is shown in Figure 1.

Models were trained in two settings: concatenation and sum. In the first setting, the factor embedding had a size of 16 and was concatenated with the token embedding. In the second setting, the factor embedding was equal to the size of the token embedding (1024) and was summed with it.

As shown in Table 4, we observe an increase in the string-based evaluation metrics (chrF and BLEU) while COMET scores remain about the same. This is in accordance with Amrhein and Sennrich (2022), who show that COMET models are not sufficiently sensitive to discrepancies in named entities.

Table 2 presents the numbers of recognized named entity categories in the training, development and test data.

3.4 Document-Level Translation

Our work on document-level translation is based on a simple data concatenation method, similar to Junczys-Dowmunt (2019) and Scherrer et al. (2019).

As our training data, we use parallel document-level datasets (GNOME, KDE4, TED2020, QED), as well as synthetically created data, concatenating random sentences to match the desired input length. Specifically, we merge datasets created in the following ways as a single, large dataset:

- Curr → Curr: sentence-level parallel data,
- Prev + Curr → Prev + Curr: previous sentence given as a context,
- 50T → 50T: a fixed window of 50 tokens after subword encoding,

Netvrdím, že bakteriální celulóza jednou nahradí bavlnu, kůži, nebo jiné látky. <SEP> Ale myslím, že by to mohl být chytrý a udržitelný přírůstek k našim stále vzácnějším přírodním zdrojům. <SEP> Možná že se nakonec tyto bakterie neuplatní v módě, ale jinde. <SEP> Zkuste si třeba představit, že si vypěstujeme lampu, židli, auto, nebo třeba dům. <SEP> Má otázka tedy zní: Co byste si v budoucnu nejraději vypěstovali vy?

Figure 2: An example document consisting of five sentences separated with <SEP> tags.

- 100T → 100T: a fixed window of 100 tokens after subword encoding,
- 250T → 250T: a fixed window of 250 tokens after subword encoding,
- 500T → 500T: a fixed window of 500 tokens after subword encoding.

By concatenating such datasets, we allow the model to gradually learn how to translate longer input sequences. It is also capable of sentence-level translation. To separate sentences from each other, we introduced a <SEP> tag. An example of a document-level input sequence is shown in Figure 2. All data used to train the document-level model were tagged with NER source factors, including the back-translated data.

3.5 Weighted Ensemble

We created a weighted ensemble of four best-performing models. It consisted of the following model types:

- (A) sentence-level models trained with NER source factors (concat 16),
- (B) sentence-level model trained with NER source factors (sum),
- (C) document-level model trained with NER source factors (concat 16).

In this case, the document-level model was used only for the sentence-level translation. The optimal weights for each model were selected using a grid search method. For the specific language pairs, we used the following model and weight combinations:

- Czech → Ukrainian: $1.0 \cdot (2{\times}\text{A}) + 0.8 \cdot (\text{B}) + 0.6 \cdot (\text{C})$,
- Ukrainian → Czech: $1.0 \cdot (2{\times}\text{A}) + 0.8 \cdot (\text{B}) + 0.4 \cdot (\text{C})$.

3.6 Quality-Aware Decoding

Having the final model ensemble, we created an n-best list containing 200 translations for each sentence with beam search. Then we merged it with a second n-best list containing 50 translations for each sentence, created by a single document-level model with document-level decoding. The idea behind it was that the hypotheses produced by the document-level decoding take into account the context of surrounding sentences, which is not the case with the ensemble. This enabled the use of quality-aware decoding (Fernandes et al., 2022).

We applied a two-stage quality-aware decoding mechanism: pruning hypotheses using a tuned reranker (T-RR) and minimum Bayes risk (MBR) decoding (Kumar and Byrne, 2002, 2004), as shown in Figure 3.

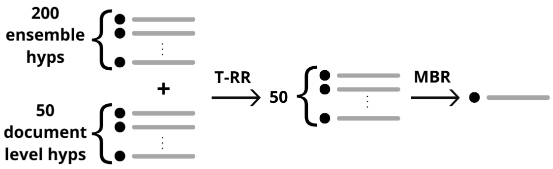

Figure 3: A two-stage (T-RR → MBR) quality-aware decoding process. 200 hypotheses generated by the ensemble are merged with 50 hypotheses generated by the document-level model. A tuned reranker is used to prune the total number of hypotheses to 50, and these are then used as input for minimum Bayes risk decoding.

First, we tuned a reranker on the development set, using as features NMT model scores, as well as existing QE models based on TransQuest (Ranasinghe et al., 2020) and COMET (Rei et al., 2020), which are based on Direct Assessment (DA) (Graham et al., 2013) scores or MQM (Lommel et al., 2014) scores. Specifically, we used:

- model ensemble log-likelihood $\log p_\theta(y|x)$ scores,

- TransQuest QE model trained on DA scores (`monotransquest-da-multilingual`),
- COMET QE model trained on MQM scores (`wmt21-comet-qe-mqm`),
- COMET QE model trained on DA scores (`wmt21-comet-qe-da`).

We tuned the feature weights to maximize the COMET reference-based evaluation metric value using MERT (Och, 2003).

After tuning the reranker, we used it to prune the n-best list from 250 to 50 hypotheses per input sentence. The resulting n-best list was used for minimum Bayes risk decoding, using the COMET reference-based metric as the utility function. Minimum Bayes risk decoding seeks, from the set of hypotheses, the hypothesis with the highest expected utility.

$$\hat{y}_{\text{MBR}} = \arg\max_{y \in \bar{\mathcal{Y}}} \underbrace{\mathbb{E}_{Y \sim p_\theta(y|x)}[u(Y, y)]}_{\approx \frac{1}{M}\sum_{j=1}^{M} u(y^{(j)}, y)} \qquad (1)$$

Equation 1 shows that the expectation can be approximated as a Monte Carlo sum using model samples $y^{(1)}, \ldots, y^{(M)} \sim p_\theta(y|x)$. In practice, the translation with the highest expected utility can be chosen by comparing each hypothesis $y \in \bar{\mathcal{Y}}$ with all other hypotheses in the set.

The described two-stage quality-aware decoding process allowed us to further optimize our system for the COMET evaluation metric, which has been shown to have a high correlation with human judgements (Kocmi et al., 2021).

3.7 Post-Processing

The final step involved post-processing. We applied the following post-processing steps for each best obtained translation:

- transfer of emojis from the source to the translation using word alignment based on SimAlign (Jalili Sabet et al., 2020),
- restoration of quotation marks appropriate for a given language,
- restoration of capitalization (e.g. if the source sentence was fully uppercased),
- restoration of punctuation, exclamation and question marks (if a source sentence ends with such a mark, we make the translation do likewise),
- replacement of three consecutive dots with an ellipsis,
- restoration of bullet points and enumeration (e.g. if the source sentence starts with a number or a bullet point),
- deletion of consecutively repeated words.

Approach	**Sim. score**	**COMET**	**chrF**
Baseline	-	0.8322	0.5263
Default	0.4	0.8316	0.5260
Best-334	0.19	0.8322	0.5259
Best-133	0.25	0.8323	0.5262

Table 3: Results of the on-the-fly adaptation method on the development set. The *default* approach is based on Farajian et al. (2017). However, only 11 sentence pairs were found in this scenario. The experiments denoted as *best-334* and *best-133* used the learning rate values of 0.002 and 10 epochs. In our development set containing 2009 sentence pairs, 334 matching sentences were found in *best-334* and 133 in *best-133*.

3.8 On-The-Fly Domain Adaptation

The General MT Task tests the MT system's performance on multiple domains. Therefore, we investigated the possibility of improving our translation system with the on-the-fly domain adaptation method.

This experiment was based on Farajian et al. (2017). Our idea was to retrieve similar sentences from the training data for each input sentence and to fine-tune the model on their translations. After the translation of a single sentence is complete, the model is reset to the original parameters. We used Apache Lucene (McCandless et al., 2010) as our translation memory to search for similar sentences. We indexed all of the training data and used the Marian dynamic adaptation feature. We compared the translation quality with and without the retrieved context. The experiments were carried out with a different similarity score used to choose similar sentence pairs for the fine-tuning process. We empirically modified the learning rate and the number of epochs to find optimal values that improved the translation quality.

Table 3 shows the results of the aforementioned experiments on the full development set. We found

Table 5: Results of COMET, chrF and BLEU automatic evaluation metrics on the test set. ChrF and BLEU metrics were computed with sacreBLEU. The final submission results are statistically significant ($p < 0.05$).

that only a small number of sentences in the training data were similar to those present in the development set. The results showed that tuning the model on similar sentences from the training data did not significantly improve translation quality. In the end, we decided not to use this method in our WMT 2022 submission.

4 Results

The results of our experiments are presented in Table 4. We evaluated our models with the COMET[1] (Rei et al., 2020), chrF (Popović, 2015) and BLEU (Papineni et al., 2002) automatic evaluation metrics. ChrF and BLEU scores were computed with the sacreBLEU[2,3] (Post, 2018) tool. We also include scores for the document-level model. In this case, the scores include improvements added by back-translation, NER source factors and fine-tuning. The document-level evaluation was split into sentence-level decoding and document-level decoding. In the first scenario, the model translates a single sentence at a time, which is not different from a sentence-level model. In the second scenario, the model translates concatenated chunks of at most 250 subword tokens at a time.

We found that the largest gain in the COMET value was achieved due to the quality-aware decoding method, at the cost of BLEU value. The chrF value remained the same in the Ukrainian→Czech translation direction, while it increased slightly in the Czech→Ukrainian direction. As discussed in section 3.3, the inclusion of NER source factors helped the model with the translation of named entities, which is not well reflected in the COMET value, as this metric is not sufficiently sensitive to discrepancies in named entities (Amrhein and Sennrich, 2022).

Table 5 shows results for our final submissions compared with the baseline. We performed a statistical significance test with paired bootstrap resampling (Koehn, 2004), running 1000 resampling trials to confirm that our submissions are statistically significant ($p < 0.05$).

5 Conclusions

We describe Adam Mickiewicz University's (AMU) submissions to the WMT 2022 General

[1] COMET scores were computed with the `wmt20-comet-da` model.

MT Task in the Ukrainian ↔ Czech translation directions. Our experiments cover a range of MT enhancement methods, including transfer learning, back-translation, NER-assisted translation, document-level translation, weighted ensembling, quality-aware decoding, and on-the-fly domain adaptation. We found that using a combination of these methods on the test set leads to a +0.22 (26.13%) increase in COMET scores in the Ukrainian→Czech translation direction and a +0.19 (24.18%) increase in the Czech→Ukrainian direction, compared with the baseline model. According to the COMET automatic evaluation results, our systems rank first in both translation directions.

Abstract

This paper describes the LT’22 team’s constrained submission to the WMT General Machine Translation task. NMT transformer-based systems have been implemented using only the WMT’22 released parallel corpora, without using any pre-trained models. Two language pairs have been tackled, namely German to English and German to French. Emphasis was placed on removing the noisy sections of parallel corpora where the degree of parallelism is very limited, for which a publicly-available tool was-used. Comparative results are reported with baseline systems.

1 Introduction

This submission presents the contribution of the LT’22 team to the WMT22: General MT Task. It focuses on studying the effectiveness of cleaning tools when these are applied to real-world parallel corpora, to eliminate noisy sections and improve the resulting NMT systems.

Traditionally, parallel corpora are used as the primary data source for machine translation (MT) models. The development of MT has been aided by the availability of extensive parallel corpora. The majority of these data have several areas of reduced parallelism and are usually characterized as imperfect or noisy. The use of noisy data may result in a neural machine translation model being inadequately prepared. Researchers (e.g. (Koehn and Knowles, 2017) (Khayrallah and Koehn, 2018)) have reported that neural machine translation models are much more affected by noisy data than statistical machine translation models.

A number of software packages to implement noise-removal from parallel corpora have been implemented and released to the community. These include publicly available tools such as qe-clean (Denkowski)[1], as well as Zipporah (Xu and Koehn, 2017). (Zariņa et al., 2015) have used a combination of alignment-indicating features to clean corpora. For cleaning large-scale corpora in multilingual setups, a cosine-distance metric has been proposed (Schwenk and Li, 2018). Finally, the suite of the paired Bifixer and Bicleaner software tools (Ramírez-Sánchez et al., 2020) has been proposed for parallel corpora cleaning purposes, with Bifixer implementing restorative cleaning and Bicleaner providing the ability to remove sentences with very low parallelism in the parallel corpus.

For the experiments reported here, two language pairs have been chosen, namely German-to-English (denoted as De-to-En) and German-to-French (denoted as De-to-Fr). Compared with other systems reported in WMT, our NMTs have a couple of identifying features: (1) the use of a fully-constrained setup with respect to WMT’22 rules and (2) the setting of a relatively low threshold to the allowed training epochs, in an effort to comply to a setup with limited computational resources. Whilst our translation systems are not as accurate as they could be if more epochs were allowed, it was decided to adopt an approach that is more realistic when training resources are not unlimited.

To implement the LT’22 participation to the WMT’22 shared task work, we used the following three software packages: (i) the Marian NMT Toolkit (Version: v1.11.5), which was used for the training of the neural machine translation models and (ii) Bifixer and (iii) Bicleaner, which were used in order to correct and clean our data.

Regarding the structure of the paper, in the second section the selection of data on which to train the translation systems is reported. In the third section, the method used to carry out all essential experiments is detailed. In the fourth section, the corpus-cleaning tools are analyzed. In the fifth section the translation systems and their parameters are reported. The sixth section is devoted to details related to experiments. Finally, we review the

findings of this series of experiments and examine potential future research directions.

2 Training Data

Our experiments involve comparing the translation outputs for a series of NMT models for two language pairs: German-to-English (denoted as De-to-En) and German-to-French (denoted as De-to-Fr). It should be noted that for these two language pairs no pretrained models for either Bifixer or Bicleaner are available at the respective repository. All the NMT models reported here are trained using only the parallel training data specified by WMT'22, and no monolingual training data are used. In-training validation has been performed using the development data recommended in WMT'22, whilst for evaluating the trained NMT systems (developed prior to the release of WMT'22 test data), the relevant test data from WMT'20 were used. Moreover, the translations submitted at the WMT22 shared task have been produced using the test data released by WMT'22.

3 Methodology

The aim of our experiments has been to evaluate methods for cleaning-up a parallel corpus and to determine if their use leads to MT systems that generate more accurate translations. For each language pair, baseline NMT models have been trained from raw (i.e. unfiltered) parallel training corpora as specified by WMT'22, while the additional NMT models have been trained with corpora subjected to a special cleaning process via the Bifixer and Bicleaner suite (Ramírez-Sánchez et al., 2020). It should be mentioned that the Bicleaner repository[2] doesn't include pre-trained classifiers for the above language pairs; consequently we trained probabilistic dictionaries in order to produce new models. An added benefit of this choice is that no pre-trained model was used to develop our NMT systems, and thus the submitted systems reviewed here are constrained.

The fundamental differences between the NMT models produced are mainly related to the quality and quantity of the training data, while there are no differences in the training parameters or in the setup of the deep neural network architectures (unless otherwise noted in the experimental section). By doing so, it is possible to safely draw conclusions about the amount of computational resources required while also examining and comparing the translation outputs using automatic assessment methods. The following were the driving factors behind the experiments reported here:

- Using the Bifixer/Bicleaner tool in other language pairs for which they have not been used to date, in order to observe their effectiveness in a different real-world scenario.

- The comparison of the results of cleaned as well as raw parallel corpora, automatically as well as manually.

- The study of the effectiveness of translation models produced with limited computing resources (Arase et al., 2021).

4 Cleaning Parallel Corpora

4.1 Bifixer

The first tool that was used in the translation pipeline is Bifixer, which undertakes to correct some very specific errors that publicly available parallel corpora usually present. Bifixer implements restorative cleaning of imperfect parallel data, working towards fixing the content and preserving unique parallel sentences before filtering out the noise (Ramírez-Sánchez et al., 2020). The steps followed involve empty side removal, character fixing, orthography fixing, re-splitting, duplicates identification. In order to apply Bifixer, we used the recommended default parameter values, without changes, and noted an improvement in the quality of the parallel corpora.

100 random sentence pairs were examined in order to ascertain the effectiveness of Bifixer. After using of the aforementioned tool, fewer noisy data were observed. Better sentence segmentation, fewer typographical errors and fewer extremely short and big sentences were the most notable modifications.

4.2 Bicleaner

Continuing the corpus-cleaning process, we proceeded to the next tool, Bicleaner. This tool filters parallel corpora in order to distinguish the noisiest sentences and then remove them to create a cleaner corpus.

In order to use Bicleaner we need to have an already trained classifier. Hence, we initiated the

[2] https://github.com/bitextor/bicleaner-data/releases/tag/v1.5

Bicleaner training process, following the steps described in the official github page [3].

The assembly of a big corpus consisting of about 10 M sentences was our first concern. In order to avoid bias, the sentences were chosen to be different from those used to train Marian NMT models. The training data went through a simple preprocessing which consists of the following steps; detokenization in case of already tokenized corpora; then tokenization of all sentences. As the same tokenization method will be used during Bicleaner running, and the parallel data needs to be aligned in both directions, we used MGIZA++ (Gao and Vogel, 2008). Another software package we used was Moses[4], which is utilized for tokenization as well as the construction of probabilistic dictionaries in combination with MGIZA++. Following this process, two probabilistic dictionaries are constructed, one for each translation direction.

The next step was to create word frequency files. Two folders are needed, for the source language and the target language. To build these two folders we needed two large monolingual corpora. Besides, ideally a very clean corpus of about 100K sentences is required, though such clean data are not readily available. According to the recommendations in github in this case the data can be cleaned by using Bifixer and the Bicleaner Hardrules, which given a parallel corpus, seek to identify evident noisy sentence pairs (Sánchez-Cartagena et al., 2018).

After gathering the aforementioned material, the final step is the training of the Bicleaner. Furthermore, to create the character language models, we utilize the KenLM software package (Heafield, 2011). Via these steps, a trained classifier ready for use in pre-processing was obtained.

5 Training the NMT Systems

For training neural machine translation models, we chose the Marian NMT toolkit (Junczys-Dowmunt et al., 2018). Marian was developed to allow rapid training and translation speed, to facilitate the standardization of research work. All the models we trained adopted the architecture of a sequence-to-sequence transformer with 8 attention heads and 6 layers in both the encoder and decoder, thus largely adhering to the standard transformer configuration from (Vaswani et al., 2017). We also decided to set a specific limit to the number of training epochs to avoid lengthy training sessions, aiming to economize as far as possible on valuable computing resources, as per the recent ACL recommendation for efficient computing (Arase et al., 2021).

The transformer is characterized as innovative and uncomplicated (Vaswani et al., 2017). In our experiments, we activated the dropout mechanism, which is a widely adopted regularisation technique in NMT.

When training our NMT systems, we opted to use the SentencePiece tokenizer, which has the ability to train subword models straight from unprocessed data (Kudo and Richardson, 2018). The vocabulary size was set to 32000 and the range for the batch size was from 64 to 100. For the workspace size we used a variable value across our experiments, as the size of the training corpora varied due to the Bicleaner filtering. As suggested by the Marian developers, the workspace was adapted via a number of trial runs at the start of the training process, to maximise the throughput of training sentences per time unit. The other main parameter choices for the transformer models are shown in Table 1. Moreover, the full command used for training is presented in Table 3.

6 Experiments

6.1 Experimental setup

As discussed above, the training data used to implement all the reported experiments were limited to the parallel corpora released for WMT22 for the two language pairs German-French and German-English. For the baseline systems the text

[3] https://github.com/bitextor/bicleaner/wiki/How-to-train-your-Bicleaner

[4] http://www2.statmt.org/moses/

corpora of the respective language pair were used as released, without any pre-processing or noise-removal. Contrariwise, the remaining experiments were carried out using the aforementioned cleaning tools. After applying Bicleaner, the content of the parallel corpus remains the same, however an extra column is added where the parallelism ratings that the classifier assigned to each pair of parallel sentences are stored. Based on this column, sentence pairs rated below a threshold are discarded. Although 0.5 is suggested as a desirable threshold in relevant literature, we chose to examine other thresholds. For this reason, we tested different threshold values within the range from 0.4 to 0.7 to to discover whether changes in this parameter affect the translation accuracy of neural machine translation models. Table 2 provides details regarding the number of sentences that are retained in the parallel corpus following each application of Bicleaner.

Corpora(de-en)	Sentences
baseline_corpus.de_en	∼2.800.000
0.7_corpus.de_en	∼1.100.000
0.6_corpus.de_en	∼1.500.000
0.5_corpus.de_en	∼1.600.000
0.4_corpus.de_en	∼1.700.000
Corpora(de-fr)	**Sentences**
baseline_corpus.de_fr	∼18.000.000
0.7_corpus.de_fr	∼7.800.000

Table 2: Volume of data before and after the cleaning process.

6.2 Computer resources

For the experiments presented here a workstation was used, equipped with a single Nvidia GeForce RTX-3090 GPU, and an Intel i9-11900 CPU with 32 GB of memory. The first two tools were run on the CPU whilst the NMT models training via Marian involved predominantly the GPU. For all experiments where execution times are reported, these times are obtained with the workstation running exclusively the reported process.

6.3 Experimental results

At this point, we will review the Marian NMT training results. In Table 4 the BLEU scores during experimental process are presented. Additionally in Table 5, the WMT22 results of the automatic evaluation metrics can be found. Regarding the German-English language pair, we can observe that the baseline system has the highest score. Implementing the cleaning steps and increasing the threshold, the size of training data gets smaller and smaller, as can be seen in Table 1. Since the size of the initial data was not very big, the decrease of the data may well affect the efficiency of the models.

Regarding the German-French language pair, the best score is observed in the model trained on cleaned data. As is mentioned in a related study (Ramírez-Sánchez et al., 2020), it has been observed that the Bifixer/Bicleaner tools work better on big data. In this case the number of the sentences continues to be adequate even after the cleaning process.

7 Conclusions and Future Work

In this paper, we have presented our submission to the WMT22: General MT Task. In order to rectify and filter noisy sentences from the corpora recommended by WMT'22, we have applied two cleaning approaches for the parallel corpus. After experimenting with various categorization criteria, we created seven distinct parallel corpora. We discovered that as expected, thoroughly cleaned corpora require fewer computer resources, as a large number of sentences are removed. Additionally, we noticed that differences in the BLEU score across cleaned corpora are relatively small.

Our main submissions to the shared task were two, one for each language pair. Regarding the language pair German to English, the highest quality translation result was obtained by training a transformer model using the raw baseline corpus, and thus the use of Bifixer/Bicleaner did not lead to an improvement. The best result was obtained for the language pair German to French by training a transformer model using the bifixed and bicleaned parallel corpus with a threshold of 0.5.

In upcoming research, the Back Translation technique is planned to be utilized in order to expand the size of the training data, since the size of the sentence pairs is reduced after the cleaning procedure. The translations that emerged from the aforementioned experimental process could be filtered and reused so as to train the NMT system with bigger and cleaner parallel corpora.

In the future, it would be highly interesting to develop probabilistic dictionaries with more than 10 M parallel sentences as well as to train the Bicleaner in more than 100 K parallel sentences. Additionally, we want to use these methods on even more information about the language pairs we previously stated. In order to achieve an even cleaner corpus, it would also be quite fascinating to investigate comparatively other cleaning techniques such as those reported in the introduction.

A final direction for future work would be to use larger models such as the Big Transformer (Vaswani et al., 2017) to see if for this architecture the effect of pre-filtering with Bifixer/Bicleaner will be more marked, and what the trade-off between the improvement in translation quality and the increased training time would be.

Limitations One potential limitation of the present work is the relatively limited range and number of Bicleaner thresholds tested, though the values include both the recommended and default values. Another limitation concerns the use of a single architecture, whilst ideally a second architecture (such as the Transformer-Big configuration of (Vaswani et al., 2017)) could be used. Finally, a comparison with other corpus-cleaning methods would be desirable, though such work is beyond the scope of the present work.

Ethics Statement The present work is not expected to have any effect on ethical issues and to the authors' best knowledge complies with the ACL Ethics Policy.

Acknowledgements The current research was carried out in the context of a master's thesis implemented by the first author in the course "Language Technology" organised by the National and Kapodistrian University of Athens and ILSP/Athena R.C.. We would like to acknowledge the assistance of the WMT'22 organisers and especially Tom Kocmi during the implementation of the experiments and the submission of our results.

Abstract

This paper describes the PROMT submissions for the WMT22 Shared General Translation Task. This year we participated in four directions of the Shared Translation Task: English to Russian, English to German and back, and Ukrainian to English. All our models are trained with the MarianNMT toolkit using the transformer-big configuration. We use BPE for text encoding, all of our models are unconstrained. We achieve competitive results according to automatic metrics in all directions.

1 Introduction

The WMT Shared General Translation Task is an annual event where different companies and researchers build and test their systems on the test sets provided by the organizers. This year the Task has shifted from news to the general domain. We participate in four directions: English to Russian, English to German and back, and Ukrainian to English. We build the transformer-big models for the first time. We also explore new data filtering techniques, data preparation and model training strategies.

The rest of the paper is organized as follows: in Section 2 we describe in detail the systems we submitted to the Shared Task. In Section 3 we present and discuss the results. We conclude the paper in Section 4 with discussion for possible future work.

2 Systems overview

All of our WMT22 submissions are MarianNMT-trained (Junczys-Dowmunt et al., 2018) transformer-big (Vaswani et al., 2017) systems. We use the OpenNMT toolkit (Klein et al., 2017) version of byte pair encoding (BPE) (Sennrich et al., 2016b) for subword segmentation. Our BPE models are case-insensitive, we use special tokens in the source and target sides to process case (see Molchanov (2019) for details).

All of the systems are unconstrained, i.e. we use all data provided by the WMT organizers, all publicly available data and some private data crawled from different web-sources.

This year we use the dual conditional cross-entropy (Junczys-Dowmunt, 2018) method for data filtering. We extend the method as proposed by the author and build neural language models for both source and target languages.

We also augment our training data with two types of synthetic data: 1) back-translations (Sennrich et al., 2016a) and 2) synthetic data with placeholders as described in Pinnis et al. (2017). The back-translations are obtained using the previous versions of our NMT models which are baseline transformers trained with less data (and without some up-to-date data like the news 2021 corpora from statmt.org). We also tag all our synthetic data with special tokens at the beginning of the source sentences as described in Caswell et al. (2019).

All models are trained with guided alignment which is used at translation time to handle named entities and document formatting. We obtain

alignments using the `fast-align` (Dyer et al., 2013) tool.

The data statistics for different language pairs are presented in Table 1.

The details regarding different directions can be found in the next Section.

2.1 Data preparation

There are several stages in our data preparation pipeline. These are mostly common filtering techniques. The main stages of the pipeline are:

- Basic filtering
  This includes some simple length-based and source-target length ratio-based heuristics, removing tags, lines with low amount of alphabetic symbols etc. We also remove lines which appear to be emails or web-addresses and duplicates.

- Language identification
  The algorithm is a fairly simple ensemble of three tools: `pycld2`[1], `langid` (Lui and Baldwin, 2012), `langdetect`[2]. For large monolingual corpora we use only pycld2.

- Bicleaner filtering
  We use the bicleaner (Ramírez-Sánchez et al., 2020) tool to filter parallel data. We discard all sentence pairs with the score threshold <= 0.3.

- Scoring with NMT models
  We finally score all parallel data and back-translations with our intermediate models to discard non-parallel sentence pairs and bad synthetic translations.

- Dual conditional cross-entropy filtering
  This year we use this algorithm for the first time. We apply it to the English-German language pair.

2.2 English-Russian

The English—Russian system was trained in two steps. First, we build the baseline model on all available data. Second, we fine-tune the model on data of high quality. Specifically, we totally remove the ParaCrawl, UN and OpenSubtitles corpora and fine-tune the model using the remains of the human data mixed with the back-translations of the news corpora (2020, 2021) from statmt.org. This approach shows good results according to automatic metrics and general translation quality. The reason for doing this is that we aim for our models to be used mostly for translation of news and formal texts like various types of documents.
The system was trained with separate vocabularies, the sizes of the BPE models are 24k for the source side and 48k for the target side.

2.3 English-German and German-English

Both models were trained with the same joint vocabulary, the BPE model size is 32k. We use all available human data. We apply basic filtering for some data which we believe to be clean (e.g. private data and high-quality open-source corpora like News-Commentary). The rest of the data is filtered with the modified dual conditional cross-entropy filtering algorithm. We noticed that using only the news corpora as general for filtering as described in Junczys-Dowmunt (2018) results in the fact that the data shifts towards the news domain. For example, a perfectly fine sentence

[1] https://pypi.org/project/pycld2/

[2] https://pypi.org/project/langdetect/

pair related to the IT domain may receive low scores from News models. Therefore, we try to build a general good quality corpus comprising different domains (news, IT, technical data etc.). We do not include colloquial corpora into these general corpora because we intend for our models to be used for translating mostly formal text, be it news, formal letters or technical documents. We set the threshold for the filtering score at 0.1. Thus, we discard around 60-70% of the original data.

2.4 Ukrainian-English

We use a lot of synthetic data for this model. We decided that we could pivot the Ukrainian-English model through our Ukrainian-Russian and English-Russian data and systems. We translate the Russian side of the English-Russian data to Ukrainian and use it as synthetic data for the final model.

The Ukrainian-Russian model is a transformer-base unconstrained model. It was built jointly to translate from Ukrainian into Russian and back. We use all available parallel data and back-translations of the news and Wikipedia corpora. Although this is a transformer-base model, the Ukrainian-Russian language pair is relatively easy for the model to learn properly and achieve very good results in. Thus, we made an assumption that even the big model would benefit from this synthetic data given the fact that the Ukrainian-English is not a high-resource language pair.

To see how much we benefit specifically from using the transformer-big architecture in addition to the synthetic data from the Russian-English pair we also build a transformer-base model for this language pair.

3 Results and discussion

The results are presented in Table 2.

As we can see, we clearly outperform our baselines (i.e. previous versions of the models). The gains we observe, however, are not that large.

We notice that our submitted models have some problems with translation of colloquial content compared to the previous versions. This can be explained by our data preparation scheme. As we have already mentioned above, we want our models to translate formal text better and thus ‘sacrifice’ colloquial data. The examples of such degradations are presented in Table 3. The first example illustrates the problem when short colloquial segments are left untranslated. We think there are two major reasons for that: 1) the fine-tuned model has partially ‘forgotten’ how to translate colloquial speech; 2) there are many technical and IT-related texts in the fine-tuning data where large constructions (e.g. model or software program names) are left untranslated. Two other examples illustrate bad choice of meaning for specific words from the fine-tuned translation model (‘screwed’ is translated literally as if the kid was attached to something with a screwdriver; ‘кредит’ is a word from the financial domain which is inappropriate in this context).

You meet me	Встретишь меня	You meet me
And this kid is screwed.	И этот парень облажался.	И этот пацан прикручен.
I don't have enough credits to graduate.	У меня недостаточно баллов, чтобы закончить школу.	У меня недостаточно кредитов, чтобы получить высшее образование.

Table 3: Examples of translation degradation for colloquial content in the English-Russian direction. Model2021 stands for the previous version of the English-Russian system which we consider the baseline.

We should also note that the gain from the transformer-big configuration for the Ukrainian-English model is not that large according to the automatic scores and our human evaluation. We think this is because the synthetic translations obtained from the English-Russian data with the Russian-Ukrainian model are ultimately not of perfect quality.

4 Conclusions and future work

In this paper we presented our submissions for the WMT22 Shared General Translation Task. We show good results in all directions we participate. We clearly outperform our baselines in all directions. A detailed analysis of the translations shows us that we lose quality in translation of colloquial speech. We plan to carefully select colloquial data of very high quality and use it for the general-domain language models for dual cross-entropy data selection. We also plan to train a transformer-big Russian-Ukrainian model and rebuild the synthetic translations for the Ukrainian-English model in the future.

Abstract

The paper describes the 3 NMT models submitted by the eTranslation team to the WMT22 general machine translation shared task. In the WMT news task last year, multilingual systems with deep and complex architectures utilizing immense amounts of data and resources were dominant. This year with the task extended to cover less domain specific text we expected even more dominance of such systems. In the hope to produce competitive (constrained) systems despite our limited resources, this time we selected only medium resource language pairs, which are serviced in the European Commission's eTranslation system. We took the approach of exploring less resource intensive strategies focusing on data selection and data filtering to improve the performance of baseline systems. With our submitted systems our approach scored competitively according to the automatic rankings in the constrained category, except for the En→Ru model where our submission was only a baseline reference model developed as a by-product of the multilingual setup we built focusing primarily on the En→Uk language pair.

1 Introduction

The eTranslation team is responsible for the development of machine translation systems providing the translation services of the European Commission's eTranslation project[1]. This is a building block of the Connecting Europe Facility (CEF), with the aim of supporting European and national public administrations' information exchange across language barriers in the EU. The project is described in more details in Oravecz et al. (2019).

During the previous years the team's participation in the WMT shared tasks allowed us to explore state-of-the-art methods to develop high quality machine translation systems. However, due to strict resource constraints, these systems do not normally carry over to production environments and there has been a continuous search for the right balance between the use of resources in production environments and the best performing but more complex architectures.

With the news translation shared task extended to being a general MT task the need for more robustness, coverage and consequently more complexity and resources has further increased. We expect a strong competition in these areas, where teams with modest resources might have some inherent disadvantages. Therefore, in this year's experiments we did not consider high resource language pairs (specifically English → German, our constant submission in previous years) and opted for the medium resource French → German and English → Ukrainian language directions. The latter system originated from a multilingual setup including Russian data, so we built and submitted a baseline English → Russian model as well.

2 Data Preparation

In this section we briefly describe the base data sets, the general selection and filtering methods we applied to prepare these initial data sets used to train the first baseline models. Further data selection and augmentation methods to improve the quality of baseline models are described in Section 3.1. We only used the provided parallel and monolingual data, so our submissions all fall into the constrained category.

2.1 Base Data Selection and Filtering

As a general clean-up, we performed the following filtering steps on the parallel data[2]:

[1] https://language-tools.ec.europa.eu

[2] In some subcorpora, only a subset (not necessarily the same) of these steps was applied, depending on the data set. No filtering was used for the dev sets.

Table 1: Number of segments in the filtered parallel data used for baseline bilingual and multilingual models.

- language identification with FastText[3] (Joulin et al., 2016),
- segment deduplication,
- deletion of segments where source/target token ratio exceeds 1:3 (or 3:1),
- deletion of segments longer than 100-150 tokens (depending on language pair),
- exclusion of segments where the ratio between the number of characters and the number of words was below 1.5 or above 40,
- exclusion of segments without a minimum number of alphabetic characters (2),
- exclusion of segments with tokens longer than 40 characters,
- exclusion of segments where the length difference between source and target in the number of tokens was higher than 8,
- removal of segments where source side contained specific noise patterns (in Fr→De ParaCrawl).

These filtering steps led to an average reduction of about 15-20% of the training data with the number of segments as shown in Table 1. For Fr→De, after some manual inspection of the raw WikiMatrix and ParaCrawl data, we decided to experiment with some further clean-up on these data sets, using dual conditional cross-entropy filtering (Junczys-Dowmunt, 2018), where we built the scoring models from a subset of filtered parallel data (7.6M segments) by excluding ParaCrawl and WikiMatrix. We then built models by deleting the worst scoring 5 and 10 % of the two data sets but none of these models was better then the baseline system, so we did not use this filtering in the submission setups. In En→Uk, we experimented with language model based filtering, where we built the language model from the Leipzig corpora and fine tuned the baseline model on the filtered data set, however, it gave no improvement, so this step was not used in the submission systems either.

2.1.1 Monolingual data

In the Fr→De models, where we used back-translation (Sennrich et al., 2016) to improve baseline performance we utilized monolingual data from the various corpora provided. The data was filtered with the same rules (where applicable) as the parallel data (see Section 2.1). Table 2 provides a summary. For the other systems, we didn't use back-translated data in the submissions[4], only the original parallel data sets.

2.1.2 Development and test data

For Fr→De, since the task had been extended from news translation to general MT, where test data was expected from "news, e-commerce, social, and conversational" text, we opted to use a custom built

[3] https://fasttext.cc/docs/en/language-identification.html

[4] See Section 3.1 for experiments with monolingual Ukrainian news. The other monolingual Ukrainian data sets that could have been used for back-translation came too late for us to be able to reschedule the trainings.

test set for development rather than some previous dev set from the news domain. We extracted a 10k random subset from the filtered original parallel data and manually selected 2k segments for test and validation each. In the manual selection we tried our best to keep segments most representative of the expected domains. These segments were then obviously removed from the training data.

For En→Uk, the validation data was extended with 2k segment pairs randomly extracted from the filtered original parallel data. In addition to the Flores test set, we used 2 development test sets: 10k segment pairs extracted at random from OPUS, and 5k segment pairs extracted from ParaCrawl.

For En→Ru, we extended the validation data again with 2k segment pairs extracted at random from the 2012–2020 dev sets. Beside the Flores test set, we used 2 additional test sets: a 5k random extraction from the parallel data and the provided 2021 news test set. In the latter two language pairs we did not apply manual selection, we considered the test sets already representative enough for the task.

2.2 Pre- and Postprocessing

As in our previous years' systems, we applied the simplest possible workflow without the standard pre- and postprocessing steps of truecasing, or (de)tokenization, and simply used SentencePiece (Kudo, 2018), which allows raw text input/output within the Marian toolkit (Junczys-Dowmunt et al., 2018)[5] in the experiments. In the submission hypotheses, some simple normalization steps were applied in post-processing, similarly to previous years.

3 Trainings

In all experiments we used Marian, as the core tool of our standard NMT framework in the eTranslation service. Trainings were run as multi-GPU setups on 4 NVIDIA V100 GPUs with 16GB RAM, typically for about 30 epochs. In general, except for the first baseline setups, we built only big transformer models, this year even for back-translation, in the hope of getting better quality output for the higher resource consumption. The development scenario was straightforward without much room for experimenting with different parameters or setups due to limited resource availability: for Fr→De, a single set of 4 member ensembles from big transformers, while in En→Uk and En→Ru, a multilingual model at the first stage, fine tuned on the specific languages at the second stage, with 4 (Uk) and 3 (Ru) models in an ensemble as our submission systems for these two language pairs. The parameter settings did not change from last year's setup: for most of the hyperparameters we used the default settings in the baseline models for the base transformer architecture in Marian[6] with dynamic batching and tying all embeddings. In Fr→De, trainings were stopped if sentence-wise normalized cross-entropy on the validation set did not improve in 5 consecutive validation steps. The multilingual systems were stopped after about 40 epochs, and then fine tuned for each target direction until they were stopped to meet the submission deadline.

In the big transformer setups, we also followed standard settings for Marian, i.e. we doubled the filter size and the number of heads, decreased the learning rate from 0.0003 to 0.0002 and halved the update value for `-lr-warmup` and `-lr-decay-inv-sqrt`.

Following common ranges of subword vocabulary sizes, we set a 32k joint SentencePiece vocabulary for all language pairs. SentencePiece models were trained from 10M random segments.

3.1 Synthetic Data

In Fr→De, we back-translated the monolingual data described in Section 2.1.1 with a single big transformer trained from all available original parallel data. The resulting synthetic data set was filtered (where applicable) with the same techniques as the original parallel data. To train the submission

[5] We kept the default settings for Marian's built-in SentencePiece: unigram model, built-in normalization and no subword regularization.

[6] See eg. `https://github.com/marian-nmt/marian-examples/tree/master/transformer`.

Table 3: Results for En→Uk models. The *Dev* column displays the global scores for all dev sets concatenated.

ready systems we upsampled the (filtered) baseline original parallel (OP) data set to a 1:1 ratio with the BT data (Ng et al., 2019; Junczys-Dowmunt, 2019). This setup was a one shot configuration, we lacked the resources to experiment with other OP-BT combinations. As in previous years, we used tagged back-translation (Caswell et al., 2019) in our workflows.

In En→Uk, back-translation of a 2.4 M subset of monolingual news data with a reverse engine trained from original parallel data did not yield any improvement over the baseline so it was not used in the submission systems.

3.2 Continued Trainings

For Fr→De, in the first phase of the trainings we used all available OP data together with the back-translated synthetic data set. As a second phase after model convergence, we continued the training for 3 additional epochs[7] only on the OP data set.

In the multilingual setup, the first phase of the trainings utilized all available OP data for En→Ru and En→Uk[8]. These trainings were stopped after about 40 epochs and continued only on the respective target data. In both phases the source language data was prefixed with the target language code. All continued trainings were stopped before the submission deadline.

4 Results

We submitted a constrained system for each of the 3 language pairs. We provide COMET (Rei et al., 2020) (with the default model `wmt20-comet-da`), ChrF (Popović, 2017) and BLEU (Papineni et al., 2002) evaluation scores for models at important stages in the development, which reflect how the performance of the models changed as we experimented with the various configurations.[9]

4.1 English→Ukrainian

Table 3 gives a summary of the of the En→Uk experiments. The baseline model (M1) was trained on the filtered original parallel (OP) data using the base transformer architecture. We did not primarily go for a system with synthetic data since the usable monolingual Uk data was small in size (2.6M after filtering) and we didn't expect substantial improvement. Instead, we decided to experiment with multilingual systems. The next model (M2) was a multilingual En→{Uk,Ru} system trained only on filtered OP data (En→Uk, En→Ru), again as a base transformer. The target language was indicated in a token that was prefixed to the source language segments. The slight drop of the scores compared to M1 is not unexpected in multilingual NMT systems when using the same architecture as the bilingual model (Wang et al., 2020). In the next step we used the model of M2 that scored best on the En→Uk development test sets and fine-tuned on En→Uk data until convergence (early-stopping set to 20 stalls). This fine-tuned model was better than the bilingual baseline (M1) and the multilingual M2. The next step (M4) was to train M2 with big transformer architecture. This model was significantly better than all 3 previous models. M5 was an M4 model fine-tuned on En→Uk data, while M6 (our submission model) was a 4 member ensemble built from M5 models. Both M5 and M6 yielded some

[7] We experimented with different number of epochs, until we saw a steady improvement on the test set.

[8] Without EU-Acts, which came too late.

improvement in the automatic metrics.

4.2 English→Russian

The main stages of the model development for the En→Ru language pair are presented in Table 4. As we described before, the En→Ru system was not intended to be a competitive submission, and this is reflected in the evaluation scores, which are below the scores of other submissions. The baseline model (M1) was trained on the filtered OP data as a base transformer. The next two models (M2 and M3) are common with En→Uk (M2 and M4) – a multilingual En→{Uk,Ru} systems trained only on filtered OP data as base/big transformers (cf. Section 4.1 above). M4 is the M3 model fine-tuned on En→Ru OP data, while M5 (our submission model) is a 3 member ensemble built from M4 models. The score improvements are similar to En→Uk.

4.3 French→German

Table 5 summarizes the results of the Fr→De experiments. The first baseline model (M1) was trained only on the (filtered) original parallel (OP) data with the base transformer architecture. The next model (M2) switched to the big transformer setup and used the back-translated (BT) data with the OP data upsampled (see Section 3.1). Despite the significant increase of the training data size, the effect on the scores on our development set was moderate, however, on the 2022 test set the increase was substantial. This might suggest that the back-translated data gave better support than the OP data to the 2022 test set as a general test set but was much less effective for our development set (which was perhaps still too restricted to the news domain). In the 3rd model (M3), we continued the training only with the OP data as described in Section 3.2, with a slight increase in the metrics. Our submission model (M4) was a 4 member ensemble built from M3 models, where the 4th model was weighted 10% more than the rest. This configuration yielded the most promising result with a significant increase in the scores suggesting that ensembling might be an efficient strategy for general MT models.[10] Model 4 ended up as the best submission of the constrained category, according to all automatic metrics.

5 Conclusion

We described the submissions of the eTranslation team to the WMT22 general MT shared task on 3 language pairs: French-German, English–

[10] In previous years, ensembling was less efficient in our submitted news specific models.

Ukrainian and English–Russian, the last submission being only a baseline setup for reference, built only as a by-product of the En→Uk system. We selected medium resource language pairs and tried to focus on data selection, filtering and evaluation with custom test sets to be able to produce strong constrained systems even with limited resources. In our two competitive systems, first automatic results seemed to justify this approach.

Abstract

We present Charles University submissions to the WMT 22 General Translation Shared Task on Czech-Ukrainian and Ukrainian-Czech machine translation. We present two constrained submissions based on block back-translation and tagged back-translation and experiment with rule-based romanization of Ukrainian. Our results show that the romanization only has a minor effect on the translation quality. Further, we describe Charles Translator, a system that was developed in March 2022 as a response to the migration from Ukraine to the Czech Republic. Compared to our constrained systems, it did not use the romanization and used some proprietary data sources.

1 Introduction

How fast can the machine translation (MT) community react to a sudden need of a high-quality MT system which was previously under low demand? This question motivated the new task at the WMT this year, which is Czech-Ukrainian translation.

Both languages belong to the Slavic language family (Czech is western Slavic, Ukrainian is eastern Slavic), and share some lexical and structural characteristics. Unlike Czech, which uses the Latin script, Ukrainian uses its variant of the Cyrillic alphabet.

We submit three systems to the WMT 22 General Translation Shared Task for this language pair in each translation direction. The first system, CUNI-JL-JH, implemented in Marian (Junczys-Dowmunt et al., 2018), uses tagged back-translation and is a result of our experiments with romanization of Ukrainian. Our second system, CUNI-TRANSFORMER, implemented in Tensor2Tensor (Vaswani et al., 2018), uses block back-translation. Finally, we submit an unconstrained system, CHARLES TRANSLATOR, implemented in Tensor2Tensor, which has been developed in spring 2022 as a response to the crisis caused by the Russian invasion of Ukraine and the following migration wave.

2 Constrained WMT Submissions

We submitted two systems in each translation direction that use the same parallel and monolingual data, but different techniques and different toolkits. This section first describes the shared data processing steps and then the specifics of each of the submissions in separate subsections.

2.1 Training Data

We use all parallel data allowed in the constrained task, along with 50 million Czech and 58 million Ukrainian sentences of monolingual data. In the following paragraphs we describe the data cleaning steps when preparing the training data. We further experiment with romanization of the Ukrainian Cyrillic alphabet and with artificial noising of the data.

Parallel data. The data for the constrained translation task consist of OPUS corpora (Tiedemann, 2012) that have a Czech-Ukrainian part, WikiMatrix (Schwenk et al., 2021) and the ELRC EU acts in Ukrainian.[1]

We clean the parallel data using rule-based filtering in the following way:

1. Filter out non-printable and malformed UTF-8 characters.

2. Detect language using FastText (Grave et al., 2018), only keep Czech and Ukrainian sentences on their respective source/target sides.

3. Only keep sentence pairs with character length ratio between 0.67 and 1.5 if longer than 10 characters.

[*] The author order was determined by a coin toss.

Table 1: Sizes of parallel data sources (number of sentence pairs).

4. Apply hand-crafted regular expressions to filter out the frequent errors, such that the system does not attempt to translate e-mail addresses, currencies, etc. In addition, regular expressions check translations of names of Czech[2] and Ukrainian[3] municipalities downloaded from Wikipedia.

We omit steps 2 and 3 for the XLEnt corpus, which seems to be very clean and consist of short phrases (likely to get misclassified for language).

The sizes of the used parallel data sources before and after cleaning are presented in Table 1.

Monolingual data. The overview of the monolingual data sources is in Table 2. For Czech, we use the Czech monolingual portion of the CzEng 2.0 corpus (Kocmi et al., 2020). For Ukrainian, we used all resources, available for WMT, i.e., the NewsCrawl, the Leipzig Corpora (Biemann et al., 2007), UberText corpus (Khaburska and Tytyk, 2019) and Legal Ukrainian Crawling by ELRC. The Uber corpus and the Ukrainian Legal corpus are distributed tokenized with removed punctuation. We automatically restored the punctuation and detokenized the models using a lightweight Transformer model (Vaswani et al., 2017; Base model with 3 layers, 8k vocabulary) trained on the NewsCrawl corpus.

For Ukrainian, we only keep sentences shorter than 300 characters. For Czech, we keep all sentence lengths from the CzEng corpus (up to 1400 characters). For both languages, we remove non-printable and malformed UTF-8 characters.

	Total	66.8 M	58.1 M

Table 2: Monolingual data sizes in number of sentences before and after filtering.

Romanization. We develop a reversible romanization than transcribes between the Ukrainian and Czech alphabets. For example, Зараз у нас є 4-місячні миші is transcribed to *Zaraz u nas je 4-misjačni myši*. This way the model can better exploit the lexical similarities between the two languages (e.g. миші should be translated to Czech as *myši*), while keeping all the necessary information to reconstruct the original Cyrillic text. Note that the transcription of Cyrillic changes when changing the target language, reflecting the phonology of that language (e.g. ш transcribes to *sh* in English, but *š* in Czech). We introduce special tags for words and characters that are written in Latin script found in Cyrillic text. The romanization is specifically designed for Ukrainian (e.g. и transcribes to *y*, not *i* as would be the case in Russian), so its reversibility occasionally fails for Russian names.

Artificial noise. We apply synthetic noise on the source side that should simulate the most frequent deviations from the standard orthography (missing capitalization, lower- or upper-casing parts of the sentences, missing or additional punctuation).

All scripts for training data processing are available at `https://github.com/ufal/uk-cs-data-scripts`. We use Flores 101 (Goyal et al., 2022) development set for validation.

2.2 Tagged-back-translation-based System (CUNI-JL-JH)

The CUNI-JL-JH submission is a constrained system and uses the data described in the paragraphs above. We train the system in 3 iterations of tagged back-translation (Caswell et al., 2019) with greedy decoding. Each iteration, we filter the back-translated data using Dual Cross-Entropy filtering (Junczys-Dowmunt, 2018) when keeping

[2] https://uk.wikipedia.org/wiki/Міста_Чехії

[3] https://cs.wikipedia.org/wiki/Seznam_měst_na_Ukrajině

$40,930,735$ synthetic sentences, i.e., 5× the size of clean authentic parallel data.

The first two back-translation iterations were done with the Cyrillic script on the Ukrainian side. In the final back-translation iteration, we performed romanization and noising of the source side. We train three models with random initialization and submit the ensemble.

For all iterations, we used a Transformer Big model with tied embeddings and a shared SentencePiece vocabulary size of 32k (fitted on 5M randomly sampled sentences; with sampling at the training time, α=0.1; Kudo and Richardson, 2018). We set the learning rate to 0.0003 and use $8,000$ warm-up steps. We initialize the models randomly in each back-translation iteration.

For validation, we use greedy decoding. At test time, we decode with beam search with beam size of 4 and length normalization of 1.0 (estimated on validation data).

The system is implemented using Marian (Junczys-Dowmunt et al., 2018).

Negative results. We experimented with Dual-Cross-Entropy filtering (Junczys-Dowmunt, 2018) for parallel data selection and came to inconclusive results. Therefore, we used all parallel data after rule-based filtering.[4]

Additionally, we experimented with MASS-style (Song et al., 2019) pre-training using monolingual data only and continue with training on parallel data. We were not able to find a hyper-parameter setting where the pre-trained model would outperform the models trained from random initialization. Therefore, we only use model trained from random initialization.

2.3 Block back-translation System (CUNI-Transformer)

The CUNI-Transformer submission is also constrained, trained on the same data as CUNI-JL-JH. The system was trained in the same way as the sentence-level English-Czech CUNI-Transformer systems submitted to previous years of WMT shared tasks (Popel, 2018, 2020; Gebauer et al., 2021). It uses Block back-translation (BlockBT) (Popel et al., 2020), where blocks of authentic (human-translated parallel) and synthetic (back-translated) training data are not shuffled together, but checkpoint averaging is used to find the optimal ratio of checkpoints from the authentic and synthetic blocks (usually 5:3). The uk→cs system was trained with a non-iterated BlockBT (i.e. cs-mono data was translated with an authentic-only trained baseline). The cs→uk was trained with two iterations of BlockBT (i.e. the uk-mono data was translated with the above mentioned uk→cs non-iterated BlockBT system). We had not enough time to train more iterations and apply noised training and romanization. The system was implemented using Tensor2Tensor (Vaswani et al., 2018).

Inline casing. We experimented with Inline casing (InCa) pre-processing in the cs→uk direction. The main idea is to lowercase all training data and insert special tags <titlecase> and <all-uppercase> before words in the respective case, so that the original casing can be reconstructed (with the exception of words like *McDonald* or *iPhone*, which use different casing patterns than all-lowercase, all-uppercase and titlecase). We improved this approach by remembering the most frequent casing variant of each (lowercased) word in the training data. The most frequent variant does not need to be prefixed with any tag, which makes the length of training sequences shorter. We also introduced a third tag <all-lowercase> for encoding all-lowercased words whose most frequent variant is different. For example, if the InCa vocabulary includes only two items: *iPhone* and *GB*, sentence *My iPhone 64GB and iPod 64 GB or 32 gb* will be encoded as <titlecase> *my iphone* <all-uppercase> *64gb and iPod 64 gb or 32 <all-lowercase> gb*. Note that *iPod* was kept in the original case because it was not included in the InCa vocabulary and it does not match any of the three "regular" casing patterns. We applied InCa on both the source and target side and experimented with training the InCa vocabulary on the authentic data only or on authentic plus synthetic (monolingual backtranslated).

Inline casing showed promising results in preliminary experiments (without backtranslation), especially when combined with romanization and artificial noise in training. Unfortunately, we had not enough time to train the backtranslated model long enough, so we submitted it only as a contrastive run and plan to explore it more in future.

[4] Note that we use Dual-Cross-Entropy for filtering the monolingual data, as described in the first paragraph of this section, but we have not done any experiments with keeping all the monolingual data.

Model	cs→uk	uk→cs
Authentic only	20.91	22.95
BT iteration 1	21.69	23.70
BT iteration 2	21.87	23.98
BT iteration 3 (seed 1)	21.53	23.76

Table 3: Validation BLEU scores for the first two iterations of BT for the tagged BT systems.

3 Charles Translator for Ukraine

Charles Translator for Ukraine is a free Czech-Ukrainian online translation service available for public at `https://translator.cuni.cz` and as an Android app. It was developed at Charles University in March 2022 to help refugees from Ukraine by narrowing the communication gap between them and other people in Czechia. Similarly to CUNI-Transformer, it is based on Transformer and iterated Block back-translation (Popel et al., 2020). The training used source-side artificial noising, but no romanization and no inline casing. It was trained on most (but not all) of the training data provided by WMT plus about one million uk-cs sentences from the InterCorp v14 corpus (Čermák and Rosen, 2012; Kotsyba, 2022), so this submission is unconstrained.

4 Results

In this section, we report BLEU scores on the Flores 101 development set that we used to make our decisions about the system development and the final automatic scores. Note that the validation set is very different from the test set. The validation set consists of clean and rather complicated sentences from Wikipedia articles, whereas the WMT 22 test set is noisy user-generated text from the logs of the production deployment of Charles Translator.[5]

Tagged BT systems. Table 3 shows validation BLEU scores from the first three iterations of back-translation. The second and third iteration did not bring substantial improvements, so we decided not to further iterate.

Table 4 shows validation BLEU scores from the last (third) BT iteration – three independently trained systems and their ensembles, and the Cyrillic and romanized versions of the data. In general, ensembling only brings a small improvement. Romanization does not bring a significant difference compared to using the Cyrillic script. In the Czech-to-Ukrainian direction, the best system was the ensemble of the romanized systems. However, in the Ukrainian-to-Czech direction, the best system was one of the Cyrillic systems that used accidentally 3 times higher batch size than the remaining ones. This result suggests that the batch size has a much stronger effect than most of the techniques that we experimented with and that we might have reached better results if we opted for higher batch size.

Model		cs→uk	uk→cs
Cyrillic	Seed 1	21.53	23.76
	Seed 2	22.28	**25.10**
	Seed 3	21.96	24.39
	Ensemble	22.45	24.86
Romanized	Seed 1	21.42	23.99
	Seed 2	21.76	23.91
	Seed 3	22.37	24.18
	Ensemble	**22.62**	24.22

Table 4: Validation BLEU scores for the last (i.e., the third) iteration of BT comparing romanized and original script.

Results on WMT test. Automatic evaluation on the WMT22 test set is presented in Table 5. Both the constrained systems and Charles Translator show comparable results. The tagged BT system reaches a slightly higher COMET score than the Block BT system, however, Czech-Ukrainian was not in the training data of the COMET score, which make the score unreliable for this particular language pair. For Czech-to-Ukrainian, Charles Translator reaches a slightly higher COMET score and slightly lower BLEU and chrF scores than both the constrained systems, but we do not consider such small differences of automatic metrics relevant.

5 Conclusions

We presented Charles University submissions to the WMT 22 General Translation Shared Task on Czech-Ukrainian and Ukrainian-Czech machine translation. We present two constrained submissions based on block back-translation and tagged back-translation and experiment with rule-based romanization of Ukrainian. Further, we describe Charles Translator, a system that was developed in March 2022 as a response to the migration from Ukraine to the Czech Republic. Compared to our constrained systems, it did not use the romanization

[5] The test set only contains sentences from users who provided their consent for this usage and the sentences were pseudonymized.

	cs→uk			uk→cs		
System	BLEU	chrF	COMET	BLEU	chrF	COMET
Best constrained (HuaweiTSC/AMU)	36.0	62.6	0.994	37.0	60.7	1.048
CUNI-Transformer	35.0	61.6	0.873	35.8	59.0	0.885
CUNI-JL-JL	34.8	61.6	0.900	35.1	58.7	0.890
Best unconstrained (Lan-Bridge/Online-B)	38.1	64.0	0.942	36.5	60.4	0.965
Charles Translator	34.3	61.5	0.908	35.9	59.0	0.901

Table 5: Final automatic results on the WTM22 test data compared to the best overall score achieved in each metric.

and used some proprietary data sources.

Our results show that the romanization only has a minor effect on the translation quality, compared to machine-learning aspects that affect translation quality. Block back-translation seems to deliver slightly better results that tagged back-translation, however the differences are only small.

The ARC-NKUA submission for the English-Ukrainian General Machine Translation Shared Task at WMT22

Dimitrios Roussis[1,2] **and Vassilis Papavassiliou**[1]
[1]Athena Research Center, Athens, Greece
[2]National and Kapodistrian University of Athens, Greece
{dimitris.roussis, vpapa}@athenarc.gr

Abstract

In what follows, we provide an overview of the ARC-NKUA ("Athena" Research Center - National and Kapodistrian University of Athens) submission to the WMT22 General Machine Translation shared task for the EN-UK (English to Ukrainian) and UK-EN (Ukrainian to English) translation directions. We describe how we constructed two Neural Machine Translation systems by training Transformer models (Vaswani et al., 2017), as well as our experiments involving: (a) ensemble decoding, (b) selected fine-tuning with a subset of the training data, (c) data augmentation with back-translated monolingual data, and (d) post-processing of the translation outputs. Furthermore, we discuss filtering techniques and the acquisition of additional data used for training the systems.

1 Introduction

Neural Machine Translation (NMT) has achieved significant improvements in translation quality in recent years, especially concerning high-resource language pairs. However, there is a lot of room for research on systems with general translation capabilities, underrepresented domains, low- or medium- resource language pairs, as well as multilingual systems. This year, the former news translation shared task widened in scope by introducing new domains, as well as the English-Ukrainian language pair among others.

We participated in the WMT22 General Machine Translation shared task for the unconstrained tracks of the EN-UK (English to Ukrainian) and UK-EN (Ukrainian to English) translation directions. The two submitted NMT systems are based on the Transformer architecture (Vaswani et al., 2017) and our experiments involve various methods and techniques such as data acquisition, filtering and selection, fine-tuning, ensemble decoding, tagged back-translation of English and Ukrainian monolingual sentences and post-processing of the translation outputs.

This paper is structured in the following way: In Section 2, we describe the parallel and monolingual corpora, as well as the acquisition, selection, filtering and pre-processing techniques that were used in our experiments. Section 3 outlines the NMT systems architecture, training parameters and the various experiments on top of our baseline systems. In Section 4, we report and discuss the experimental results of the two translation directions we participated in, while Section 5 concludes and summarizes our work.

2 Datasets

We participated in the unconstrained tracks of this year's general machine translation shared task for the English-Ukrainian and Ukrainian-English translation directions. We made use of most of the datasets given by the organizers: corpora from OPUS[1] (Tiedemann, 2012), ParaCrawl v9[2] and ELRC - EU acts in Ukrainian[3] from the ELRC-SHARE repository. Other parallel resources from this repository that were used in our systems include:

- Multilingual English, French, Polish to Ukrainian Parallel Corpus (processed)[4]

- Official web-portal of the Parliament of Ukraine, primary legislation[5]

- Official web-portal of the Parliament of Ukraine, Ukrainian laws in EN[6]

- Official web-portal of the Parliament of Ukraine, abstracts of UK laws[7]

- SciPar UK-EN-RU[8] (Roussis et al., 2022a)

- A Bilingual English-Ukrainian Lexicon of Named Entities Extracted from Wikipedia[9]

We also made use of three monolingual datasets given by the organizers: News crawl[10], Leipzig Corpora[11] and Legal Ukrainian Crawling[12] from the ELRC-SHARE repository. After manually inspecting the other given dataset, UberText Corpus[13], we decided not to use it for back-translation (see Section 3.2), as most punctuation is missing. Instead, we make use of monolingual corpora that we acquired (see Section 2.1), as well as the Ukrainian monolingual corpus of WikiMatrix.

2.1 Acquisition of Additional Corpora

In order to acquire additional parallel English-Ukrainian data, we used the ILSP-FC toolkit[14] (Papavassiliou et al., 2013) to crawl candidate parallel documents from websites and the LASER toolkit[15] (Artetxe and Schwenk, 2019) to mine bitexts with the use of its margin-based alignment score, after splitting each document into sentences. It is worth noting that manual inspection was also moderately applied so as to exclude machine translated websites. Additional parallel data acquisition techniques that were used are mentioned in more detail in Roussis et al. (2022a; 2022b). During parallel data acquisition, monolingual sentences in English and Ukrainian were also collected and were later used for back-translation (see Section 3.2).

The aforementioned techniques were used to compile the first five bulleted corpora listed in section 2, as well as EU acts in Ukrainian which was given by the organizers. Nevertheless, we attempted to enrich the acquired data by also targeting approximately 300 websites to extract EN-UK parallel sentences and more than 2,000 websites to extract monolingual UK sentences. This process resulted in ~2M additional EN-UK sentence pairs and ~31.9M monolingual UK sentences.

2.2 Parallel Corpus Filtering

The following filtering methods are used on all of the parallel data (including the subset that we selected for fine-tuning, as well as the synthetic data) after punctuation normalization and tokenization with the Moses toolkit[16] (Koehn et al., 2007):

- Sentence pairs with identical source and target sides are removed (Papavassiliou et al., 2018; Pinnis, 2018).

- Duplicate sentence pairs are removed, based on either source or target side; i.e. no English or Ukrainian sentence (after being lowercased and having its digits removed) appears more than once in the training set.

[14] http://nlp.ilsp.gr/redmine/projects/ilsp-fc/
[15] https://github.com/facebookresearch/LASER/
[16] https://github.com/moses-smt/mosesdecoder/

- Sentence pairs in which either side consists of more than 50% non-alphabetic characters are removed (Rikters, 2018).

- Sentence pairs in which the length ratio in terms of digit characters is over 2:1 (or below 1:2) are removed.

- Sentence pairs in which either the source or target sentence contains more than 250 tokens or more than 1000 characters are removed.

- Sentence pairs in which the token ratio between the longest and the shortest sentence is higher than 2 are removed.

- Sentence pairs in which either sentence contains letters not in the range of Unicode character sets relevant to Latin and Cyrillic scripts are removed (Papavassiliou et al., 2018).

- The repeating token filter[17] from Rikters (2018) was used to remove sentence pairs originating from machine-translated content.

- Language identification with fastText[18] (Joulin et al., 2017) is used to remove sentence pairs with different languages than expected.

In Table 1, we report the number of the raw (unfiltered) English-Ukrainian sentence pairs (57.7M), the number actually used for training the baseline systems after filtering (19M), and the selected subset used for fine-tuning (10.2M). Additionally, we list the number of filtered synthetic parallel sentences generated from English monolingual sentences with the EN-UK system (60M) and from Ukrainian monolingual sentences with the UK-EN system (54.5M).

2.3 Data Selection

As we will describe in more detail in Section 3.4, we also experimented with fine-tuning the NMT systems (see Section 3.3). In particular, after training a system we continue its training with a subset of the parallel data which has been selected according to some stricter criteria. LASER-based corpus filtering has been shown to have promising results (Chaudhary et al., 2019), it has already been computed for many of the used datasets and we believe that it may prove especially useful in counteracting possible quality degradation in NMT systems trained with additional back-translated data (Tran et al., 2021).

Type of data	Sentence pairs
Raw EN-UK parallel	57,727,556
Filtered EN-UK parallel	19,023,045
Filtered EN-UK parallel selected for fine-tuning	10,203,198
Back-translated from monolingual EN	60,055,592
Back-translated from monolingual UK	54,517,999

Table 1: Number of used EN-UK sentence pairs

To this end, we decided to select an appropriate subset of the training data with the utilization of the alignment score given by the LASER toolkit. For this reason, the LASER scores of the parallel sentences of the available corpora were examined and the following data selection strategy was adopted:

- A LASER score threshold of 1.1 was set for sentence pairs originating from the CCMatrix, CCAligned and ParaCrawl corpora. These three datasets contain a total of 42.1M raw sentence pairs and have been collected from the web.

- A LASER score threshold of 1.06 was set for sentence pairs originating from the WikiMatrix corpus as well as for those that we acquired (see Section 2.1).

2.4 Pre-Processing and Vocabulary

As mentioned in section 2.2, the Moses toolkit is used to normalize the punctuation and tokenize the datasets. Additionally, in order to handle casing, we use the "inline casing" technique (Bérard et al., 2019; Etchegoyhen and Ugarte, 2020; Molchanov, 2020) which uses specific tags to denote uppercase (<UC>), title case (<TC>) or mixed case (<MC>) words. Depending on the tags which the decoder has generated, the output sentences are re-cased

[17] https://github.com/M4t1ss/parallel-corpora-tools/blob/master/parallel/repeating-tokens.php

[18] https://fasttext.cc/docs/en/language-identification.html

during post-processing. Inline casing has been shown as the optimal approach in handling casing (Etchegoyhen and Ugarte, 2020).

After the application of the filtering pipeline, as well as the addition of tags (from inline casing or tagged back-translation) and NFC Unicode normalization, a separate BPE tokenizer with 18k merge operations is trained independently for English and Ukrainian with SubwordNMT [19] (Sennrich et al., 2016a) and BPE-dropout with probability of 0.1 is applied on the source sentences for each translation direction (Provilkov et al., 2020).

3 System Overview

Both submitted systems follow the Transformer architecture (Vaswani et al., 2017) and were trained using two RTX 2080 Ti GPUs with the utilization of the Fairseq toolkit (Ott et al., 2019). In the subsections that follow, we describe the training process of both NMT systems, as well as the techniques that we experimented with in order to improve translation quality.

3.1 Model Architecture and Training

The "big Transformer" architecture (Vaswani et al., 2017) is used as our NMT model, although we made use of 8 encoder layers instead of 6, as increasing the number of encoder layers has been shown to improve performance in many scenarios (Subramanian et al., 2021; Wang et al., 2021b). We apply dropout with probability 0.3, activation dropout with probability 0.1 and attention dropout with probability 0.1. The Adam optimizer (Kingma and Ba, 2014) is used with a peak learning rate of 0.0007 after 4,000 warmup steps which then follows inverse square root decay. The models are trained using half precision training (FP16), with 2,800 tokens per batch, while the parameters are updated every 4 batches (Ott et al., 2018). Checkpoints are saved every 20,000 updates and every 10,000 updates when fine-tuning, while the training stops if the BLEU score on the validation set does not improve for 5 checkpoints. Finally, checkpoint averaging 5 was applied to all NMT systems, i.e., we average the parameters of the 5 last checkpoints in order to obtain the final model parameters.

3.2 Tagged Back-Translation

Back-translation (Sennrich et al., 2016b; Edunov et al., 2018) has been proven as an effective data augmentation technique which leverages large amounts of monolingual data and is particularly useful for domain adaptation and low-resource settings (Bérard et al., 2019; Wang et al., 2021a; Wang et al., 2021b). We follow Caswell et al. (2019) in using tagged back-translation, i.e., inserting a <BT> tag in the beginning of each source sentence which has been synthetically generated; a method which is simple and robust.

For each of the two translation directions, the reverse fine-tuned models trained on parallel data are used (with beam size 5) in order to generate the synthetic outputs (see Table 1). When we enrich the training set with back-translated data, we upsample the original parallel data by a factor of 2.

3.3 Selected Fine-Tuning

Fine-tuning is usually used to adapt a NMT model to a specific domain, i.e., to improve its quality on inputs with specific characteristics. Since this year the former news translation shared task changed its focus to more general translation capabilities, there is not a specific domain which we would like our systems adapted to.

Nevertheless, fine-tuning has also been shown to have a corrective effect on systems which exhibit decreased performance after having been trained with large amounts of synthetic data (Tran et al., 2021; Wang et al., 2021a). Thus, after the training of the NMT models ends, we continue to train them using a selected subset of the training set (see Section 2.3), while also halving the dropout probability to 0.15.

3.4 Ensemble Decoding

Ensemble decoding has been shown to have mostly minor effects on performance, although it can improve performance on specific translation directions (Oravecz et al., 2020; Tran et al., 2021; Subramanian et al., 2021; Wang et al., 2021a; Wang et al., 2021b). During inference, the probability distributions over the next token are averaged

Table 2: BLEU scores on FLORES101 and WMT22 test sets for
English to Ukrainian (EN-UK) and Ukrainian to English (UK-EN) systems.

according to the systems used in ensemble decoding.

It is generally better to use ensemble decoding with NMT systems trained with different seeds or different subsets of the training set (Oravecz et al., 2020; Subramanian et al., 2021). Unfortunately, hardware and time constraints did not allow us to follow this approach and thus, we experimented with ensembling 2 or 3 models from the resulting systems mentioned in the paper.

3.5 Post-Processing

In the WMT 2022 test data provided by the organizers, we observed specific peculiarities which were handled by post-processing scripts. In particular, the Ukrainian data used in the evaluation of the Ukrainian-English systems contained emojis which our systems were not able to handle. We used a simple post-processing script on the English outputs to copy emojis from the beginning or the end of the original Ukrainian input sentences. As regards the Ukrainian outputs of the English-Ukrainian systems, we used a script to replace double quotes ("…") with angled quotation marks («…»), as well as to fix anonymous placeholders according to their original style in the English inputs.

4 Results

We perform the evaluation of our systems using the FLORES101 test set (Goyal et al., 2022) and the WMT22 General Machine Translation test set given by the organizers. Scores are reported in terms of the detokenized case-sensitive BLEU score (Papineni et al., 2002) and have been computed with the SacreBLEU toolkit[20] (Post, 2018). In Table 2, we can see the resulting scores from our experiments, as well as the scores of the submitted models.

4.1 English to Ukrainian

The submitted NMT system for English to Ukrainian has been trained only with parallel data, fine-tuned with a subset of them (see Section 3.3) and its outputs have been post-processed (see Section 3.5). In Table 2, we can see that the effect of back-translation is negative for the EN-UK system. Selected fine-tuning exhibited a corrective effective which, nevertheless, was not enough to offset the initial degradation caused by the addition of synthetic data. However, we also obtain a small improvement (+0.2 BLEU on the WMT22 test set) when fine-tuning the baseline system trained only with parallel data. The largest increase in BLEU scores (+0.8) on the WMT22 test set, is observed after the application of post-processing on the outputs of the final system, which has been trained only with parallel data and fine-tuned on a selected subset of them. This increase does not concern the FLORES101 test set, since there are significant differences in the use of quotation marks between the two test sets. Finally, ensemble decoding did not provide any advantage in our experiments.

4.2 Ukrainian to English

As we can see in Table 2, back-translation initially degrades translation quality but, contrary to the results discussed in Section 4.1, ultimately leads to increased performance after fine-tuning with a selected set of the training data. Ensemble decoding usually has a marginal effect on NMT systems and we see a small increase by its use here as well. For this translation direction, we do not observe any significant difference after the application of post-processing, although we

[20] https://github.com/mjpost/sacreBLEU

decided to use it in the final system, since we do not believe it has any negative effects (less than 50 sentences were affected). Thus, the submitted NMT system for Ukrainian to English is based on all the techniques that we experimented with: back-translation (see Section 3.2), selected fine-tuning (see Section 3.3), ensemble decoding (see Section 3.4) and post-processing (see Section 3.5).

5 Conclusion

In this paper, we have presented the ARC-NKUA submission to the WMT22 General Machine Translation shared task for the English to Ukrainian and Ukrainian to English translation directions. The submitted systems follow the Transformer architecture and were determined after experimentation with back-translation, selected fine-tuning, and ensemble decoding. We showed that the corrective effect of fine-tuning with a subset of the training set can ultimately increase the translation quality of a system which has exhibited degradation due to having been exposed to a large number of synthetic data, while it also proved useful for systems trained only with parallel data.

Our systems underperformed in comparison with other submitted systems, according to automatic scores calculated by the organizers[21], although human judgements will be used for official ranking. In the future, we aim at better investigating the effects of acquiring additional parallel and monolingual data, following different filtering, selection and pre-processing strategies, as well as implementing several techniques which have been generally shown to increase translation quality, but hardware and time constraints did not allow us to experiment upon. Possible techniques that could be investigated include reranking, larger NMT model architecture, iterative back-translation, ensembling models trained on different subsets of the training set and exploiting higher-resource similar languages.

Abstract

This paper describes the NiuTrans neural machine translation systems of the WMT22 General MT constrained task. We participate in four directions, including Chinese→English, English→Croatian, and Livonian↔English. Our models are based on several advanced Transformer variants, e.g., Transformer-ODE, Universal Multiscale Transformer (UMST). The main workflow consists of data filtering, large-scale data augmentation (i.e., iterative back-translation, iterative knowledge distillation), and specific-domain fine-tuning. Moreover, we try several multi-domain methods, such as a multi-domain model structure and a multi-domain data clustering method, to rise to this year's newly proposed multi-domain test set challenge. For low-resource scenarios, we build a multi-language translation model to enhance the performance and try to use the pre-trained language model (mBERT) to initialize the translation model.

1 Introduction

We participate in the WMT22 General MT task, including Chinese→English (ZH→EN), English→Croatian (EN→HR), and Livonian↔English (LIV↔EN) in four directions. All of our systems are built with constrained data sets. We adopt some methods that have been proven to work well in WMT over the past few years (Li et al., 2019; Zhang et al., 2020; Zhou et al., 2021). At the same time, we also adopt some new model structures (Li et al., 2022; Jiang et al., 2020), data clustering (Aharoni and Goldberg, 2020), initialization (Guo et al., 2020), and training methods (Liu et al., 2021), which are described in detail below.

For data preparation and augmentation, since filtering data could hurt the model performance on the general domain machine translation task, we apply several soft data filtering rules to preserve as much data as possible (Zhang et al., 2020; Zhou et al., 2021). To obtain the in-domain data, we use the open-source toolkit XenC (Rousseau, 2013) and specially try a domain clusters method based on the BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) model in the ZH→EN direction. We also use back-translation (Sennrich et al., 2016a) and knowledge distillation (Freitag et al., 2017) iteratively to increase the size of in-domain data, which has been proved effective in recent years (Zhang et al., 2020; Zhou et al., 2021).

For model architectures, our system is built on several Transformer variants, including Transformer-RPR, Transformer-DLCL (Wang et al., 2019), Transformer-ODE (Li et al., 2021), Transformer-UMST (Li et al., 2022), and Transformer-based model with domain mixing (Jiang et al., 2020). We build a wide and deep model based on the pre-norm structure (Wang et al., 2019) and relative position representation(RPR) (Shaw et al., 2018), inspired by the effectiveness of the deep model. Furthermore, we select four single models to build the ensemble model for better performance. Particularly, in the EN↔LIV direction, we build a multilingual machine translation system (Johnson et al., 2017) based on the above models.

For model initialization, training, and decoding strategies, we use nucleus sampling(Top-P) (Holtzman et al., 2020), top-k sampling(Top-K), and beam search as decoding methods in all languages. At the same time, we adopt scheduling sampling (Liu et al., 2021) in ZH→EN direction during fine-tuning. Furthermore, we attempt to initialize the translation model with the pre-trained language model based on lightweight adapter (Guo et al., 2020) in the EN↔LIV direction.

Based on the softer filtering rules and appropriate hypo-parameter settings, we achieve better results on the deep model than last year. In the ZH→EN direction, fine-tuning with the normal training and the scheduling sampling also obtain

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 366 - 374
December 7-8, 2022 ©2022 Association for Computational Linguistics

good results. Furthermore, we use an unsupervised multi-domain data clustering method and some simple domain classification methods. However, we find no significant domain differences in the constrained data. Initializing the translation model with the pre-trained model leads to poor performance in the EN↔LIV direction. It may be due to the sensitivity to the size of the training set.

The rest of the paper is organized as follows: In Section 2, we describe our system in detail, including the data preprocessing and filtering, model structure, back-translation and knowledge distillation, fine-tuning, and post-editing. In Section 3, we introduce our experimental settings and results according to different tasks and give a brief analysis. In Section 4, we summarize our work.

2 System Overview

In Figure 1, we describe the whole process of our system. We use three different colors to represent the different translation tasks. At the data preparation stage, we perform several data processing methods to obtain the training set. Then, we train several models with different structures and use back-translation(BT) and knowledge distillation(KD) iteratively based on ensemble model. Finally, we obtain our final submission based on fine-tuning and post editing.

2.1 Data Preprocessing and Filtering

In the word segmentation stage, we choose different word segmentation methods for the three languages according to the language characteristic. In ZH→EN, we use the `NiuTrans` (Xiao et al., 2012) word segmentation tool for both Chinese and English, which makes it easier for the model to align the words in the bilingual sentence. In EN↔LIV, we use `Reldi-Tokeniser`[1] for each language. In EN→HR, we use `Reldi-Tokeniser` for Croatian and `Niutrans` for English. Further, we apply BPE (Sennrich et al., 2016b) with 32K operations and not shared vocabulary in most language pairs. Specifically, in EN↔LIV, we use five languages, including EN, CS, LIV, ET, and LV, to build a multilingual translation system. We apply BPE with different operations for different languages, as shown in Table 1. Furthermore, we manually construct a dictionary based on `fast_align` (Dyer et al., 2013) to improve word-level alignment.

language	operations
EN	32K
CS	32K
LIV	10K
ET	10K
LV	10K

Table 1: Bpe operations in Livonian↔English

We mainly use the previous filtering method (Zhou et al., 2021). Nevertheless, we adopt softer filtering rules to improve the model performance on the general MT task as follows:

- Filter out sentences that contain long words over 40 characters and sentences that contain over 200 words.
- The word ratio between the source and target sentence must be in the range of [1/3, 3].
- Use Unicode to filter uncommon characters that never appear in previous years' test sets.
- Filter out the sentences which contain HTML tags or duplicated translations.

We use the same filtering rules for monolingual and bilingual data, and based on the filtering rules, we retain more data to do domain filtering further. Based on these filtering rules, we effectively reduce the <UNK> proportion on the previous years' newstest set, while retaining some longer sentences to meet the challenge of the general test set.

2.2 Model Architectures

In recent years, the deep model has been widely proven to be a very effective model structure (Wang et al., 2019; Zhang et al., 2020; Zhou et al., 2021), so we use a variety of deep models, including Transformer-RPR, Transformer-DLCL (Wang et al., 2019), and Transformer-ODE (Li et al., 2021). In addition, we use a new model structure, Transformer-UMST (Li et al., 2022), which uses multi-scale information to enhance the representation ability of model representation. The explicit information of the above model is shown in Table 2.

Transformer-RPR: Compare to Vanilla Transformer, we only increase the number of encoder layers and add RPR into the self-attention at each layer to efficiently consider the relative positions between different representations.

[1] https://github.com/clarinsi/reldi-tokeniser/blob/master/LICENSE

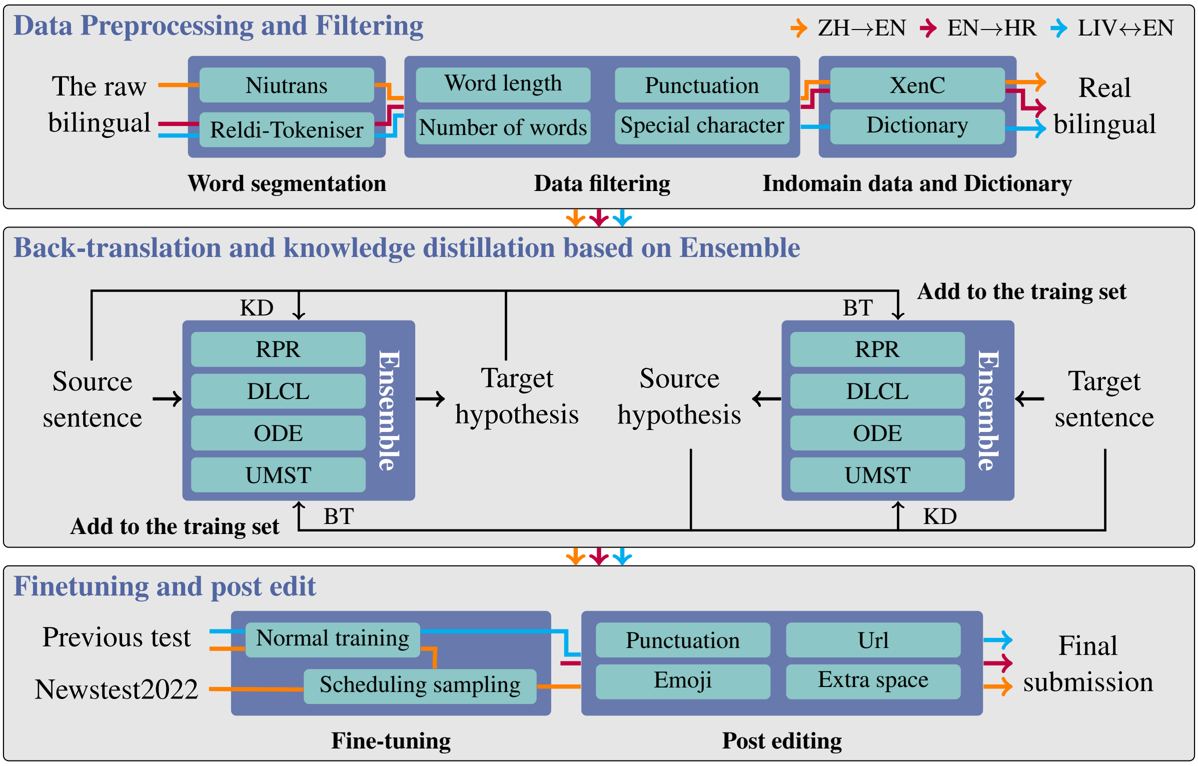

Figure 1: The whole process of our system.

Transformer-DLCL: Build a deeper network with dense inter-layer connections based on the vanilla Transformer, which can increase the information flow at the lower layer.

Transformer-ODE: Based on the relationship between numerical methods of Ordinary Differential Equations(ODEs) and Transformer, A more efficient Transformer calculation method can be obtained by solving ODEs.

Transformer-UMST: Enhance the representation ability of vanilla Transformer by importing sentence-level and word-level information to attention.

2.3 Back-Translation And Knowledge Distillation

Back-translation (Sennrich et al., 2016a) is a popular data augmentation method to improve the performance of machine translation models. We use iterative back-translation(Hoang et al., 2018) based on the in-domain monolingual data to alleviate the domain adaptation problem (Zhang et al., 2020). In addition to use pseudo data directly, we also try Tagged Back-translation (Caswell et al., 2019) in the EN→HR direction. Based on iterative back-translation, we utilize iterative knowledge distillation, which iteratively transforms knowledge (Zhou et al., 2021) from an ensemble model to sub-models based on sequential knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016). We use the following steps for iterative back-translation and knowledge distillation:

1. Select the good quality monolingual data from the source language, filter the data closest to the single domain by XenC toolkit, and obtain bilingual pseudo-data by a forward translation.
2. Filter the data, mix the pseudo data with the training set, and train the back translation model.
3. Search for the best ensemble model combination among all existing models.
4. Use the ensemble model to translate the filtered monolingual data of the target language, and obtain the pseudo data.

We use the `newstest2021` to evaluate our model performance, and repeat steps 1-3(BT) or 2-4(KD) of the above process until the model performance no longer improves[2]. When performing steps 1

[2] It is worth noticing that we do a set of KD after a set of BT, these two methods are combined sequentially

and 4, we use various decoding methods, including beam search, Top-K, and Top-P. In the tasks of ZH→EN, EN→HR, the ratio of raw bilingual data to pseudo data in the training set was about 2 : 1. In the EN↔LIV tasks, the size of pseudo data is much larger than the raw bilingual data.

2.4 Model Ensemble

The ensemble model can significantly improve the translation quality by considering the output of every single model. We search for the model ensemble combined with the highest BLEU score on the `newstest2021` and use the model ensemble repeatedly in knowledge distillation, back-translation, and fine-tuning. This ensures that we can obtain the optimal models at every stage.

2.5 Fine-tuning

A model trained on a large amount of data may not outperform a model trained on a small amount of in-domain data (Zhou et al., 2021). This phenomenon indicates a mismatch between the domain of the training set and the test set, which becomes an obstacle to performance improvement. For a specific domain, we adjust the size of the training datasets that are more focused on a single domain. However, We find it hard to separate bilingual data into multiple domains. In the case that the training set domain is inseparable, fine-tuning by domain is a reasonable way.

Fine-tuning the model with in-domain data is an effective way to alleviate the domain mismatch (Luong and Manning, 2015; Zeng et al., 2021; Tran et al., 2021). In the ZH→EN direction, we split the test set into four domains according to the domain label in the test set and fine-tune the model in the single domain for each of the four domains.

Take the news domain as an example, and fine-tuning process consists of the following three steps:

1. Translate sentences in the news domain to generate pseudo data by the best ensemble model on `newstest2021`.

2. Fine-tune all sub-models in the ensemble model with pseudo-data, `newstest2020`, and `newstest2021`.

3. Based on the data mentioned in the previous step and `test2022`, we utilize the scheduling sampling strategy (Liu et al., 2021) for fine-tuning further.

For the other three domains, we do not use Step 2 because we do not have any other in-domain data.

2.6 Post Editing

Post editing is a way to correct significant errors in the model translation. In all directions, we insist on using common rules to correct significant errors in the model translation. The errors include:

- Misalignment of symbols and emoji between source and target languages.

- The unnecessary space between Url, HTML, and the text in parenthesis.

In the final submission, this process corrects approximately 2% of all tokens in the test set (most of them are symbols such as extra Spaces between characters).

3 Experiment

3.1 Experiment Settings

The implementation of our models was based on `fairseq` (Ott et al., 2019), and the total data we used were shown in Table 3. In the ZH→EN direction, All models were trained on 8 RTX 2080Ti GPUs, and all other direction models were trained on 4 RTX 3090 GPUs. We used Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.997$ during training. Except for the base model, all of our models adopted the pre-norm structure (Wang et al., 2019). Following the idea of the work (Wang et al., 2019), we adopted the deep and wide model to increase the model capacity (Zhou et al., 2021; Wang et al., 2019). Under the GPU memory constraint, we accumulated the gradient four times and set the batch size to 2048 tokens.

For the deep model, we trained the model for 15 epochs at most. We set max learning rate = 0.002 and warmup step = 8000 for all deep models. All dropout probabilities were 0.1. Meanwhile, we also used FP16 to accelerate the training process. All experiments were evaluated on `newstest2021` using `SacreBLEU` (Post, 2018) in the EN→HR and the EN↔LIV directions. In the ZH→EN direction, we used `multi-bleu.perl`[3]. At last, we introduced a patience factor during decoding, which provided a more flexible decoding depth (Kasai et al., 2022). However, this method led to a significantly slower decoding speed. So we only applied this method to generate the final output.

EN→HR	46M	5M	20M
EN↔LIV	600	0.15M	0.04M

Table 3: The sentences we use in each direction after filtering(The M stands for million).

3.2 ZH→EN

For the ZH↔EN tasks, we only submit in the ZH→EN direction. We filter out the part of data from ParaCrawl, News Commentary V16, WikiMatrix, UN Parallel Corpus V1.0, and the CCMT Corpus as the training set. We use the filtering rules and XenC mentioned above for data filtering. We end up with 12 million raw bilingual data as the training set.

Regarding the multi-domain adaptation, we try an unsupervised data clustering method that uses the pre-trained model's hidden state to do domain classification in the training set. We also use TF-IDF to select keywords from the test set to represent each domain and then use these keywords to select in-domain sentences from constrained data. Unfortunately, the aforementioned methods show poor performance except in the news domain. We find no significant domain difference between the constrained bilingual data and constrained monolingual data we used.

Based on the training set, we train several deep models mentioned above. We use `newstest2020` as the valid set and `newstest2021` as the test set to modify the hyper-parameters and find the optimal ensemble combination. In addition, we also realize a multi-domain translation model which introduces layer-wise Domain Mixing into the vanilla Transformer. However, the model performs poorly on the inseparable domain data, so it is not included in our model ensemble.

For the first round of back-translation, we filter multiple groups' English monolingual data from the News crawl, News discussions, Europarl v10, News Commentary, Common Crawl, and Leipzig Corpora. The amount of data is about 4 million to 8 million sentences. We use the best ensemble model to translate monolingual data with Beam Search, Top-K, and Top-P decoding. By directly concatenating the raw training and pseudo data, we fine-tune the existing model and achieve +0.85 BLEU improvement after the first back-translation iteration, then achieve +0.59 BLEU improvement after the second back-translation iteration.

For knowledge distillation, we filter 3 million monolingual data from News crawl, News Commentary, Common Crawl, Extended Common Crawl, and Leipzig Corpora. We use the best ensemble model to translate the monolingual and obtain the pseudo data, and then fine-tune each sub-model in the ensemble model. We obtain the improvement of 0.16 BLEU points. We select the best four models to construct the ensemble model every time during back-translation and knowledge distillation in both directions.

For fine-tuning, we first do fine-tuning on the news domain to search the optimal hypo-parameters. We use `newstest2019`, `newstest2020` in both ZH→EN and EN→ZH directions as the training set, and obtain the optimal learning rate of 0.001 on `newstest2021`. We achieve +0.93 BLEU improvement in the ZH→EN direction. Then we add `newstest2021` to the training set for fine-tuning. In order to improve the performance of the model in a single domain, we divide the `test2022` into five domains according to the domain labels: news, social, conversational, e-commerce, and biomedical. Finally, we do domain adaptation separately in four domains except biomedical by fine-tuning the model with scheduling sampling.

At last, we use four single-domain models to generate translation in every single domain and use post-processing methods to correct the error in the translation, which brings us +0.81 BLEU improvement in the ZH→EN direction. Our experimental results are shown in Table 4.

3.3 EN→HR

For the EN→HR tasks, we choose ParaCrawl v9, Tilde MODEL corpus, WikiMatrix, and OPUS total of four parallel data corpora of about 90M. We choose all of the News Crawl and Leipzig Corpora for the Croatian monolingual data of about 20M. In order to strengthen the generalization of the model in the social, conversational, and e-commerce domains, we choose the Web and Wikipedia parts from Leipzig Corpora about 10M for the English monolingual data to distill our models.

In addition to the common data filtering process, we calculate the Levenshtein ratio of two adjacent sentences from sorted sentences to remove duplication sentences whose Levenshtein ratio are not less than 0.85. After the data filtering, about 46M sentence pairs are left to build our system. Additionally, we use a shared vocabulary and set the merge operations of BPE to 32K.

Since the domain of the official development set focuses on e-commerce and reviews, we make a general domain test set by ourselves to evaluate the model generalization ability better. To use the Croatian monolingual data, we implement tagged back-translation, which brings us +0.35 BLEU improvement on the official development set and +0.5 BLEU improvement on our test set. We also implement knowledge distillation to use English monolingual data, which brings us +0.3 BLEU improvement on the official development set and +0.14 BLEU improvement on our test set.

We use XenC to select 5M sentence pairs similar to the official development set from the original training set and then fine-tune each model for several epochs. However, we find that not only fine-tuning significantly reduces the model's generalization, but also has a slightly better performance on the official development set and significantly worse performance on our test set. Finally, we put all models together to search for the best ensemble greedily. This method brings us +0.51 BLEU improvement on the official development set and +0.25 BLEU improvement on our test set.

During post-processing, we use rules to adjust the order of punctuation, case inconsistencies and remove some extra spaces, which brings us +0.43 BLEU improvement on the official development set.

3.4 EN↔LIV

For the EN↔LIV tasks, we create a many-to-many multilingual submission for WMT2022. The multilingual submission includes seven language directions, which are CS→EN, ET→EN, LV→EN, EN↔LIV, ET→LIV, and LV→LIV. For CS→EN , we only use ParaCrawl v9 dataset and obtain 50M parallel data after cleaning. After the data filtering, we sample the top 10M data according to a language model trained with CS→EN data. For ET→EN, LV→EN, EN↔LIV, ET→LIV, and LV→LIV directions, we only use OPUS liv4ever v1 dataset, separately obtaining 956, 997, 540, 11420, 10786 parallel data after cleaning. We use the valid set and test set in OPUS liv4ever v1 data set as our valid set and test set. It is worth noting that we delete the same sentences in the test set and the train set.

We use a combination of multiple language directions to train the baseline model, including many-to-many and many-to-one, and find that models trained by all language directions data and many-to-many is 1 BLEU point higher on average than the model trained by several language directions data or many-to-one in the test set. We find that data in different language directions can provide semantic help to EN↔LIV model because CS, LV, ET and LIV are similar languages. So, we select all language directions data and many-to-many to train our model.

We also use pre-trained model for language modeling. Since the constrained track, we choose the AB-Net (Guo et al., 2020) model whose encoder and decoder are initialized with mBERT. However, the performance of AB-Net model was lower than that of the baseline model, so it is not included in our final submission results. The poor performance may be due that: first, the pre-trained model doesn't contain LIV, and second, the parallel data of EN↔LIV is too scarce. This leads to a big challenge to transform the knowledge of the pre-trained model into the EN↔LIV translation model.

Due to the lack of EN↔LIV parallel data, the model cannot capture the alignment information at the word level. Therefore, we make a parallel

System	ZH→EN	EN→HR	EN→LIV	LIV→EN
Baseline	24.27	31.28	4.1	6.57
Deep model	27.2	32.68	5.66	8.79
+ Dict	–	–	8.16	13.79
+ Iteratively BT	28.64	33.03	–	–
+ Iteratively KD	28.8	33.33	8.96	15.99
+ Fine-tuning	29.73	–	10.26	16.89
+ Ensemble	-	33.84	10.48	16.95
+ Post edit	30.54	34.27	–	–

Table 4: BLEU evaluation results on the WMT 2021 ZH→EN, EN↔LIV test sets and WMT 2021 EN→HR development sets.

dictionary of EN↔LIV. First, we use fast_align [4] tool to align the words on the EN↔LIV dataset, and then manually check and modify it. Finally, we obtain a parallel dictionary of EN↔LIV with a dictionary size of 3127. We mix the parallel dictionary and parallel data of EN↔LIV to obtain new parallel data. Then, we train the model by new parallel data and bring us +5 BLEU improvement in the LIV→EN direction and +2.5 BLEU improvement in the EN→LIV direction.

We also use iterative back-translation and iterative knowledge distillation to enhance the model. Since the many-to-many method, the back-translation implemented in the LIV→EN direction is the same as the knowledge distillation in the EN→LIV direction. During the back-translation on the EN→LIV direction, we use 40000 LIV monolingual data from OPUS liv4ever v1 data set. And then during the knowledge distillation on the EN→LIV direction, we use the test set in OPUS liv4ever v1 as in-domain data, and we use the XenC tool to sample 150000 EN monolingual data from Europarl v10 based on in-domain data. We generate pseudo data by using both post-ensemble and ensemble methods. We obtain the improvement of 2.2 BLEU points and 0.8 BLEU points in the back-translation (knowledge distillation) in LIV→EN and EN→LIV. After KD, we use the OPUS liv4ever v1 valid set to fine-tune our models for five epochs with the 0.0003 learning rate and obtain +0.9 and +1.3 BLEU improvement in the LIV→EN and EN→LIV directions.

3.5 Submission Results

The results of our best submissions in four directions this year are shown in Table 5. In the EN→HR direction, our system performed well trained on large amounts of bilingual data. In the EN↔LIV direction, our multilingual model performance is better than the model initialized by the pre-trained model(e.g., mBERT), indicating that the multilingual model has potential in the low resource language. In the ZH→EN direction, KD is not performing well enough in `newstest2021` as usual. On the one hand, this may be related to our data filtering method and the domain changes on the test set; on the other hand, it may be related to our stronger deep model.

Direction	Submission
ZH→EN	26.2
EN→HR	18.1
EN→LIV	12.3
LIV→EN	13.0

Table 5: Our final submission results in four directions.

4 Conclusion

This paper introduces our submissions on WMT22 in four directions. We train our system with constrained data in all directions. The system is constituted by the ensemble model based on multiple deep models.

For training data, we use a softer data filtering method to obtain more data and make the model more robust in the general domain. Based on this data, model performance is better than our last year's systems. We use iterative back-translation and knowledge distillation methods which have been proven to be very effective in the past. In addition, fine-tuning using both normal training and scheduling sampling also achieves good results.

In the ZH→EN direction, we mainly build the news domain translation model. Also, we try the multi-domain data clustering method and

[4] https://github.com/clab/fast_align

multi-domain adaptation method to build the multi-domain model. However, because the sentences in constrained data have no noticeable domain difference, the performance of the above method is not satisfactory. In the EN↔LIV direction, we try the multilingual model and initialization method, which initialize the translation model with the pre-trained model. We find that the multilingual model show more considerable potential than the model initialized with mBERT, even under minimal data.

Abstract

In recent years, large multilingual pre-trained neural machine translation model research has grown and it is common for these models to be publicly available for usage and fine-tuning. Low-resource languages benefit from the pre-trained models, because of knowledge transfer from high- to medium-resource languages. The recently available M2M-100 model is our starting point for cross-lingual transfer learning to Finno-Ugric languages, like Livonian. We participate in the WMT22 General Machine Translation task, where we focus on the English-Livonian language pair. We leverage data from other Finno-Ugric languages and through that, we achieve high scores for English-Livonian translation directions. Overall, instead of training a model from scratch, we use transfer learning and back-translation as the main methods and fine-tune a publicly available pre-trained model. This in turn reduces the cost and duration of training high-quality multilingual neural machine translation models.

1 Introduction

We participate in the WMT 2022 General Machine Translation shared task where we submit a system for English-Livonian and Livonian-English translation directions. Our system is trained in the unconstrained setting utilizing data from other languages that are all in a way related to Livonian.

Recently, the development of large multilingual models has been increasing (Johnson et al., 2017; Gu et al., 2018; Fan et al., 2021; NLLB Team et al., 2022) and thus there are multiple pre-trained multilingual models available for further fine-tuning to a specific task. Fine-tuning these models on in-domain data saves time and computational costs by not having to train a multilingual model from scratch. We utilize the M2M-100 multilingual pre-trained neural machine translation (NMT) model (Fan et al., 2021) and do cross-lingual transfer learning to low-resource language pairs from the Finno-Ugric language family, including the Livonian language. We further improve our model with two back-translation iterations and a final fine-tuning on languages that have available original parallel data paired with Livonian.

The languages we use to support the English (en)-Livonian (liv) directions are from the Finno-Ugric language family or geographically close to that family of languages: Finnish (fi), Estonian (et), Latvian (lv), Norwegian (no), Võro (vro), North Sami (sme), South Sami (sma), Inari Sami (smn), Skolt Sami (sms), Lule Sami (smj).

The structure of the article consists of giving insight into the related work in the field of low-resource NMT and from the Finno-Ugric language family perspective in Section 2, the description of data in Section 3, the overview of our system architecture and training methods in Section 4, description of experiments in Section 5 and the results in Section 6.

2 Related work

2.1 Low-resource setting

There have been a lot of efforts in trying to achieve high-quality translation for low-resource languages in order for them to catch up with high- and medium-resource languages. The main benefits seem to come from performing transfer learning to low-resource languages with previous knowledge acquired from a high-resource language (Gu et al., 2018).

Another aspect is data augmentation. Commonly, low-resource languages have a lot more monolingual data available than parallel data, which enables producing synthetic parallel samples that have been shown to improve the accuracy of translation (Sennrich and Zhang, 2019).

For the Finno-Ugric languages, in Rikters et al. (2018), they note that in efforts of achieving better translation quality for Estonian, training a multi-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 375 - 380
December 7-8, 2022 ©2022 Association for Computational Linguistics

lingual model gets the best result. It usually helps even more if the high- or medium-resourced languages in the mix during training are closely related to the low-resource languages as shown in Tars et al. (2021). In Kocmi and Bojar (2018), the authors proved transfer learning to be very beneficial for languages with low amounts of parallel resources. However, in some cases, they saw more improvements when the high-resource language was not related to the low-resource language.

2.2 M2M-100

M2M-100 is a massively multilingual pre-trained machine translation model featuring many-to-many translations between 100 languages (Fan et al., 2021). It was trained on 7.5 billion parallel sentence pairs which, unlike datasets for many previous approaches, were chosen to make the dataset non-English-Centric. Fan et al. (2021) were able to compose the non-English-Centric training dataset through the use of bitext mining and back-translation. The improvement of M2M-100 over previous models is especially visible in non-English directions and low-resource languages. The vast amount of training data, many supported languages, and promising results reported by Fan et al. (2021) give us reason to believe that M2M-100 would be also a good starting point for training a Finno-Ugric system.

3 Data

3.1 Additional languages

We did not limit ourselves to only English-Livonian training data, because the amount of parallel data for that language pair seemed too scarce to train a quality machine translation system. Instead, we decided to leverage our previous research into Finno-Ugric languages (Tars et al., 2021) and include the language pairs that are closely related to Livonian grammatically as well as geographically.

We added four languages that were high- or medium-resource: Estonian, Finnish, Latvian, Norwegian. The aim of including these languages was for them to aid the low-resource Finno-Ugric languages in the training process. The low-resource languages that we included were: Võro, North Sami, South Sami, Inari Sami, Skolt Sami, Lule Sami.

As Livonian has historically been spoken mainly in the areas that are nowadays Latvia, its language has shaped Livonian noticeably, even though Latvian itself is part of the separate Baltic branch of languages. Multiple low-resource languages that we also included are Sami languages, which are mainly spoken in the areas of Norway, Sweden and Finland. Most of the parallel data available for Sami languages is paired with either Finnish or Norwegian. Norwegian is not part of the Finno-Ugric language family, but as was the case for Latvian, it is spoken in the same area as some of the Sami languages and has influenced them over time, for example sharing some orthographic symbols in the vocabulary.

3.2 Pre-processing and filtering

The data not provided by the shared task was collected from various openly available sources, such as META-SHARE[1] and translation memory compiled by the Arctic University of Norway[2]. Further details about the data sources are described in Tars et al. (2021). We compiled all of the filtered parallel data and the monolingual data and publish it on our HuggingFace page [3].

Following the collection phase, we applied multiple pre-processing and filtering heuristics to the parallel data, as well as deduplicated the whole dataset. We normalized punctuation and detokenized the data with the help of Moses scripts, however, we modified the normalization script for it to be more applicable to Finno-Ugric languages[4]. Detokenization language code defaulted to English if the script did not recognize the language code of a low-resource language. Filtering and whitespace normalization was done with the OpusFilter tool (Aulamo et al., 2020). We provide a list of filters used:

- maximum segment length: 1000 characters or 400 words
- maximum word length: 50 characters
- source and target segment length difference: max 3 times
- ratio of numeric characters in segment: 0.5 or less

lang-pair	et-vro	fi-sme	fi-sma	fi-smn	fi-sms	no-sma	no-sme	no-smj	sme-sma	sme-smj	sme-smn	en-liv	et-liv	lv-liv
filtered	29 775	62 837	2766	9459	2708	15 702	195 970	11 627	19 963	14 985	894	280	12 887	10 763

Table 1: Parallel data numbers after filtering (in sentence pairs).

language	vro	sma	sme	sms	smn	smj	liv
nr of segments	162 807	55 088	33 964	76 685	122 916	128 180	40 329

Table 2: Monolingual data numbers.

- ratio of alphabetic characters in latin alphabet: 1
- ratio of alphabetic characters in segment: 0.75 or more
- ratio of similar numerals between segments, with zeros removed: 0.5 or more

Some of the values are default from OpusFilter, but others had to be tuned to filter out the noisy training samples that were left undetected with the default parameters. The data numbers of all the parallel data for all of the translation directions left after filtering can be seen in Table 1. Additionally, we sampled 20 000 segments from corpora available in OPUS (Tiedemann, 2012) for each language pair between high- to medium-resource languages (et, en, lv, no, fi).

3.3 Monolingual data

We also gathered monolingual data for all the languages involved. The monolingual data for high- and medium-resourced languages was acquired from previously available WMT sources. For the low-resource languages, the data was scraped from various files from the web, that were collected either by the Arctic University of Norway or ourselves.

We sampled 500 000 random segments for all of the high- to medium-resource languages from publicly available data (et, en, lv, no, fi). The amounts of monolingual data for low-resource languages can be seen in Table 2. No filtering was done to the monolingual data, but the data segments all went through the same detokenization and normalization scripts that were applied to parallel data. After the back-translation iterations explained in Section 4.2, the synthetic parallel samples were also not filtered.

For the English-Livonian directions, the only parallel and monolingual data used was the data provided by the WMT.

3.4 Evaluation benchmarks

In order to evaluate the multiple translation directions we had other than English-Livonian, we created new test sets[5] for them, because there are no publicly available benchmarks for translation directions like Finnish-Inari Sami, for example. The test sets are composed of held-out data from the parallel datasets. For all the language pairs containing at least one of the low-resource languages, we extracted 500 sentences for evaluation and 200 sentences for validation.

4 System overview

4.1 M2M-100 settings

Our final system builds on the large pre-trained multilingual neural machine translation model M2M-100. Livonian along with other low-resource Finno-Ugric languages were not part of the training process of M2M-100. We use the HuggingFace implementation of M2M-100[6]. Fine-tuning this model for previously unseen languages requires introducing new symbols to the vocabulary and increasing the embedding matrix. We created scripts[7] that allow expanding the embedding matrix of a pre-trained model and thus make it possible to do cross-lingual transfer learning.

4.2 Stages of training

This section describes the training of our final system. The first stage of transfer learning used all of the original Finno-Ugric parallel data that we had. We decided to go with the M2M-100's 1.2 billion parameter model (1.2B) as our starting point because our previous experiments showed that it improves more than the smaller, 418 million parameter model (418M) on the data that we have (Tars et al., 2022).

[5] https://huggingface.co/datasets/tartuNLP/finno-ugric-benchmark

[6] https://huggingface.co/docs/transformers/model_doc/m2m_100

[7] https://github.com/TartuNLP/m2m-100-finetune

After that, we performed the first iteration of back-translation with all of the monolingual data. Combining the original parallel data and the synthetic data, we fine-tuned the M2M-100 1.2B model again and performed the second iteration of back-translation with the newly fine-tuned model. The monolingual data stayed the same.

For the next step we went back to do transfer learning from the beginning on the 1.2B model, but this time the data we used consisted of the original parallel data and the data produced in the second iteration of back-translation, leaving the data from the first iteration out. Finally, we fine-tuned the model on original parallel data for language pairs between `en-liv-et-lv`.

5 Experiments

5.1 Experimental settings

All our systems, including the final system, were trained on one Tesla A100 GPU with 40GB vRAM. Our experiments were done on two versions of the M2M-100 model: 418M model and 1.2B model. The learning rate was initialized with the default value from HuggingFace code. Batch size was 12 with gradient accumulation steps set to 8.

5.2 Different experiments

The size of the model was one aspect of experimentation that we looked into. As smaller models are easier and quicker to fine-tune and deploy, comparing the 418M and 1.2B models seemed necessary. 1.2B model has more parameters, but the intuition was that maybe the 418M model is also big enough for this specific dataset, because it is relatively small.

The main approach to enhance `en-liv` results was leveraging information from other Finno-Ugric languages. We trained models on all the Finno-Ugric language data described, as well as dividing the languages into even smaller groupings, as described in Tars et al. (2022). Subsequently, we performed additional experiments to see whether the added languages really help the Livonian language.

We repeated the stages of training described in Section 4.2 but with different-sized models and with a smaller dataset, consisting only of languages paired with Livonian.

	COMET-A ↓	ChrF-all
`en-liv`	-36.8	39.2
`liv-en`	-5.8	53.5

Table 3: Automatic metric results of our primary system on WMT22 test set.

6 Results

6.1 Automatic metrics

According to the automatic metric results, our system performs the best in the Livonian-English translation direction and achieves second place in the English-Livonian direction. The metrics that were used were COMET and ChrF. The results of the automatic evaluation can be seen in Table 3.

During the development period, we measured most of our additional experiments on BLEU. The results of those experiments compared to the earlier results for English-Livonian translation directions can be seen in Table 4. For further understanding of where the gain in performance happened, we describe the results of intermediate models that were trained before arriving at the final system.

Firstly, we can observe that `en-liv` results are about half of the `liv-en` results and that the BLEU score improvements come from different techniques for either of the translation directions. For `en-liv`, the main source of improvement is the last stage of fine-tuning the model on the original parallel `en-et-lv-liv` data. For `liv-en` however, the biggest gain happens with back-translation. This could be explained by the amount of monolingual data, as Livonian had only about 40 000 segments but for English, we sampled 500 000 segments.

Another aspect we can point out is the relatively small difference between the smaller (418M) and the larger (1.2B) model results. The 1.2B model is better at every stage as expected, but considering how much more computational cost and deployment resources the larger model requires, the trade-off in quality might be tolerable.

Lastly, compared to the previous best results reported by Rikters et al. (2022), our models surpass those results by about 4 BLEU for `en-liv` and 12 BLEU for `liv-en`.

6.2 Results for other language pairs

Additionally, we report results on our held-out test set described in Section 3.4 for low-resource language pairs that were a part of our final system development. The results can be seen in Table

	`en-liv`	`liv-en`
1.2B (baseline)	10.15	18.92
+ bt1	11.24	28.67
+ bt2	12.16	29.37
+ tuned on `liv`	**15.19**	**31.06**
+ bt1 only-`liv`	10.66	27.88
+ bt2 only-`liv`	11.21	29.85
+ tuned on `liv`	11.56	30.33
Rikters et al., 2022	*11.03*	*19.01*

	`en-liv`	`liv-en`
418M (baseline)	10.29	15.78
+ bt1	11.25	27.52
+ bt2	10.62	27.38
+ tuned on `liv`	**12.83**	27.23
+ bt1 only-`liv`	11.39	27.74
+ bt2 only-`liv`	11.63	28.81
+ tuned on `liv`	11.53	**29.27**
	11.03	*19.01*

Table 4: Experiment results on BLEU. "1.2B" and "418M" refer to models trained with all original parallel data. "bt1" is trained on parallel + first back-translation iteration data, "bt2" on parallel + second back-translation iteration data. "only-`liv`" - only data between `et-en-lv-liv` languages was used for training. "tuned on `liv`" refers to the "bt2" model that was tuned on `et-en-lv-liv` original parallel data. Last row represents previously best results for `en-liv-en` by Rikters et al. (2022).

5 and Table 6. The language pairs were evaluated on the final system and although the final system was chosen on `en-liv-en` validation data, we see good overall results for other low-resource language pairs as well. However, the results in Table 5 are significantly lower than the results reported in Tars et al. (2022) on the same test data. This is probably caused by the fact that as the last training stage, the final system was fine-tuned only on `et-en-lv-liv` original parallel data.

For `et-liv-et` and `lv-liv-lv` directions, however, we report new state-of-the-art results on the test data that was also used in Rikters et al. (2022).

7 Conclusion

Large pre-trained multilingual neural machine translation models prove to be beneficial to low-resource Finno-Ugric languages, such as Livonian. We placed in the top 2 for the English-Livonian language pair in the WMT22 General Machine Translation shared task. Training in an unconstrained setting gets reasonable and good-quality results, especially when using languages close to Livonian to help achieve a better translation quality. In the future, we plan to test additional and more recent pre-trained multilingual models as a starting point for cross-lingual transfer learning and add more low-resource Finno-Ugric languages into the dataset.

Limitations

The 1.2B M2M-100 model has a lot of parameters which makes deploying this model very costly and difficult because it needs a lot of memory and is computationally unfeasible. In turn, it also makes the training somewhat slower in terms of loading the model parameters and updating them. We are working on trying to reduce the vocabulary and number of parameters, by removing parts of the vocabulary not necessary for Finno-Ugric languages. Another thing we left out of the process was filtering monolingual and synthetic data, which might be a useful addition to the pre-processing pipeline.

Abstract

Previous works mostly focus on either multilingual or multi-domain aspects of neural machine translation (NMT). This paper investigates whether the domain information can be transferred across languages on the composition of multi-domain and multilingual NMT, particularly for the incomplete data condition where in-domain bitext is missing for some language pairs. Our results in the curated leave-one-domain-out experiments show that multi-domain multilingual (MDML) NMT can boost zero-shot translation performance up to +10 gains on BLEU, as well as aid the generalisation of multi-domain NMT to the missing domain. We also explore strategies for effective integration of multilingual and multi-domain NMT, including language and domain tag combination and auxiliary task training. We find that learning domain-aware representations and adding target-language tags to the encoder leads to effective MDML-NMT.

1 Introduction

Multilingual NMT (MNMT), which enables a single model to support translation across multiple directions, has attracted a lot of interest both in the research community and industry. The gap between MNMT and bilingual counterparts has been reduced significantly, and even for some settings, it has been shown to surpass bilingual NMT (Tran et al., 2021). MNMT enables knowledge sharing among languages, and reduces model training, deployment, and maintenance costs. On the other hand, multi-domain NMT aims to build robust NMT models, providing high-quality translation on diverse domains. While multilingual and multi-domain NMT are highly appealing in practice, they are often studied separately.

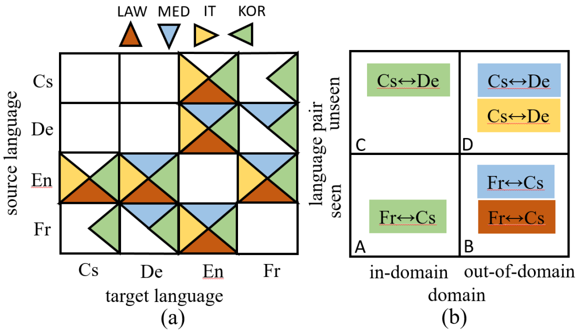

Figure 1: An example of the multi-domain multilingual incomplete data condition (best seen in colours). (a) The colour indicates the availability of bitext in the corresponding domain for each language. (b) Domain and language-pair matrix for the data condition in (a).

To accommodate the domain aspect, previous MNMT works focus on learning a domain-specific MNMT by finetuning a general NMT model on the domain of interest (Tran et al., 2021; Bérard et al., 2020). Recently, Cooper Stickland et al. (2021) propose to unify multilingual and multi-domain NMT into a holistic system by stacking language-specific and domain-specific adapters with a two-phase training process. Thanks to the plug-and-play ability of adapters, their system can handle translation across multiple languages and support multiple domains. However, as each domain adapter is learned independently, their adapter-based model lacks the ability of effective knowledge sharing among domains.

In this paper, we take a step further toward unifying multilingual and multi-domain NMT into a single setting and model, *i.e.,* multi-domain multilingual NMT (MDML-NMT), and enable effective knowledge sharing across both domains and languages. Unlike the *complete* data assumption in the multi-domain single language-pair setting where training data is available in all domains, we assume the existence of bitext in all domains for only a subset of language-pairs, as illustrated in Figure 1(a). In fact, it is highly improbable to obtain in-domain bitext for all domains and all language pairs in

[*]Work done while doing internship at eBay Inc.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 381 - 396
December 7-8, 2022 ©2022 Association for Computational Linguistics

many real-life settings. Depending on the availability of parallel data, we categorise a translation task from a source to a target language into four categories based on the following dimensions:

- *in-domain*/*out-of-domain*, wrt to the domain of interest, and
- *seen*/*unseen*, wrt to the translation direction during training.

Please note the domain and language-pair matrix in Figure 1(b). In this figure, parallel data available in the training set specifies the group A, the *in-domain seen* tasks. Given this training dataset, most MNMT research focuses on cross-lingual transfer to *in-domain unseen* translation tasks (A→C), while the studies on multi-domain NMT and domain adaptation seek to generalise to *out-of-domain seen* translation tasks (A→B). Integrating domain and language aspects in the incomplete data condition gives rise to an interesting and more challenging setting that transfers to *out-of-domain unseen* translation tasks (A→D). We hypothesise that the out-of-domain "seen and unseen" translation tasks (A→B+D) can benefit from the in-domain translation tasks if there exists the domain transfer across languages in MDML-NMT.

Specifically, we ask the following research questions: (1) Do out-of-domain translation tasks benefit from the out-of-domain and in-domain bitext in other seen translation pairs? and (2) What is effective method to handle the composition of domains and languages? Furthermore, beyond the cross-lingual transfer (A→C) and the out-of-domain generalisation (A→B), we also consider the challenging setting where the translation direction of interest may not have any bitext in any domain, i.e. the zero-shot setting (A→D).

In general, we can vary the degree of domain transfer based on the number of domains in which parallel data for a translation task is available. Combining with the number of language pairs of interest, there are large numbers of incomplete data conditions, even for our toy examples in Figure 1. In this study, we assume the highest degree of domain transfer and carefully design controlled experiments where one domain is left out for some language pairs (Table 1). We then examine the potential of MDML-NMT on this incomplete data condition. We also explore training strategies for effective integration of multi-domain and multilingual NMT, mainly on (i) how to combine the language and domain tags, and (ii) using auxiliary task training to learn effective representations. Our contributions are as follows:

	LAW	IT	KORAN	MED	SUB
En-Fr	✔	✔	✔	✔	✔
En-De	✔	✔	✔	✔	✔
De-Fr	✔	✔	✔	✔	✔
En-Cs	✗	✔	✔	✔	✔
En-Pl	✗	✔	✔	✔	✔

Table 1: Illustration of leave-one-out LAW experiment setting. ✗, ✔describes whether there is bitext in the corresponding domain for the given language pairs.

- We investigate effective strategies to jointly learn multi-domain and multilingual NMT models under the incomplete data condition.
- Our empirical results show that MDML-NMT model can improve translation quality in the zero-shot directions by mitigating the **off-target translation** issue that an MNMT model translates the input sentence to a wrong target language. Additionally, MDML-NMT exhibits domain transfer ability by achieving up to +4 BLEU improvement over the multi-domain NMT on the translation direction where in-domain training data is absent. Thanks to the effective cross-domain and cross-lingual knowledge sharing, MDML-NMT outperforms the adapter-based method (Cooper Stickland et al., 2021) by a large margin in the language-domain zero-shot setting.
- Our study sheds light on effective MDML-NMT training. Our experimental results reveal that: (i) for the domain, it is important to make the encoder domain-aware by either providing the domain tags or training with the auxiliary task; and (ii) for the language, the best practice is to prepend the target language tag to the encoder.

2 Multi-domain Multilingual NMT

In this section, we first provide the necessary background on multilingual NMT (MNMT) and multi-domain NMT individually. We then describe effective modelling approaches for the integration of multi-domain and multilingual NMT (MDML-NMT).

2.1 Multilingual NMT

Given a set of languages L, the primary goal of MNMT is to learn a single NMT model that can handle all translation directions of interest in this set of languages (Dabre et al., 2020). According to the parameter sharing strategy, MNMT can be categorised into: 1) partial parameter sharing (Dong et al., 2015; Firat et al., 2016; Zhang et al., 2021), and 2) full parameter sharing (Ha et al., 2016; Johnson et al., 2017). The latter has been widely adopted because of its simplicity, lightweight, and its zero-shot capability. Thus, we adopt the full parameter sharing strategy in our work.

In the fully parameter-shared MNMT, all parameters of encoders, decoders and attentions are shared across tasks. Special language tags are introduced to indicate the target languages. One can prepend the target language tags to either the source or target sentences. The model is then trained jointly to minimise the negative log-likelihood across all training instances:

$$\mathcal{L}_{\text{ML}}(\boldsymbol{\theta}) := -\sum_{(s,t)\in T}\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{C}_{s,t}} \log P(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta}) \quad (1)$$

where $\boldsymbol{\theta}$ is model parameters, $\mathcal{C}_{s,t}$ denotes a bilingual corpus for the source language s and the target language t, $(\boldsymbol{x},\boldsymbol{y})$ is a pair of parallel sentences in the source and target language, and T denotes the translation tasks for which we have bitext available. Among all possible language pairs $(s,t) \in L \times L$, we often only have access to bilingual data for a subset of them. We denote these pairs as *seen* (observed) translation tasks, and the rest as *unseen* tasks corresponding to the zero-shot setting.

2.2 Multi-domain NMT

Multi-domain NMT aims to handle translation tasks across multiple domains for a given language pair. Similar to MNMT, tagging the training corpus is the most popular approach, where a tag indicates the domain of a sentence pair. We also minimise the negative log-likelihood across all domains to train the model:

$$\mathcal{L}_{\text{MD}}(\boldsymbol{\theta}) := -\sum_{d\in D}\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{C}^{d}_{s,t}} \log P(\boldsymbol{y}|\boldsymbol{x};\boldsymbol{\theta}) \quad (2)$$

where D is the set of domains, and $\mathcal{C}^d_{s,t}$ denotes the parallel bitext in the source language s, target language t, and the domain d.

Apart from tagging, some auxiliary tasks have also been incorporated into the training process. A common practice is the use of domain discrimination, which aims to force the encoder to capture *domain-aware* characteristics (Britz et al., 2017). For this purpose, a domain discriminator is added to the NMT model at training time. The input to the discriminator is the encoder output, and its output predicts the probability of the domain of the source sentence. The discriminator is jointly trained with the NMT model, and is discarded at inference time.

Let $\mathbf{h} = \text{enc}(\boldsymbol{x})$ be the representation of sentence $\boldsymbol{x}$ computed by the mean-pooling over the hidden states of the top layer of the encoder. The training objective for the domain-aware encoder is as follows:

$$\mathcal{L}_{\text{disc}}(\boldsymbol{\theta},\boldsymbol{\psi}) := -\sum_{d\in D}\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{C}^{d}_{s,t}} \log \Pr(d|\mathbf{h};\boldsymbol{\psi}) \quad (3)$$

$$\mathcal{L}_{\text{MD-aware}}(\boldsymbol{\theta},\boldsymbol{\psi}) := \mathcal{L}_{\text{MD}}(\boldsymbol{\theta}) + \lambda\mathcal{L}_{\text{disc}}(\boldsymbol{\theta},\boldsymbol{\psi}) \quad (4)$$

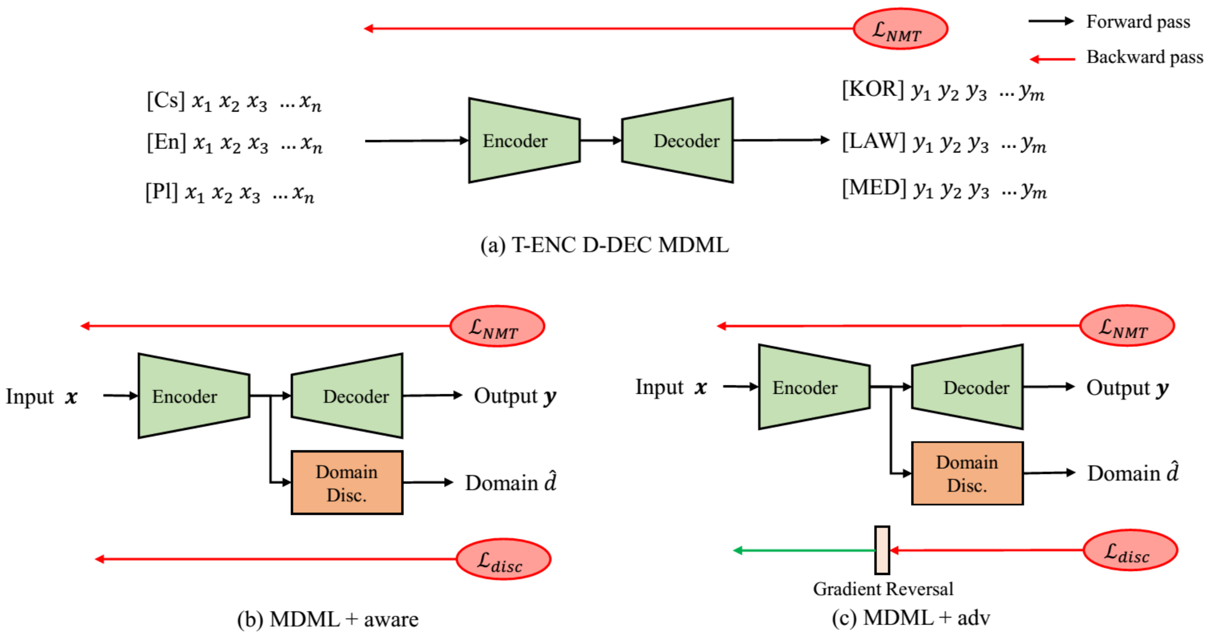
where $\boldsymbol{\psi}$ is the parameter of the domain discriminator classifier, and λ controls the contribution of the domain discriminator into the training objective of the multi-domain NMT model.

Alternatively, one can design an adversarial training objective in order to learn domain-agnostic representations by the encoder. This is achieved by inserting a gradient reversal layer (Ganin and Lempitsky, 2015) between the encoder and the domain discriminator. The gradient reversal layer behaves as an identity layer in the forward pass but reverses the gradient sign during back-propagation. It has the opposite effect on the encoder, forcing it to learn domain-agnostic representations. This encourages the domain specific characteristic to be learned mainly by the decoder of the NMT model.

2.3 Composition of Domains and Languages

In this paper, we explore strategies for composing multi-domain and multilingual NMT. We consider the incomplete multi-domain multilingual data condition where in-domain data may be only available in a subset of language pairs. For example, Table 1 shows one of the data conditions explored in our experiments in Section 3. Given the five language pairs and five domains, we assume that the domain data in some language pairs are missing. Our goal is to investigate effective techniques to train a high-quality MDML-NMT model covering all combinations of domains and language pairs.

Given a specific domain, we define *in-domain languages* as those having data available in the domain as part of some bilingual corpora; the rest



(a) T-ENC D-DEC MDML

(b) MDML + aware

(c) MDML + adv

Figure 2: Illustration of domain and languages composition strategies: (a) prepending domain (D) and target language (T) tag to encoder (ENC) or decoder (DEC). This example shows a T-ENC D-DEC model where the target language tag and domain tag are added to encoder and decoder respectively; (b) combining the tagging method with the domain aware auxiliary task (MDML + aware) to learn domain-aware representation; and (c) combining the tagging method with the domain adversarial auxiliary task (MDML + adv) to learn domain-agnostic representation.

Trans. direction	Eval. domain	MDML task type

En→Cs	LAW	seen in→out
Pl→En	LAW	seen out→in
De→Cs	LAW	unseen (zero-shot) in→out
Cs→De	LAW	unseen (zero-shot) out→in
Pl→Cs	LAW	unseen (zero-shot) out→out

Table 2: Examples of MDML task types in the leave-one-domain-out LAW training scenario of Table 1. Please refer to Table 1 for the in/out and seen/unseen settings.

of the languages are referred to as *out-of-domain languages*. We consider all combinations of in-domain/out-of-domain source/target languages for both seen and unseen translation directions (see examples in Table 2) in Section 3.

We investigate different combinations of the tagging strategy and auxiliary task training to effectively train MDML-NMT models, as shown in Figure 2.

Language and Domain Tags. We explore different ways of injecting the target language tags and domain tags into the translation process. Following the standard convention, we explore inserting the target language tag at the beginning of either the source sentence or the translation. Furthermore, the domain tag can also be added to either the source or the target side.

Auxiliary Task Training. We investigate the effect of encoder-based auxiliary tasks on MDML-NMT. As described in Section 2.2, we consider two types of auxiliary objectives to train encoder which are domain-aware or domain-agnostic. The former aims to amplify the domain-related features, while the latter focuses on the domain invariant representation in the encoder.

3 Experiments

In this section, we evaluate the MDML-NMT approaches and seek to answer the following research questions (**RQs**):

- **RQ1**: *Do out-of-domain translation tasks benefit from the out-of-domain and in-domain bitext in other translation pairs?*

  We explore the benefits of having a single MDML model trained on all available training data from multiple languages and domains over the multi-domain bilingual (MDBL) and the single domain multilingual (SDML) models learned on a subset of training data from a single language pair or domain. We carefully design controlled experiments to build incomplete data conditions and study the translation quality of the unified MDML-NMT model on both seen and unseen (zero-shot) translation directions. We hypothesise that the translation involving the out-of-domain languages can be beneficial from the in-domain languages thanks to the knowledge sharing across domain and languages.

- **RQ2**: *What is effective method to handle composition of domains and languages?*

  We investigate strategies for effective integration of existing multi-domain and multilingual NMT methods, including the use of language and domain tags and auxiliary task training.

3.1 Setup

We describe the experimental setup in this section, and then present our results.

Dataset. We conduct experiments with translation directions among five languages English (En), Czech (Cs), German (De), French (Fr) and Polish (Pl). Following the recipe in Koehn and Knowles (2017), we create five domains: Law (LAW) , IT (IT), Koran (KOR), Medical (MED), and Subtitles (SUB) from OPUS (Tiedemann, 2012). These corpora are deduplicated and randomly selected, from each corpus 2K sentences extracted as the development and test sets in all possible translation pairs. The statistics of the training dataset are reported in Appendix A.

Seen vs Unseen Language Pairs. We categorise the evaluated languages into two groups, high-resource languages including En, De, and Fr, for which bilingual data among these languages is easy to obtain. We also consider low-resource languages, including Cs and Pl, for which only English-centric data is available, resulting in two language pairs. As a result, there are five *seen* language pairs, consisting of ten seen translation directions.[1] There are also five *unseen* language pairs, resulting in ten unseen translation directions; they are the ones for which we do not have any bitext in the dataset.[2]

Leave-one-domain-out (LODO). We curate the incomplete MDML data condition by removing the data of one domain for the translations tasks involving low-resource languages. An example of the leave-one-domain-out data condition is shown in Table 1. In total, there are five LODO conditions, each of which corresponding to removing the bitext of one domain for both En-Cs and En-Pl (*i.e.,* our low-resource language pairs). For each of these LODO conditions, we have five seen language-pairs and five unseen language-pairs, hence a total of 20 translation tasks in both directions.

In the multi-domain NMT literature, this setting is related to domain generalisation which evaluates the NMT model on out-of-domain data in a zero-shot manner. By carefully removing only a specific domain, we would like to examine whether extra data (*i.e.,* the in-domain and out-of-domain data for high-resource languages, and out-of-domain data for low-resource languages) can boost the generalisation of MDML-NMT to the domain of interest.

Models. We use Transformer (Vaswani et al., 2017) as the NMT model architecture and Fairseq implementation (Ott et al., 2019). For all MDML-NMT models, we initialise them with mBART_large (Liu et al., 2020). We describe the model training details in Appendix B.

As described in Section 2.3, our approaches to MDML problem include combining language and domain tags, and adding domain auxiliary task to the standard multilingual NMT objective. In the first approach, the target language tags can be inserted to the source sentence (T-ENC) or the target sentence (T-DEC). The domain tags can also be handled in similar manners denoted as D-ENC and D-DEC respectively. On combining these tags, the language tag always appears first in the sentence. In addition to the domain and language tag combination, we also explore whether learning domain-aware or domain-agnostic representation in the encoder with auxiliary task can aid MDML-NMT performance. Figure 2 summarises the MDML-NMT approaches evaluated in this paper.

We also report the results of the adapter-based domain-specific MNMT, proposed by Cooper Stickland et al. (2021). Language adapters (Bapna and Firat, 2019) are firstly injected to each layer of a pre-trained MNMT model and then trained while freezing the backbone. Then, domain adapters are stacked on top of the language adapters and trained without backpropagating to the MNMT backbone and the language adapters. Since we do not consider any additional parallel

data apart from the multi-domain dataset, we train the MNMT backbone as well as the language and domain adapters using this multi-domain multilingual dataset (instead of Paracrawl) for fair comparison.

Evaluation. We report the detokenised BLEU scores calculated by SacreBLEU (Post, 2018) (Post, 2018) and the micro-average of BLEU score in a group as the measure of overall performance.[3]

3.2 Results and Discussions

Can multilinguality help the multi-domain learning? (MDBL vs. MDML) We first examine the potential of MDML over the counterpart multi-domain NMT model. Table 3 shows the BLEU scores of MDBL and MDML for En→Cs translation on various LODO settings. A breakdown of BLEU scores on leave-out domains is shown in Table 11 in the Appendix C. The MDBL models are trained on all En→Cs bilingual data except of the domain of interest. Within the same tagging method, augmenting the NMT training with the domain auxiliary objectives (*i.e.,* domain-aware and domain-agnostic encoders) enhances the translation performance. The MDML models consistently surpass the corresponding MDBL settings, with an exceptional case, where both domain and language tags are applied to the decoder (*i.e.,* T-Dec D-Dec). This observation suggests there is knowledge sharing from in-domain languages to out-of-domain languages.

Can multi-domain data help multilingual NMT? (SDML vs. MDML) SDML models are domain-specific multilingual NMT models trained on the multilingual dataset in a given domain. As in-domain parallel data is absent for several language pairs, the MDML models are exposed to more seen translation tasks than SDML models thanks to the availability of out-of-domain data. Hence, for a given domain, we divide the evaluation translation tasks into three groups: seen-both, unseen-SDML and unseen-both. The seen-both and unseen-both groups consist of translation directions which are observed and unobserved respectively by both models in training. The unseen-SDML group corresponds to those unseen by SDML, but seen by MDML models. We report the average performance of the MDML and SDML model on the

Table 6: Average BLEU score on leave-out domain for different translation tasks. We categorise 20 translation direction into *seen* where the training data for the translation direction is available, otherwise *unseen*. *in* and *out* show whether the corresponding domain is observed during training or not (see Table 2 for a concrete example). The number in parentheses shows how many translation directions are in the corresponding category. The best score of each column overall and within each tagging group are marked in **bold** and underline respectively.

leave-out domains in Table 4. The detailed results on each leave-out domain can be found in Table 12 in the Appendix C. As expected, SDML works well on the seen directions (seen-both) but behaves badly on the zero-shot settings (unseen-SDML and unseen-both). We speculate it is due to the negative inference among domains. On the other hand, MDML outperforms SDML in unseen-SDML by a large margin thanks to the out-of-domain parallel data. Additionally, leveraging multi-domain data also helps to improve multilingual NMT on unseen-both tasks up to +6 BLEU score on average.

What is an effective method to MDML? We have previously shown the benefits of MDML over multi-domain and multilingual NMT models. The remaining question is how to integrate the multi-domain and multilingual approaches effectively. We report the average BLEU scores of different MDML methods across all five LODO scenarios and 20 translation tasks in Table 5. Similar to the previous observation on En→Cs translation, models with domain discriminator outperform the vanilla MNMT model in all tagging methods. More specifically, the domain-aware MNMT models (+aware) are the winning method in most scenarios. These results emphasise the importance of having domain-aware representation in the encoder. Furthermore, it shows MDML is more effective than the adapter-based approach.

As illustrated in Table 2, translation tasks in MDML setting can be categorised into seen and unseen (zero-shot) tasks involving the in-domain or out-of-domain languages. Table 6 reports the performance of MDML-NMT models in the leave-out domains on different task categories, e.g. Law in the example in Table 1. The results for other domains, i.e. excluding the leave-out domains, can be found in Appendix C. Consistent with previous findings, the domain discriminative mixing methods outperform the other models. While the best multilingual NMT model (MDML T-Enc) performs comparably with other MDML-NMT models on seen translation tasks, the main benefit of MDML-NMT models comes from unseen translation tasks. As expected, for both seen and unseen tasks, the quality of translation when translating into in-domain languages is consistently higher than into out-of-domain languages. Stacking the

Table 7: On-target translation ratio of MDML-NMT models on the seen and unseen translation tasks.

language and domain adapters works particularly well in seen translation direction to in-domain target languages. Aligned with previous findings, the adapter-based method struggles to translate to out-domain target languages due to the unobserved combination of language and domain adapters during training (Cooper Stickland et al., 2021).

4 Analysis

4.1 Domain-specific token generation

In this section, we will look at how well MDML models are in generating domain-specific tokens. We concatenate all training data in a given domain in each language, remove stopwords, and extract the top 1000 domain-specific tokens with TF-IDF. The stopwords for each language are obtained from stopwords-iso[4]. Table 8 reports the F1 score of MDML models in generating leave-out domain-specific tokens. As expected, translation to in-domain languages (in→in, out→in) has a higher F1 score than translation to out-of-domain languages (in→out, out→out). Compared to MDML, both MDML-aware and MDML-adv models are able to generate more domain-specific tokens.

4.2 On-target translation ratio

One challenge of multilingual NMT (MNMT) is the off-target translation in zero-shot direction. Off-target translation is an issue that the MNMT model translates the input sentence to the wrong language, causing low BLEU scores. In this section, we assess the ability to alleviate the off-target issue in MDML models. Table 7 reports the on-target translation ratio of MDML models on seen and unseen translation for different target languages. We detect the language of translated targets using langdetect[5] tool and calculate the on-target translation ratio as the percentage of translated sentences having the target language detected correctly. As expected,

		in→in	in→out	out→in	out→out
T-Enc	MDML	63.22	21.45	35.58	16.42

		0	25	50	75	100

Table 9: On target ratio of T-DEC D-DEC MDML on the leave-out (LO) and other domains. Rows and columns correspond to the source and target languages.

the seen translation tasks have more than 90% sentences in the correct target language, except T-DEC D-DEC models. On the other hand, the unseen tasks suffer from a low ratio, especially for Cs and Pl. We also observe significant improvement from MDML-aware and MDML-adv over the MDML models on unseen translation tasks to Cs and Pl.

Generally, T-DEC D-DEC model always underperforms other models and have a much lower on-target ratio on unseen tasks. Table 9 further confirms this phenomenon on the leave-out domains. While heavily suffering from the off-target issue in the leave-out domains, it has comparable ratios to other methods in other domains on seen tasks En-Pl and En-Cs. One possible explanation is that the combination of the target language and domain tags has never been observed during training for the unseen tasks with out-of-domain languages.

4.3 Language and domain tag contribution

To understand the role of the target and language tags to the generated prediction, we estimate the total contribution of source tokens at each position to the whole target sentence using Layerwise Relevance Propagation (Voita et al., 2021). We filter out the pairs having too short or too long target sentences and compute the contribution to target sentences of length between 10 and 100.

Results of T-ENC D-ENC MDML models on Pl→Cs translation in the leave-out medical domain are shown in Figure 3. The language and domain tag are the first two source tokens in respective order. It can be seen that all models have a similar trend in which the contribution of source tokens decreases toward later positions and suddenly increases at a few last positions. Additionally, the target language tags play an important role in the final prediction of all MDML models. Interestingly, while still having a fairly high contribution compared to other tokens, the domain tag seems less important for the domain adversarial models. It can be explained that the encoder learns to produce domain agnostic representation; hence less depends on the domain tags.

5 Related works

Multilingual NMT. As a remarkable branch of NMT, multilingual NMT (MNMT) has been appealing for its capability of supporting translations among different language pairs. Dong et al. (2015) opened the door to the MNMT by conducting a one-to-many translation. Firat et al. (2016) effectively extend this approach to a many-to-many setting. Since these approaches consider each translation as an independent system, they suffer from two major drawbacks. First, as the parameter size is proportional to the language size, it is not parameter-efficient when scaling to tens or hundreds of languages. In addition, the separate architectures cannot fully benefit from cross-lingual knowledge transfer. Johnson et al. (2017); Ha et al.

(2016) devise a universal MNMT system to alleviate these issues by prepending a target language tag to the inputs and training a shared SEQ2SEQ model on the concatenation of all bitext. However, owing to the negative interference, high-resource languages suffer from translation inferiority, compared to the corresponding bilingual NMT models. As a remedy, Zhang et al. (2021); Kudugunta et al. (2021) leverage a mixture-of-experts design to separate language-specific features from the generic features by incorporating language-specific components into the universal MNMT model. Besides, Bapna and Firat (2019); Zhu et al. (2021) propose to fine-tune a lightweight adapter as a means of compensation for the quality loss caused by the adverse effect.

Multidomain NMT. While both involving training on dataset coming from multiple domains, NMT domain adaption is different from multi-domain NMT. The former aims to transfer the knowledge of out-of-domain data into the in-domain data (Luong and Manning, 2015; Zoph et al., 2016; Freitag and Al-Onaizan, 2016), while the latter focuses on building a system, performing well on multiple domains (Pham et al., 2021). Since lexical and topic variations have been observed in different domains, it is challenging to handle the mixed-domain data with a generic NMT model (Farajian et al., 2017). To operate translation in multiple domains, recent research focuses on exploiting domain-shared and domain-specific knowledge by introducing a domain tag to the source sentence (Kobus et al., 2017), using auxiliary objectives such as domain discrimination loss (Britz et al., 2017; Gu et al., 2019), domain knowledge distillation (Currey et al., 2020), and modifying the architecture to capture this information explicitly (Zeng et al., 2018). Rather than using a heavy domain-specific encoder-decoder architecture, Wang et al. (2020) introduce lightweight domain transformation layers between the shared encoder and decoder.

Multilingual & multi-domain NMT. Previous works have mainly considered multilingual and multi-domain NMT models as two disjoint systems. Until recently, Cooper Stickland et al. (2021) propose to unify these two settings into a holistic system, but focus more on the domain adaptation angle. They investigate the combination of language and domain adapters by superimposing domain adapters on language adapters. They noticed that domain adapters and back-translation could boost the translation quality on the out-of-domain languages. In contrast, our work creatively stitches multilingual and multi-domain NMT together and explores the capability of a cross-lingual domain transfer within a unified model without adaption.

6 Conclusion

We study the problem of MDML-NMT for which a single NMT can support multiple translation directions and domains. We investigate whether the tagging and auxiliary task learning method can be combined for MDML-NMT. Our empirical results reveal a positive transfer from in-domain to out-of-domain languages, especially in the zero-shot scenario. This study provides insights into the synergy of the domain and language aspects of training an MDML-NMT model. The main findings include: (i) it is crucial to make the encoder domain-aware; and (ii) it is best to prepend the target language tag to the encoder in MDML. These findings lay the groundwork for future research in this direction.

B Training Details

For all MDML-NMT models, we initialise them with mBART_large (Liu et al., 2020) and train with mixed-precision training up to 200K update steps (around 13 epochs) using a batch size of 8192 tokens and early stopping on 8 V100 GPUs. The multi-domain NMT (MDBL) is trained in a similar manner, except with the total update steps of 60K which is equivalent to around 30 epochs. We apply Adam with an inverse square root schedule, a linear warmup of 5000 steps and a learning rate of 3e-5. We set dropout and label smoothing with a rate of 0.3 and 0.2. We use temperature-based sampling with $T = 5$ to balance training size between domains and languages (Arivazhagan et al., 2019).

For the NMT model with auxiliary task, the domain discriminator is a 2-layer feed-forward network with hidden size of 1024. We set the mixing hyperparameters λ in Equation 4 to 1, *i.e.,* the domain discriminative loss and NMT loss contributes equally to the training signal.

Followed (Cooper Stickland et al., 2021), we use adapter bottle-neck of 1024 for the adapter-based models. The monolingual language adapters are trained all together on the multi-domain dataset while the NMT backbone are frozen. In contrast, we train domain adapters separately for each domain and build homogeneous batches containing sentences from the same language direction and domain. We also apply domain-adapter dropout (DADrop) where the domain adapters are skipped 20% of time.

C Additional Results

MDBL vs. MDML. Table 11 shows the BLEU scores of different models for En→Cs translation on various LODO settings. Each domain column reports the results corresponding to the LODO setting in which the bitext of that domain is removed.

SDML vs. MDML. We report the performance of the MDML and SDML model on each leave-out domains in Table 12.

MDML Result. The average BLEU scores on each domain across all five LODO scenarios and 20 translation tasks are reported in Table 13. Table 14 reports the performance of MDML-NMT models on other domains (excluding the leave-out domains) on different task categories.

Abstract

This paper describes DUTNLP Lab's submission to the WMT22 General MT Task on four translation directions: English to/from Chinese and English to/from Japanese under the constrained condition. Our primary system are built on several Transformer variants which employ wider FFN layer or deeper encoder layer. The bilingual data are filtered by detailed data pre-processing strategies and four data augmentation methods are combined to enlarge the training data with the provided monolingual data. Several common methods are also employed to further improve the model performance, such as fine-tuning, model ensemble and post-editing. As a result, our constrained systems achieve 29.01, 63.87, 41.84, and 24.82 BLEU scores on Chinese → English, English → Chinese, English → Japanese, and Japanese → English, respectively.

1 Introduction

DUTNLP Lab participates in the WMT22 General MT Task on four translation directions: English ↔ Chinese and English ↔ Japanese. Our translation system is trained on the officially provided bilingual and monolingual data under the constrained condition. Several strategies such as fine-grained data pre-processing, large-scale synthetic data augmentation, diverse model architectures and domain fine-tuning are utilized to enhance the performance of the final ensemble model.

Since the quality of the training data is crucial to the translation performance, all the training sets are filtered by the off-the-shelf toolkits and some manual rules. Details will be discussed in Section 2. Those data pre-processing strategies are also employed to filter out the synthetic data generated by different data augmentation methods.

To generate synthetic parallel data, four data augmentation methods including back-translation (Sennrich et al., 2016), forward-translation (Wu et al., 2019), knowledge distillation (Freitag et al., 2017) and R2L training (Liu et al., 2016) are employed in our experiments. Specifically, we leverage source-side monolingual data by exploring forward-translation, knowledge distillation and R2L training, while target-side monolingual data by back-translation. These strategies increase the data size to a large extent. The generated data and the original parallel data are combined to train NMT models.

For model architectures, starting from Transformer-Big (Vaswani et al., 2017) settings, several Transformer variants are used to improve the model capacity and diversity. Previous studies (Bapna et al., 2018; Li et al., 2020) have shown that the translation performance can be significantly improved by increasing the model capacity. Therefore, we build different model architectures with either wider FFN layers (Ng et al., 2019) or deeper transformer encoder (Sun et al., 2019). Moreover, the Pre-Norm (Wang et al., 2019) is also adopted in all our experiments as its performance and training stability are better than the Post-Norm counterpart.

Domain fine-tuning is the most effective method in our experiments, which greatly improves the translation performance. We first employ previous WMT test sets as the domain data to fine-tune several models with different architectures. Then we ensemble those fine-tuned models and translate the test sets to construct pseudo parallel data. Finally, the original and the pseudo test sets are merged for further domain fine-tuning.

This paper is structured as follows: Section 2 describes the data pre-processing strategies. We present the details of our systems in Section 3 and show the experiment settings and results in Section 4. We draw the conclusion in Section 5.

2 Data Pre-processing

For each language pair, we follow the constrained data requirements and make full use of the provided bilingual and monolingual data. Table 1 lists the data we used in our experiments.

Language Pair	Filtered Bilingual	Monolingual
En-Zh	34.5M	En:15M Zh:15M
En-Ja	20.1M	En:20M Ja:20M

Table 1: Statistics of the training dataset.

As the quality of the parallel training data is crucial to the final translation performance, we perform fine-grained data filtering with the off-the-shelf toolkits and some manual rules. For both language pairs, the pre-processing strategies are as follows:

- Normalize punctuation with Moses scripts (Koehn et al., 2007) for English. Chinese and Japanese text are separately segmented by jieba[1] and MeCab[2] toolkits.
- Filter out the duplicated sentence pairs.
- Filter out sentences containing html tags, illegal characters and invisible characters.
- Filter out sentences with the character-to-word ratio higher than 12 or lower than 1.5 following (Wei et al., 2021).
- Filter out sentences with the source-to-target token ratio higher than 3 or lower than 0.3 following (Wei et al., 2021).
- Filter out sentences in other languages by applying language identification (Joulin et al., 2016).
- Filter out sentence pairs with low alignment score by using fast-align (Dyer et al., 2013).
- For Chinese, we convert full-width format to half-width format and convert traditional Chinese characters to simplified ones.

3 System Overview

3.1 Model Architectures

Previous studies (Bapna et al., 2018; Li et al., 2020; Wei et al., 2021; Li et al., 2021) have shown that the translation performance can be significantly improved by increasing the model capacity. Considering the model performance, we adopt the Deep Encoder and Shallow Decoder architecture with wider FFN layer. For En-Zh pair, we adopt the Deep 35-6 big model as baseline model following (Wei et al., 2021). For En-Ja pair, in view of the training cost we choose the Deep 24-6 big model as baseline model following (Subramanian et al., 2021; Zhou et al., 2021). The details about the models are as follows:

- **Deep 24-6 model**: This model features 24-layer encoder, 6-layer decoder, 512 dimensions of word vector, 4096 dimensions of FFN, 16-head self-attention and uses Pre-Norm strategy(Wang et al., 2019).
- **Deep 35-6 big model**: This model features 35-layer encoder, 6-layer decoder, 768 dimensions of word vector, 3076 dimensions of FFN, 16-head self-attention and uses Pre-Norm strategy(Wang et al., 2019).

3.2 Data Augmentation

In this task, four data augmentation strategies are utilized to generate synthetic data, which have shown their effectiveness on improving the performance of NMT model in previous works (Wei et al., 2021; Zhou et al., 2021; Wang et al., 2021; Zeng et al., 2021).

Back-Translation (Sennrich et al., 2016) is the most commonly used data augmentation technique which generates pseudo parallel data by translating the target monolingual sentences into source language with a pre-trained target-to-source NMT model. Our back-translation is divided into three stages:

- Training an ensemble target-to-source NMT model with the provided bilingual parallel data.
- Translating the target monolingual sentences to source language with the pre-trained target-to-source NMT model to generate synthetic parallel data.
- Training models with the bilingual and synthetic parallel data in a ratio of 1:1.

[1] https://github.com/fxsjy/jieba
[2] http://taku910.github.io/mecab/

Forward-Translation (Wu et al., 2019) is another data generation technique. Different from back-translation, forward-translation translating the source monolingual corpus into target corpus with a pre-trained source-to-target NMT model. Here, the forward-translation is only applied to Ja → En direction.

Knowledge Distillation (Freitag et al., 2017) is a powerful technique to improve a student model by distilling knowledge from a group of teacher models. In our experiments, we first train several teacher models on the original bilingual data and generate synthetic training corpus with the ensemble teacher models. Then the student model is trained on the combination of the original and synthetic training set.

R2L Training Previous work (Liu et al., 2016) has shown that R2L training is an effective way to boost translation quality by addressing the error propagation problem in auto-regressive generation tasks. Following this strategy, we train an R2L model with the original source sentences and inverse target sentences and translate the source monolingual sentences into target sentences. In our experiment, we mix the synthetic data generated by both R2L and L2R models to for iterative joint training.

3.3 Domain Fine-tuning

Domain fine-tuning plays a key role in improving the model performance. Following Sun et al. (2019), we take previous development and test sets as in-domain data and fine-tune the models. For En ↔ Ja task, since previous development and test sets are too small to use, we search for additional in-domain data which are similar to the development sets. Specifically, we obtain the low-frequency domain-specific words in the development/test sets by employing the TF-IDF algorithm and filter sentences in the training set which contain those words.

3.4 Model Ensemble

Model ensemble is a widely used method in previous WMT shared tasks (Garmash and Monz, 2016), which can enhance the translation performance by combining the predictions of several models at each decoding step. In our work, we employ two kinds of ensemble methods, namely, checkpoint average and voting based ensemble. For checkpoint average, we average the top-5 checkpoints of each model according to their BLEU performance on the development set. While for model ensemble, we train several models with different architectures to increase the model diversity.

3.5 Post-editing

We apply post-editing to obtain the final translation outputs. For En → {Zh, Ja}, the post-editing includes removing the redundant spaces, converting punctuation to the language-specific format and replacing some of the English in the translation (such as the person name) with the English in the source sentence. For {Ja, Zh} → English, we de-tokenize the sentences with the Moses toolkit.

4 Experiments and Results

4.1 Settings

The implementation of our models is based on open-source fairseq (Ott et al., 2019) and we use sacreBLEU (Post, 2018) to measure system performances which is officially recommended. We select Transformer-big as the baseline for all tasks. The Zh ↔ En models are carried out on single NVIDIA 3090 GPU which has 24GB of memory and the Ja ↔ En models are carried out on 8 RTXA6000 GPUs each of which has 48GB of memory. For all tasks, the dropout probabilities are set to 0.1. We use the Adam optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.997$ (Zhou et al., 2021) during training. Table 2 lists the fairseq parameter setting in training.

Parameter	**Zh ↔ En**	**Ja ↔ En**
batch size	4096	8192
update-freq	4	2
learning rate	0.0005	0.002
warmup steps	4000	8000
save-interval-updates	4000	2000

Table 2: Fairseq parameter setting in training.

4.2 Zh ↔ En

For Zh ↔ En tasks, the training data consists of ParaCrawl v9, News Commentary v16, Wiki Titles v3, WikiMatrix, UN Parallel Corpus V1.0 (Ziemski et al., 2016) and CCMT Corpus. We take newsdev2017 as the development set and newstest2021 as the test set to tune the hyper-parameters. The training data is filtered by aforementioned methods and obtain the training data of 34.5M. The joint

System	En → Zh	Zh → En
Baseline	32.1	23.4
+ Back Translation	32.3(+0.2)	23.5(+0.1)
+ Checkpoint Average	32.8(+0.5)	24.2(+0.7)
+ Domain Fine-tuning	34.1(+1.3)	26.9(+2.7)
+ Ensemble	34.5(+0.4)	27.4(+0.5)
+ Post-edit	37.9(+3.4)	27.4

Table 3: The experimental result of En ↔ Zh task.

vocabulary with 32K words is generated by using sentencepiece(Kudo and Richardson, 2018). The officially provided back-translation data are not used in our experiments since no obvious improvements are obtained when adding it to the training set. The results of En ↔ Zh on newstest2021 are shown in Table 3.

We perform back-translation with the deep 35-6 big model in the target-to-source direction to generate the synthetic parallel data. Comparing with the baseline model, the back-translation technique leads to an improvement of 0.2 and 0.1 BLEU in En → Zh and Zh → En directions, respectively. The checkpoint average method brings another BLEU improvements of 0.5 and 0.7.

In the fine-tuning stage, we use previous WMT test sets as the in-domain data. We first perform fine-tuning on several different models with the combination of newstest2017-2019. Then we translate the in-domain data by the ensemble model to obtain pseudo parallel data and perform further fine-tuning on both the original and pseudo data. In our final submission, we add the newstest2020 and newstest2021 test set to the in-domain data. Domain fine-tuning is the most effective method in our experiment, which achieve an improvement of 1.3 and 2.7 BLEU scores in En → Zh and Zh → En directions, respectively.

We ensemble several models with better performance on the test set, in order to obtain more robust translation system. In our work, model ensemble further lead to a 0.4 and 0.5 BLEU improvement, respectively. Moreover, we apply post-editing to the translation outputs. It should be noted that post-editing can mainly improve the BLEU of En → Zh, which is about 3.4 BLEU. The punctuation format of Chinese translation has a great impact on BLEU. Finally, we obtain 37.9 BLEU scores in En → Zh direction and 27.4 BLEU scores in Zh → En direction.

4.3 Ja ↔ En

For Ja ↔ En tasks, we choose ParaCrawl v9, News Commentary v16, Japanese-English Subtitle Corpus (Pryzant et al., 2018), The Kyoto Free Translation Task Corpus (Neubig, 2011) and TED Talks as the training bilingual corpus. The final training bilingual corpus we used to train the model is about 20.1M. The source and target side each has a vocabulary with 32K words. We use the combination of newsdev2020 and newstest2020 as the development set and newstest2021 as the test set, respectively. Table 4 summarizes our results on newstest2021.

As shown in Table 4, all the four data augmentation methods improve the translation performance in both translation directions. We apply the deep 24-6 model to implement four data augmentation methods and We find that back-translation contributes the largest BLEU improvements (+4.1 BLEU) of the four data augmentation methods on En → Ja direction, while knowledge distillation performs best in the opposite direction (+2.1 BLEU). Moreover, we also evaluate the combination of the four data augmentation methods. In En → Ja direction, we combine the synthetic data from back-translation and R2L model with the original parallel data in a ratio of 0.5:0.5:1. By contrast, in Ja → En direction, we mix the synthetic data from back-translation, forward-translation and knowledge distillation with the original parallel data in a ratio of 0.5:0.5:0.5:1. The combination of multiple data augmentation methods brings 4.5 and 2.0 BLEU gains in En → Ja and Ja → En directions.

We further use newsdev2020, newstest2020 and selected in-domain data to fine-tune the model and achieve another 3.6 and 1.8 BLEU improvement in En → Ja and Ja → En directions, respectively. Then, the model ensemble further bring 1.1 and 0.6 BLEU improvement. Finally, we apply post-editing to the translation outputs and it further bring 0.2 and 0.1 BLEU improvement in En → Ja and Ja → En directions.

5 Conclusion

This paper presents the DUTNLP Translation systems for WMT22 General MT Task. Our main exploration is to improve the translation performance with the fine-grained data filtering, diverse model architectures, large-scale data augmentation and domain fine-tuning. The effectiveness of each method is demonstrated in our experiments. Model

Abstract

This paper presents the submissions of Huawei Translate Services Center (HW-TSC) to the WMT 2022 General Machine Translation Shared Task. We participate in 6 language pairs, including Zh↔En, Ru↔En, Uk↔En, Hr↔En, Uk↔Cs and Liv↔En. We use Transformer architecture and obtain the best performance via multiple variants with larger parameter sizes. We perform fine-grained pre-processing and filtering on the provided large-scale bilingual and monolingual datasets. For medium and high-resource languages, we mainly use data augmentation strategies, including Back Translation, Self Training, Ensemble Knowledge Distillation, Multilingual, etc. For low-resource languages such as Liv, we use pre-trained machine translation models, and then continue training with Regularization Dropout (R-Drop). The previous mentioned data augmentation methods are also used. Our submissions obtain competitive results in the final evaluation.

1 Introduction

This paper introduces our submissions to the WMT 2022 General Machine Translation Shared Task. We participate in 6 language pairs including Chinese/English (Zh↔En), Russian/English (Ru↔En), Ukrainian/English (Uk↔En), Croatian/English (En→Hr), Ukrainian/Czech(Uk↔Cs), and Livonian/English (Liv↔En). For Zh↔En translation, we use additional in-house in-domain data, so the final submission for this language pair is unconstrained. For Liv↔En translation, although we did not use additional data, we used M2M-100 (Fan et al., 2020) as the pretrained model, and the final submission is also unconstrained. All other languages pair participate in the constrained evaluation. Our method is mainly based on previous works (Wei et al., 2020, 2021; Yang et al., 2021) but with fine-grained data cleansing techniques and language-specific optimizations.

For each language pair, we perform multi-step data cleansing on the provided dataset and only keep a high-quality subset for training. At the same time, several strategies are tested in a pipeline, including Backward (Edunov et al., 2018) and Forward (Wu et al., 2019a) Translation, Multilingual Translation (Johnson et al., 2017), Iterative Joint Training (Zhang et al., 2018), R-Drop, Pretrained NMT model, Ensemble Knowledge Distillation (Freitag et al., 2017; Li et al., 2019), Fine-Tuning (Sun et al., 2019), Ensemble (Garmash and Monz, 2016), and Post-Processing.

Our system report includes four parts. Section 2 focuses on our data processing strategies while section 3 describes our training details. Section 4 explains our experiment settings and training processes and section 5 presents the results.

2 Data

2.1 Data Source

We obtain bilingual and monolingual data from data sources such as CCMT, UN, ParaCrawl, WikiMatrix, WikiTitles, News Commentary, Leipzig Corpora, News Crawl, and Common Crawl. The amount of data we used is shown in Table 1. It should be noted that in order to obtain better performance in the general domain, we mix the monolingual data from Common Crawl and News Crawl.

2.2 Data Pre-processing

Our data processing procedure is basically the same as our method last year (Wei et al., 2021), including deduplication, XML content processing, langid (Joulin et al., 2016b,a) and fast-align (Dyer et al., 2013) filtering strategies, etc. As we use the same data pre-processing strategy as last year's, we will not go into details here.

2.3 Data Denoise

Regarding Hr↔En, the CCMatrix data is highly noisy, so more fine-grained data cleaning is nec-

language pairs	Raw bi data	Filter bi data	Used mono data
Zh/En	39M	37M	En: 150M (C&N), Zh: 150M (C)
Ru/En	28M	26M	En: 160M (C&N), Ru: 160M (C&N)
Hr/En	69M	55M	Hr: 22M (N)
Uk/En	39M	36M	En: 150M (C&N), Uk: 60M (N)
Cs/Uk	8.4M	8M	Cs: 60M (C&N), Uk: 60M (N)
Liv/En	1.1k	1.1k	Liv: 50K, En: 1M

Table 1: Bilingual data sizes before and after filtering, and monolingual data used in the task. Regarding monolingual data, **N** means that the data comes from News Crawl; **C** means that the data comes from Common Crawl; and **C&N** means half of News and Common Crawl.

essary. We adopted the data denoise strategy by Wang et al. (2019, 2018). The strategy uses a small amount of high-quality data to tune the base model, and then leverages the differences between the tuned model and the baseline to score bilingual data. The score is calculated based on formula 1.

$$score = \frac{\log P(y|x;\theta_{clean}) - \log P(y|x;\theta_{noise})}{|y|} \tag{1}$$

Where θ_{noise} denotes the model trained with noisy data; θ_{clean} denotes the model after fine-tuning on a small amount of clean bilingual data, and $|y|$ denotes the length of the sentence. Higher $score$ means higher quality.

3 System Overview

Our method basically follows our previous training strategies (Wei et al., 2020, 2021), such as commonly used Back-Translation (Edunov et al., 2018), Iterative Joint Training (Zhang et al., 2018), Multilingual enhancement (Johnson et al., 2017; Kudugunta et al., 2019; Zhang et al., 2020), Data Diversification (Nguyen et al., 2020) (for details, please refer to our previous work Yang et al. (2021)), Ensemble and Fine-tuning, etc. We will not detail these strategies in this report. The following paper focuses on new strategies used in this year.

3.1 Model

We continue using Transformer (Vaswani et al., 2017) as our NMT architecture, but we do not use the four model variants as last year. For convenience, we only use a 25-6 deep model architecture. The parameters of the model are the same as Transformer-big. We just change the post-layer-normalization to the pre-layer-normalization, and increase the encoder layers to 25.

3.2 R-Drop

Dropout-like method (Srivastava et al., 2014; Gao et al., 2022) is a powerful and widely used technique for regularizing deep neural networks. Though it can help improve training effectiveness, the randomness introduced by dropouts may lead to inconsistencies between training and inference. R-Drop (Wu et al., 2021) forces the output distributions of different sub models generated by dropout be consistent with each other. Therefore, we use R-Drop training strategy to augment the baseline model for each track and reduce inconsistencies between training and inference.

3.3 Pretrained NMT Model

There are many pre-trained Sequence-to-Sequence models, such as Mbart (Liu et al., 2020), MT5 (Xue et al., 2020), M2M-100 (Fan et al., 2020), etc. These pre-trained models are very useful for ultra-low resource tasks. For the ultra-low-resource track Liv↔En, very few bilingual data (1k) is available, so we use a method similar to Adelani and Alabi (2022) to continue training on the basis of M2M-100 (418M) [1]. Since M2M-100 does not support the Liv language, we select an existing language tag (Estonian) similar to Liv to identify this language. For unknown tokens in Liv, we replace them with very low-frequent words in the vocabulary. We find this strategy effective for performance improvement.

3.4 Noised Self-Training

Self-training (Imamura and Sumita, 2018) (ST), also known as Forward translation (Wu et al., 2019b), usually refers to using a forward NMT model to translate source-side monolingual data so as to generate synthetic bilinguals, which aims at

increasing the training data size. Forward translation usually relies on beam search-based (Freitag and Al-Onaizan, 2017) decoding when generating synthetic data. He et al. (2019) find that drop-out plays an important role in ST and adding a certain noise to the original text can further improve the effect of ST, which is called Noised ST. We adopt this method during training.

3.5 Data Rejuvenation

We score all the training bilingual data through Equation 1, and filter out 10% - 20% of the data according to the score distribution. We use the remaining 80% - 90% clean data to continue training on the previous model for denoising. This strategy is particularly effective with noisy data and is used in several several languages in this task. We refer to it as Data Rejuvenation in the following.

4 Experiment Settings

We use the open-source fairseq (Ott et al., 2019) for training and sacreBLEU (Post, 2018) to measure system performances. The main parameters are as follows: Each model is trained using 8 V100 GPUs. The size of each batch is set as 2048, parameter update frequency as 4, and learning rate as 5e-4 (Vaswani et al., 2017). The number of warmup steps is 4000, and model is saved every 1000 steps. The architecture we used is described in section 3.1. We adopt dropout, and the rate varies across different language pairs. R-Drop is used in model training, and we set parameter λ to 5 for all language pairs.

5 Results and Analysis

5.1 Zh↔En

Regarding Zh↔En, we use R-Drop, Knowledge Distillation (Kim and Rush, 2016), Self Training + Back Translation, and fine-tuning. The results of Zh→En and En→Zh are shown in Tables 2 and 3.

To better measure the generalizability of our models, we also calculate BLEU on WMT Biomedical 2020 and Flores test sets (Goyal et al., 2021).

We see that R-Drop can stably bring about 1.5 BLEU improvement, and data enhancement can bring 1.0 BLEU improvement. In the final result we submitted, we only use the news test sets to fine-tune the model, but we see that it was still able to bring 1 BLEU improvement on the WMT 2022 test set.

In the end, our submission uses a combination of our domain-related in-house data and the WMT

Ensemble	-	-	-	-	-	**45.1**

Table 5: Ru→En BLEU scores on WMT 2020 News (WMT20), WMT 2021 News (WMT21), WMT 2020 Biomedical (Med20) and Flores test sets, and their average (Avg) scores based on different training strategies. We also report part of WMT 2022 (WMT22) test set results.

data, and we find that domain-related data is critical for quality improvement. By using the extra data, we get an improvement of about 2.0 BLEU over using only the WMT data. Our final Zh→En and En→Zh submissions achieve 49.7 and 29.8 BLEU respectively.

5.2 Ru↔En

Regarding Ru↔En (Table 4 and 5), we use strategies including Iterative Self Training + Back Translation, R2L enhancement, and general domain monolingual enhancement.

We see that in addition to the average 1 BLEU improvement brought by fine-tune, the most effective strategy is adding more general domain data. On En→Ru, after the Common Crawl monolingual is added, we observe 2.0 BLEU improvement on WMT 2022 test set.

The data enhancement strategy could bring stable improvement like that in Zh↔En, with an increase of 2 BLEU compared to the baseline model in an average.

The BLEU scores of our final Ru→En and En→Ru submissions are 45.1 and 30.8 respectively.

System	En→Liv	Liv→En
M2M-100 finetune	8.0	16.0
OOV process	9.6	17.6

Noised ST	14.6	-
R-Drop	15.1	25.8
WMT22 Submission	**12.8**	**23.4**

Table 6: The results of Liv↔En for WMT 2022 dev test set. We remove overlapping sentences in the dev set that also appear in the training set.

5.3 Liv↔En

Regarding Liv↔En (Table 6), we first fine-tune the M2M-100 model with 1K bilingual data, and then replace the out-of-vocabulary (OOV) token in Liv with low-frequency sub-words in the vocabulary, we see that this strategy brings 1.6 BLEU improvement on En→Liv.

Then we use the Liv/Et and Liv/Lv data together to fine-tune the model. This strategy can bring significant improvement on both directions (1.4 BLEU on En→Liv and 4 BLEU on Liv→En. It should be pointed out that regarding En→Liv, we use additional data from Et→Liv and Lv→Liv, while for

System	dev	Flores	Avg
R-Drop	31.5	33.2	32.4
Data Rejuvenation	32.1	33.5	32.8
Sampling BT	33.2	32.9	33.1
Finetune	33.1	33.0	33.0
Ensemble	33.2	33.4	33.3
WMT22 Submission		**18.1**	

Table 7: The results of En→Hr on WMT 2022 dev test set and Flores.

Liv→En, we use data from Liv→Et and Liv→Lv to enhance the model.

We do three rounds of Tagged BT (Caswell et al., 2019) in total and observe that the improvement is still significant (an average improvement of 3 BLEU on two directions). For En→Liv, we adopt the strategy of Noised ST because we have a large amount of English monolinguals. We used 1M English monolinguals for Noised ST. We see that this strategy can bring an additional 1.3 BLEU improvement.

Additionally, we employ the R-Drop strategy during training and find that on Liv2En, this strategy brings an improvement of 1.8 BLEU.

Finally, using dev fine-tune and ensemble of 4 models, our submissions achieve 12.8 BLEU on En→Liv, and 23.4 BLEU on Liv→En.

5.4 En→Hr

The results of En→Hr are shown in Table 7. We use 22M Hr monolinguals for BT and find that the results on the dev set is different from that on the test set as the magnitude of improvements are inconsistent. The overall improvement on dev set is only 0.8 BLEU, but 3 BLEU on the test set. The main improvement is brought by data denoising. We assume that this is because the provided En2Hr bilingual data is highly noisy. Our final submission achieves 18.1 BLEU.

5.5 Uk↔En and Cs↔Uk

Regarding Uk↔En (Table 8), we conduct Sampling BT and see 2.2 BLEU improvement on Uk→En but no improvement on En↔Uk. After adding self-training data, an additional 0.5 BLEU improvement is gained on Uk→En. We then use real bilinguals data to continue training the model that have been augmented with synthetic data. This strategy further leads to an average improvement of 0.4 BLEU. We do not use dev fine-tuning but directly ensemble the 4 models. The final En→Uk and Uk→En submissions achieve 26.5 and 41.6 BLEU respectively on the WMT22 test set.

The strategy for Cs↔Uk is basically the same as that for Uk↔En, but we further apply multilingual enhancement. We use additional En→Uk data for enhancing Cs→Uk translation and En→Cs data for enhancing Uk→Cs translation. Multilingual enhancement brings 1.2 BLEU improvement on Uk→ Cs. Monolingual data augmentation also brings significant improvement. Ensemble further leads to 1 BLEU increase on Uk→Cs. Our final Cs↔Uk submissions achieve 36.0 BLEU on the WMT22 test sets.

6 Discussion

6.1 General Domain

In this year, WMT changed its focus on news domain to the broader general task, with three additional domains putting into consideration (social, conversational, and ecommerce). We also use test sets from other domains to measure the generalizability of our models.

However, for language pairs we participate in, most of the knowledge in domains other than news can only be learned from Common Crawl monolinguals. Without in-domain data, a model's performance in social, conversational and ecommerce domains can hardly be improved. We add additional bilingual data related to the three domains for the Zh↔En track and observe an average of 2.0 BLEU improvement. As a result, how to maximize the effectiveness of in-domain data is crucial.

6.2 Evaluation Method

N-gram matching metrics such as BLEU and chrF (Popović, 2015) are widely used in machine translation evaluation. However, as machine translation technology improves, relying only on BLEU to evaluate a model's performance become increasingly risky. For example, in last year's evaluation, the BLEU score of our De→En model ranks among the top, but the human evaluation results show that our model performs the worst. In this year's En→Uk evaluation, widely-used back-translation lead to no BLEU increase as shown in Table 8. So far, we are not sure whether back-translation does lead to no improvement or the improvement cannot be measured by BLEU. We believe that more researches are required on robust metrics (Sellam et al., 2020; Rei et al., 2020), reliable test set constructions, and sound human evaluation methods

considering the great advances in NMT and subtle differences among systems.

7 Conclusion

This paper presents the submissions of HW-TSC to the WMT 2022 General Machine Translation Task. We participate in six language pairs and perform experiments with a series of pre-processing and training strategies. The effectiveness of each strategy is demonstrated. Our experiments show that in very low-resource scenarios, fine-tuning on pre-trained NMT models can significantly improve system performance. R-Drop also brings stable improvement across languages. Certainly, commonly-used data augmentation strategies are still effective for model training. Our submissions finally achieve competitive results in the evaluation.

Abstract

We describe the JD Explore Academy's submission of the WMT 2022 shared task on general machine translation. We participated in all high-resource tracks and one medium-resource track, including Chinese↔English (Zh↔En), German↔English (De↔En), Czech↔English (Cs↔En), Russian↔English (Ru↔En), and Japanese↔English (Ja↔En). **[Method]** We push the limit of our previous work – bidirectional training (Ding et al., 2021d) for translation by scaling up two main factors, *i.e.* language pairs and model sizes, namely the **Vega-MT** system. As for language pairs, we scale the "bidirectional" up to the "multidirectional" settings, covering all participating languages, to exploit the common knowledge across languages, and transfer them to the downstream bilingual tasks. As for model sizes, we scale the Transformer-BIG up to the extremely large model that owns nearly 4.7 Billion parameters, to fully enhance the model capacity for our Vega-MT. Also, we adopt the data augmentation strategies, *e.g.* cycle translation (Ding and Tao, 2019) for monolingual data, and bidirectional self-training (Ding and Tao, 2021) for bilingual and monolingual data, to comprehensively exploit the bilingual and monolingual data. To adapt our Vega-MT to the general domain test set, generalization tuning is designed. **[Results]** Based on the official automatic scores[*] of constrained systems, in terms of the SACREBLEU (Post, 2018) shown in Figure 1, we got the 1st place in {Zh-En (33.5), En-Zh (49.7), De-En (33.7), En-De (37.8), Cs-En (54.9), En-Cs (41.4) and En-Ru (32.7)}, 2nd place in {Ru-En (45.1) and Ja-En (25.6)}, and 3rd place in {En-Ja(41.5)}, respectively; W.R.T the **COMET** (Rei et al., 2020), we got the 1st place in {Zh-En (45.1), En-Zh (61.7), De-En (58.0), En-De (63.2), Cs-En (74.7), Ru-En (64.9), En-Ru (69.6) and En-Ja (65.1)}, 2nd place in {En-Cs (95.3) and Ja-En (40.6)}, respectively. Models will be released to facilitate the MT community through GitHub[†] and OmniForce Platform[‡].

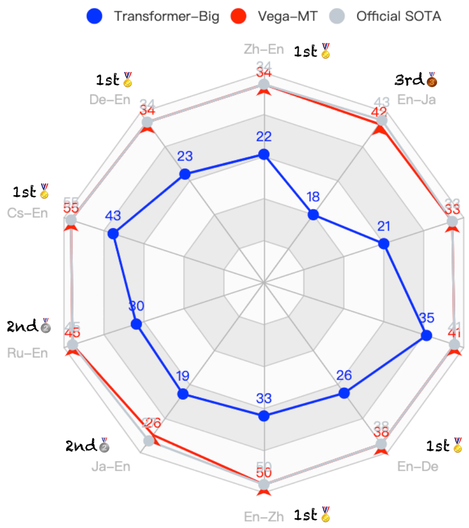

Figure 1: Vega-MT achieves 7 state-of-the-art BLEU points out of 10 high-resource translation tasks among all constrained systems, and significantly outperforms the competitive Transformer-BIG baselines.

1 Introduction

In this year's WMT general translation task, our Vega-MT translation team participated in 10 shared tasks, including Chinese↔English (Zh↔En), German↔English (De↔En), Czech↔English (Cs↔En), Russian↔English (Ru↔En), and Japanese↔English (Ja↔En). We use the same model architectures, data strategies and corresponding techniques for all tasks.

We aim to leverage the cross-lingual knowledge through pretraining (PT) to improve the high-resource downstream bilingual tasks. Although recent works (Song et al., 2019; Lewis et al., 2020; Liu et al., 2020b; Wang et al., 2022) attempt to leverage sequence-to-sequence PT for neural machine translation (NMT; Bahdanau et al., 2015a; Gehring et al., 2017; Vaswani et al., 2017a) by using a large amount of unlabeled (*i.e.* monolingual) data, Zan et al. (2022b) show that it usually fails to achieve notable gains (sometimes, even worse) on resource-rich NMT on par with their random-initialization counterpart, which is consistent with our preliminary experiments. Ding et al. (2021d) show that bidirectional pretrained model as initialization for downstream bilingual tasks could consistently achieve significantly better performance. It is natural to assume that scaling the "bidirectional" to the "multidirectional" setting with {1) *multilingual pretraining* and 2) *large enough model capacity*} could benefit the downstream resource-rich bilingual translations. Tran et al. (2021) and Lin et al. (2020) also provide empirical evidences to support our motivation of supervised multilingual pretraining. Different from Tran et al. (2021) that explores the effectiveness of multilingual training, we show that further tuning on the bilingual downstream task provide more in-domain knowledge and thus could gain better translation quality. Compared with Lin et al. (2020), our model do not require any alignment information during pretraining, which will consume more extra time and computation resources, making our strategy flexible to be applied to any language.

For model frameworks in §2.1, we tried autoregressive neural machine translation, including Transformer-BIG and -XL (Vaswani et al., 2017b), and non-autoregressive translation models (Gu et al., 2018), where the Transformer-XL is employed as the foundation model and autoregressive BIG and non-autoregressive models are used during augmenting. For the core training strategy of our Vega-MT, we cast the multilingual pretraining as foundation models in §2.2, including MULTI-DIRECTIONAL PRETRAINING (§2.2.1) and SPECIFIC-DIRECTIONAL FINETUNING (§2.2.2). For data augmentation strategies, we employ CYCLE TRANSLATION (§2.3.1) and BIDIRECTIONAL SELF-TRAINING (§2.3.2) for both monolingual and parallel data. In order to adapt our Vega-MT to the general domains, we employ GREEDY BASED ENSEMBLING (§2.4.1), GENERALIZATION FINETUNING (§2.4.2) and POST-PROCESSING (§2.4.3) strategies.

The subsequent paper is designed as follows. We introduce the major approaches we used in Section 2. In Section 3, we provide the data description. We also present the experimental settings and results in Section 4. Conclusions are described in Section 5.

2 Approaches

2.1 Neural Machine Translation Frameworks

The neural machine translation task aims to transform a source language sentence into the target language with a neural network. There are several generation paradigms for translation, *e.g.* Autoregressive Translation (AT, Bahdanau et al., 2015b; Vaswani et al., 2017b) and Non-Autoregressive Translation (NAT, Gu et al., 2018).

Autoregressive Translation Given a source sentence $\mathbf{x}$, an NMT model generates each target word $\mathbf{y}_t$ conditioned on previously generated ones $\mathbf{y}_{<t}$. Accordingly, the probability of generating $\mathbf{y}$ is computed as:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{x}, \mathbf{y}_{<t}; \theta) \tag{1}$$

where T is the length of the target sequence and the parameters θ are trained to maximize the likelihood of a set of training examples according to $\mathcal{L}(\theta) = \arg\max_{\theta} \log p(\mathbf{y}|\mathbf{x}; \theta)$. Typically, we choose Transformer (Vaswani et al., 2017b) as its state-of-the-art performance and scalability. We carefully employ the standard Transformer-BASE ($\mathcal{M}_{\textbf{Base}}$) and Transformer-BIG ($\mathcal{M}_{\textbf{Big}}$) in the preliminary studies, and also scale the framework up to an extremely large setting (Tran et al., 2021) – Transformer-XL ($\mathcal{M}_{\textbf{XL}}$) to maintain powerful

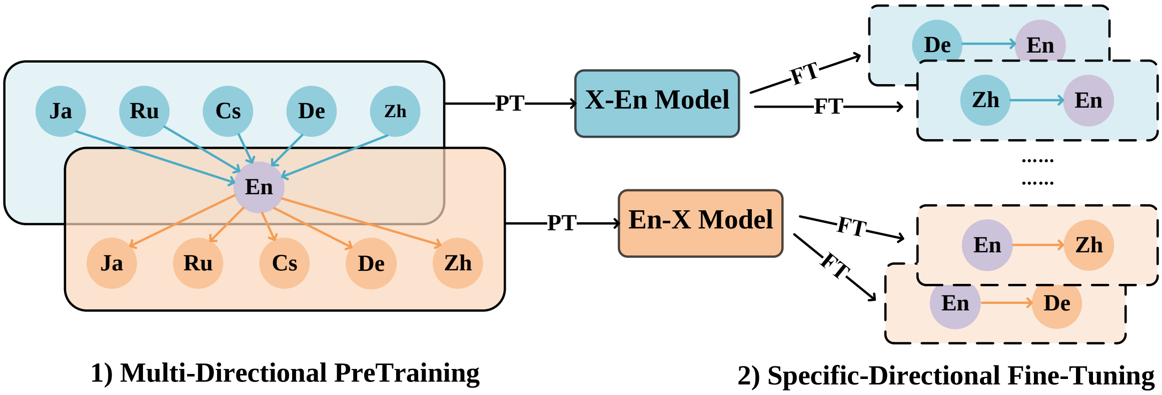

Figure 2: The schematic structure of the two main stages of the Vega-MT.

model capacity (see Table 1) . In Vega-MT, we utilized the autoregressive translation (AT) model with $\mathcal{M}_{\textbf{Big}}$ and $\mathcal{M}_{\textbf{XL}}$ for multi-directional pretraining (§2.2.1), specific-directional finetuning (§2.2.2), bidirectional self-training (§2.3.2) and generalization fine-tuning (§2.4.2) as its powerful modelling ability and generation accuracy.

Non-Autoregressive Translation Different to autoregressive translation (Bahdanau et al., 2015b; Vaswani et al., 2017b, AT) models that generate each target word conditioned on previously generated ones, non-autoregressive translation (Gu et al., 2018, NAT) models break the autoregressive factorization and produce the target words in parallel. Given a source sentence $\mathbf{x}$, the probability of generating its target sentence $\mathbf{y}$ with length T is defined by NAT as:

$$p(\mathbf{y}|\mathbf{x}) = p_L(T|\mathbf{x};\theta)\prod_{t=1}^{T} p(\mathbf{y}_t|\mathbf{x};\theta) \qquad (2)$$

where $p_L(\cdot)$ is a separate conditional distribution to predict the length of target sequence. Typicallly, most NAT models are implemented upon the framework of $\mathcal{M}_{\textbf{Base}}$. We utilized the NAT for bidirectional self-training (§2.3.2) as NAT can nicely avoid the error accumulation problems during generation, and generate diverse synthetic samples. Also, we employ several advanced structure (Gu et al., 2019; Ding et al., 2020) (*Levenshtein* with source local context modelling) and advanced training strategies (Ding et al., 2021a,b,c, 2022b; Ding, 2022) to obtain high quality and diverse translations.

2.2 Multidirectional Pretraining as Foundation Models

This section illustrates how we scale the "bidirectional" training in Ding et al. (2021d) up to "multi-directional" pretraining with all high-resource parallel corpora, including Zh, De, Cs, Ru, Ja to/from En. The pretrained foundation models will be fine-tuned for the downstream specific-directional task, *e.g.* Zh-En. Such two-stage scheme is shown in Figure 2.

2.2.1 Multi-Directional Pretraining

Recent works on real-world `WMT` translation datasets have verified that it is possible to transfer the pretrained cross-lingual knowledge to the downstream tasks with the pretrain-finetune paradigm, hence improving performance and generalization ability (Ding et al., 2022b,a; Wang et al., 2020a).

Here, we propose multi-directional pretraining by extending Bidirectional Pretraining (Ding et al., 2021d, BiT) to utilize multiple translation corpora of different languages. Compared with BiT, multi-directional pretraining could utilize the cross-lingual knowledge among more languages, thus further exploiting the cross-language knowledge and facilitating the downstream transferring. The main modifications could be summarized twofold:

1) We increase language numbers to utilize the cross-lingual knowledge of various languages. The straight setting for multi-directional pretraining is multi-lingual translation, which is divided into Many-to-Many (M2M), One-to-Many (O2M), and Many-to-One (M2O), according to the language number that the model supports. M2M has potential of capturing more cross-

lingual knowledge from $N * N$ pairs compared with $N * 1/1 * N$ pairs of M2O/O2M but usually leads to worse performance because of the imbalanced language data distribution question (Freitag and Firat, 2020). Inspired by (Tran et al., 2021), we focus on pretraining two separate systems, including English-to-Many and Many-to-English. We also prepend the corresponding language token to source & target sentences.

2) We further expand model size to an extremely large setting. While enjoying the benefit of cross-lingual knowledge transferring, the difficulty of modeling extremely large-scale data and language-specific feature pushes us to enlarge Transformer-BIG to an extremely large size (4.7 Billion parameters, see Table 1). This ensures our models are capable of better mastering multiple translation corpus.

2.2.2 Specific-Directional Finetuning

The off-target problem, which widely exits in multilingual translation systems (Yang et al., 2021), indicates model often generates the translation with some non-target words. To reduce non-target word translation ratio in multi-directional pretrained models, we consider a two-stage specific-directional finetuning strategy. As shown in Figure 2, the English source/target model is tuned with an English source/target bilingual corpus.

Specifically, we first replace the multilingual embedding with a bilingual one. To fit model and bilingual vocabulary, we freeze all parameters of the Transformer backbone and only tune embedding layers in this stage. Next, we employ full model finetuning on large-scale translation corpus. This allows the model to fully adapt to the specific directional translation task, thus further achieving gains. To balance both finetune stages, we set the ratios of update step as $1 : 4$ for embedding- and full model-tuning, respectively.

For future work during specific directional finetuning, it will be interesting to design tuning data order (Liu et al., 2020a; Zhou et al., 2021) by leveraging the learning difficulty of each training sample estimated in the pretraining stage.

2.3 Data Augmentation Strategies

In Vega-MT, we consider augmenting both the parallel and monolingual data comprehensively. Specifically, we employ the cycle translation (Ding and Tao, 2019) for regenerating the low-quality *monolingual data*, and adopt bidirectional self-training (Ding and Tao, 2021) to distill, diversify *both the monolingual and parallel data*.

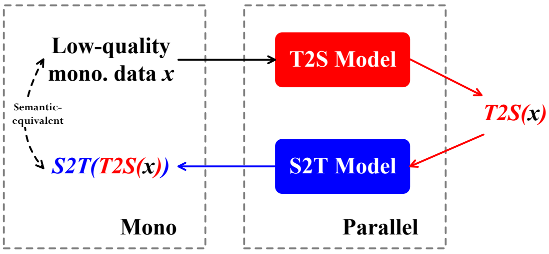

Figure 3: The Cycle Translation process, into which we feed the low quality monolingual data x, and then correspondingly obtain the improved data $\mathcal{CT}(x)$ (denoted as $S2T(T2S(x))$). Note that models marked in red and blue represent the target-to-source and source-to-target model trained with $\mathcal{M}_{\textbf{Big}}$. The dotted double-headed arrow between the input **x** and the final output $\mathcal{CT}(x)$ means they share the semantic but differ in fluency.

#	Cycle Translated Sentence "1"→"2"
1	*She stuck to her principles even when some suggest that in an environment often considered devoid of such thing there are little point.*
2	*She insists on her own principles, even if some people think that it doesn't make sense in an environment that is often considered to be absent.*

Table 2: Example of difference between original sentence (line 1) and cycle translated result (line 2). Pretrained BERT model using all available English corpora show that the $\mathcal{L}oss$ decreased from 6.98 to 1.52.

2.3.1 Cycle Translation for Mono. Data

There is a large amount of monolingual data incomplete or grammatically incorrect. To fully leverage such part of monolingual data for better data augmentation, *e.g.* back translation (Sennrich et al., 2016) or sequence -level knowledge distillation (Kim and Rush, 2016), we adopt Cycle Translation (Ding and Tao, 2019) (denoted as $\mathcal{CT}(\cdot)$, as Figure 3) to improve the monolingual data below the quality-threshold (the latter 50% will be cycle translated according to Ding and Tao (2019)'s optimal setting). We give an example in Table 2 to clearly show how the cycle translation improves the quality of the sentence.

2.3.2 Bidirectional Self-Training for Both Mono&Para Data

Currently, data-level methods have attracted the attention of the community, including exploiting the parallel and monolingual data. The most representative approaches include:

- Back Translation (**BT**, Sennrich et al. 2016) introduces the target-side monolingual data by translating with an inverse translation model, and combines the synthetic data with parallel data;

- Knowledge Distillation (**KD**, Kim and Rush 2016) generates the synthetic data with sequence-level knowledge distillation;

- Data Diversification (**DD**, Nguyen et al. 2020) diversifies the data by applying KD and BT on parallel data.

Clearly, self-training is at the core of above approaches, that is, they generate the synthetic data either from source to target or reversely, with either monolingual or bilingual data.

To this end, we employ the bidirectional self-training (Ding and Tao, 2021; Liao et al., 2020) strategy for both parallel and monolingual data (including source and target, respectively). Specifically, baseline AT models with $\mathcal{M}_{\textbf{Big}}$ setting and NAT models with $\mathcal{M}_{\textbf{Base}}$ setting are trained with original (distilled for NAT) parallel data in the first iteration, and based on these forward- and backward-teachers, all available source & target language sentences can be used to generate the corresponding synthetic target & source sentences. The authentic and synthetic data (generated by AT and NAT models) are then concatenated to train the second round AT and NAT models. We run the bidirectional self-training by totally 2 rounds for each translation direction. And for each round, we train 3 forward- and 3 backward- AT models, and 1 forward- and backward- NAT models to perform self-training. In this way, the amount of bidirectional synthetic data will be 8x larger than the original parallel and monolingual data.

2.4 Generalization Adaptation for Downstream Translation

To adapt Vega-MT to the general domain translation task, we employ several strategies, including ensembling, generalization finetuning, and post-processing. Note that in our preliminary study, we find that noisy channel reranking with the target-to-source MT model and language model does not work in our setting, thus we have not reranked the results in the final submission.

Algorithm 1: Generalization Finetuning with Iteratively Transductive Ensemble

```
Input: Single Model $M_n$,
       General Seed $D$=$\{D_1, D_2..D_k\}$,
       Ensemble $N$ models $E_N$.
Output: New Model $M_n^{'}$
$t := 0$
while not convergence do
    Translate $D_1$ with $E_N$ and get $D_1^{E_N}$
    ..
    Translate $D_k$ with $E_N$ and get $D_k^{E_N}$
    $D^{E_N} = D_1^{E_N} \cup ..D_k^{E_N}$
    Train $M_n$ on $D \cup D^{E_N}$ and get $M_n^{'}$,
      then $M_n = M_n^{'}$
    $t := t + 1$
end
```

+post	*Siltala's previous season in the league was 2006-07*

Table 3: Example of the effectiveness of post-processing in handling inconsistent number translation.

2.4.1 Greedy Based Ensembling

Greedy based ensembling adopts an easy operable greedy-base strategy to search for a better single model combinations on the development set, which consistently shows better performance than simply average in our preliminary study, therefore we technically follow the instruction of Deng et al. (2018) to choose the optimal combination of checkpoints to enhance the generalization and boost performance of the final model. We refer to this method as "Ensemble" in the following.

2.4.2 Generalization Finetuning

As the general domain evaluation is on multi-domain directions, *i.e.* containing (up to) four dif-

Languages	**# Sents**	**# Ave. Len.**

Ru	8,351,860,471	28.5
Ja	5,534,872,418	27.9

Table 4: Data statistics after pre-processing.

ferent domains, we design generalization finetuning strategy to transductively finetune (Wang et al., 2020b) on each domain, and ensemble them into one single model, to empower the general translation ability. The proposed generalization finetuning is shown in Algorithm 1. The main difference from Multi-Model & Multi-Iteration Transductive Ensemble (Wang et al., 2021) is that the k_{th} domain seed D_k is extracted from the test set using heuristic artificial knowledge.

2.4.3 Post-Processing

In addition to general post-processing strategies (*e.g.* de-BPE), we also employ a post-processing algorithm (Wang et al., 2018) for inconsistent number, date translation, for example, "*2006-07*" might be translated to the wrong translation "*2006 at 07*". Our post-processing algorithm will search for the best matching number string from the source sentence to replace these types of errors (see Table 3). Besides, we also conduct punctuation conversion, including convert quotation marks to German double-quote style (Czech, German), convert punctuation to language-specific characters (Japanese, Chinese).

3 Data Preparation

We participated in translation of all high-resource tracks and one medium-resource track, including Chinese↔English (Zh↔En), German↔English (De↔En), Czech↔English (Cs↔En), Russian↔English (Ru↔En), and Japanese↔English (Ja↔En).

In this section, we take the En↔Zh translation as example and describe how to prepare the training data. The setting is the same for other language pairs. We use all available parallel corpus for En↔Zh [§], including ParaCrawl v9, News Commentary v16, Wiki Titles v3, UN Parallel Corpus V1.0, CCMT Corpus, WikiMatrix and Back-translated news. For monolingual data, we randomly sample from "News Crawl" and "Common Crawl". The final corpus statistics are presented in Table 4.

To improve the quality of parallel data, we further propose to filter the low-quality samples. First, we remove the sentence pair which is predicted as wrong language with `Fasttext` (Joulin et al., 2017, 2016). Second, we replace unicode punctuation and also normalize punctuation with `mosesdecoder`. We also remove duplicate sentence pairs and filter out sentences with illegal characters. For length, we remove sentences longer than 250 words and with a source/target length ratio exceeding 3.

4 Experiments

Settings We use the extremely large Transformer ($\mathcal{M}_{\textbf{XL}}$) for all tasks and Transformer-BIG ($\mathcal{M}_{\textbf{BIG}}$) for bilingual baselines. For $\mathcal{M}_{\textbf{BIG}}$, we empirically adopt large batch strategy (Edunov et al., 2018) (*i.e.* 458K tokens/batch) to optimize the performance. The learning rate warms up to 1×10^{-7} for 10K steps, and then decays for 70K steps with the cosine schedule. For regularization, we tune the dropout rate from [0.1, 0.2, 0.3] based on validation performance, and apply weight decay with 0.01 and label smoothing with $\epsilon = 0.1$. We use Adam optimizer (Kingma and Ba, 2015) to train models. We evaluate the performance on an ensemble of last 10 checkpoints to avoid stochasticity. For the main model $\mathcal{M}_{\textbf{XL}}$, we adopt 1M Tokens/Batch to optimize the performance both in multilingual pretraining and bilingual finetuning. We set 0.1 as the label smoothing ratio, 4000 as warm-up steps, and 1e-3 as the learning rate. We optimize Vega-MT with Adam (Kingma and Ba, 2015). We use 100k updates for multi-directional pretraining, 40k updates for each specific-directional finetuning. For

evaluation, we select SacreBLEU (Post, 2018) as the metric for all tasks. `news-test2020` and `news-test2021` are selected for validation and test respectively.

All parallel data will be used in the multi-directional PT stage, and during specific-directional FT, corresponding bilingual data augmented by bidirectional self-training are utilized. Each sentence are jointly tokenized in to sub-word units with SentencePiece (Kudo and Richardson, 2018), which is trained on all concatenated multilingual parallel data for Transformer-XL with merge operation 120K at the pretraining stage, and during finetuning stage, is trained on corresponding bilingual data with merge operation 60K for English and 75K for other languages. And for each baseline with Transformer-BIG, the joint bilingual vocab size is 80K. During pretraining, we select the sample with temperature-based method (T=5) to preserve the representation of relatively low-resource language, *e.g.* Japanese. We grid-search the beam size within the range of [3,4,5,..,8] on validation set for each translation task. All models are trained on 32 DGX-SuperPOD A100 GPUs for about two weeks pre-training and five days fine-tuning.

Main Results To illustrate the effectiveness of each strategy in our Vega-MT, we report the ablation results in Table 5 on Zh↔En tasks. Clearly, directly generating the translations with the multi-directional pretrained model could obtain average +3.2 and +1.9 BLEU improvements for Zh-En and En-Zh, respectively, which is consistent with the findings of Tran et al. (2021). We show that tuning on downstream bilingual data could further improve the translation by +1.4 BLEU points, showing the necessity of bridging the cross-lingual gap with in-domain learning during leveraging multilingual pretrain (Zan et al., 2022a). Bidirectional self-training actually contains several strategies, *e.g.* back translation, distillation and data diversification, and we empirically show that such data augmentation strategy nicely complement pretraining, which is also verified by Liu et al. (2021). Other strategies could consistently enhance the translation performance besides the generalization FT for the news domain

Models	Zh→En	De→En	Cs→En	Ru→En	Ja→En	Δ

Table 7: **COMET-Scores of our submissions in WMT2022 general translation task.** "Baseline" indicates the performance of the baseline systems. And "Best Official" denotes the best results of constrained systems in each direction.

test2021, where the Zh-En model decreases the BLEU scores (-0.8 BLEU) because the generalization FT is designed and tuned for the general domain test2022.

Table 6 and Table 7 show the final submissions in terms of SacreBLEU and COMET scores, including Zh, De, Cs, Ru and Ja to/from En, listing the baseline and our final submissions. We also report the best official scores among all constrained systems "Best Official" as reference. As seen, SacreBLEU and COMET results show identical trends, where our Vega-MT outperforms baseline Transformer-BIG by +11.2/ +38.6 and +14.0/ +52.3 BLEU/ COMET points, showing the effectiveness and universality of our model. Interestingly, we observe that the improvements upon En-X are more significant than that of X-En, which will be investigated in our future work. For more system rankings, please refer Table 8 and Table 9 in Appendix for SacreBLEU and COMET results, respectively.

5 Conclusion

This paper presents the JD Explore Academy machine translation system Vega-MT for WMT 2022 shared tasks on general machine translation. We investigate various frameworks, including autoregressive and non-autoregressive Transformer with BASE, BIG and XL settings, respectively, to build strong baseline models. Then we push the limit of bidirectional training by scaling up two main factors, *i.e.* language pairs and model scales, to develop the powerful foundation Vega-MT model. Also, the popular data augmentation methods, *e.g.* cycle translation and bidirectional self-training, are combined to improve their performance. We carefully design the generalization adaptation strategies to further improve the multi-domain performance. Among all participated constrained systems, our Vega-MT won 7 champions, 2 runners-up and 1 third place w.r.t sacreBLEU. And according to the COMET, we won 8 champions and 2 runners-up.

Acknowledgments

The authors wish to thank the organizers of WMT2022 for their great efforts in the organization, and their prompt responses to our questions. The authors are grateful to the anonymous reviewers for their insightful comments and careful proofreading. The authors also specially thank Yukang Zhang (JD Explore Academy), who kindly supports us by maintaining a stable computing platform.

No Domain Left Behind

Hui Zeng
LanguageX AI Lab
felix_zeng_ai@aliyun.com

Abstract

We participated in the WMT General MT task and focus on four high resource language pairs: English to Chinese, Chinese to English, English to Japanese and Japanese to English). The submitted systems (LanguageX) focus on data cleaning, data selection, data mixing and TM-augmented NMT. Rules and multilingual language model are used for data filtering and data selection. In the automatic evaluation, our best submitted English to Chinese system achieved 54.3 BLEU score and 63.8 COMET score, which is the highest among all the submissions.

1 Introduction

Training neural machine translation models for a specific domain is a well-studied task. However, maximizing the performance of a single NMT model for multiple domains remains difficult. As a former translator and a current machine translation engineer, I always dream about building a versatile machine translation system – no domain left behind. Our neural machine translation system is developed using big transformer (Vaswani et al., 2017) architecture and the toolkit I used is fairseq (Ott et al., 2020). Rules, multilingual language model and faiss (Johnson et al., 2021) are used to align, clean and select parallel data. The following techniques are used in model training: a. Data mixing is used to mix general domain corpus with specific domain corpus; b. Back translation (Sennrich et al., 2016) is not applied because it is time-consuming. Instead, Neural Machine Translation with Monolingual Translation Memory (Cai et al., 2021) is used to fully utilize the monolingual corpus.

2 Data Filtering and Selection

The Chinese-English parallel data is mainly from CCMT Corpus[1], inhouse domain data from translation projects, as well as parallel data aligned from multilingual websites and e-books. The monolingual data for multiple domains is collected from the internet and e-books. WMT newstest2021 is used to evaluate the model's general domain performance. Multiple domain-specific test sets are created to evaluate the model's specific domain performance. Each domain has a test set of 1,000 sentences.

In order to build a versatile machine translation system, a total of 15 domains are covered in preparing the parallel and monolingual corpus. The primary domains and subdomains are listed as follows:

Literature
Web novel
Famous literary work
Literature/Poetry
Idioms/maxims/sayings
Slang
Conversation
Names (personal, company)
Symbols / Abbreviations / Acronyms

Art, History and Philosophy
Arts/crafts/painting
Cooking/culinary/gastronomy

2.1 Monolingual Data Filtering

The monolingual data for 15 primary domains are mainly collected from websites and e-books. The following rules are used for a simple cleaning:
•Remove duplicated sentences.
•Remove the sentences containing special characters.
•Remove the sentences containing html addresses or tags.

2.2 Parallel Corpus Aligning

There are a large number of multilingual websites and multilingual e-books, which are easily accessible. However, these data need to be aligned to create sentence level parallel corpus. To this end, a corpus aligner is created using Sentence-BERT (Reimers et al., 2019) and faiss (Johnson et al., 2021).

Regardless of order, thousands of source sentences and target sentences are first encoded into sentence embeddings using Sentence-BERT, and then faiss is used to retrieve the target sentences which is most similar in meaning to the source sentences. The aligning of thousands of parallel sentences could be finished within a few seconds.

2.3 Parallel Data Filtering Using Rules

The following rules are used to filter parallel corpus.

a. Remove duplicated sentence pairs.
b. Remove the lines having identical source and target sentences.
c. Remove the sentence pairs containing special characters.
d. Remove the sentence pairs containing html addresses or tags.
e. Remove the sentence pairs with empty source or target side.

2.4 Parallel Data Filtering Using Multilingual Language Model

As mentioned in section 2.2, a corpus aligner is created using Sentence-BERT (Reimers et al., 2019) and faiss (Johnson et al., 2021). This can also be used to filter parallel data.

Apart from the corpus aligned from websites and e-books, in-house data from translation projects and public corpus like CCMT are also used.

The aforesaid corpus aligner can be used to score each parallel sentence pair so that the pairs with extremely low scores can be removed.

3 System Description

This section illustrates how the model is trained step by step.

3.1 Data pre-processing

For data preprocessing, we use the tokenizer developed on my own to process both Chinese and English. Chinese text (including punctuations and numbers) is split to single character level. We keep the upper- and lower-case letters of English as they are, since we believe they are also important features for the model. Numbers in English text are also split into single digits. We use byte pair encoding (BPE) (Sennrich et al., 2016) to create a shared vocabulary, so that the vocabulary size is reduced to 45467. We also wrote a post-processor to restore the Chinese and English text to normal form.

3.2 Baseline Model Training

WMT newstest2021 is used to evaluate the model's general domain performance. Multiple domain-specific test sets are created to evaluate the model's specific domain performance. Each domain has a test set of 1,000 sentences.

The CCMT parallel Corpus filtered by rules and corpus aligner is used to train big transformer (Vaswani et al., 2017) English to Chinese and Chinese to English translation models as the general domain baselines.

Validation is performed every 2000 steps. The training is terminated if there is no gain in BLEU (Papineni et al., 2002) for 20 consecutive validations.

The BLEU scores on specific domains are also calculated as baselines.

3.3 Training on Mixed Data

Data mixing (Hasler et al., 2021) is used to improve translation quality for multiple new domains represented by small amounts of parallel data while maintaining the performance of a high-quality, general-purpose NMT model.

The importance of the training data sample can be increased by increasing its size, thereby

Model + Corpus	Literature EN2ZH	Law EN2ZH	Medical EN2ZH	Newstest2021 EN2ZH
filtered CCMT Corpus big transformer	21.5	23.2	19.8	28.7
filtered CCMT Corpus data mixing (general data, domain specific data) big transformer	28.7	38.6	36.3	35.9
filtered CCMT Corpus data mixing (general data, domain specific data) NMT with domain specific monolingual translation memory	31.2	43.5	40.1	39.2

Table 1: Different systems and their BLEU scores (only three typical domains are listed)

changing the ratio of training data and domain data to influence the trade-off between generic and domain performance.

3.4 NMT with Monolingual Translation Memory

Prior work has proved that Translation memory (TM) can boost the performance of Neural Machine Translation (NMT). In contrast to existing work that uses bilingual corpus as TM and employs source-side similarity search for memory retrieval, Cai (Cai et al., 2021) proposed a new framework that uses monolingual memory and performs learnable memory retrieval in a crosslingual manner.

This framework has unique advantages. First, the cross-lingual memory retriever allows abundant monolingual data to be TM. Second, the memory retriever and NMT model can be jointly optimized for the ultimate translation goal. The "plug and play" property of TM is useful for domain adaptation, where a single general-domain model can be adapted to a specific domain by using domain-specific monolingual TM.

3.5 Results

The BLEU scores on general test sets and some domain specific test sets for each corpus plus model combination are shown in Table 1.

In the automatic evaluation, our best submitted English to Chinese system achieved 54.3 BLEU score and 63.8 COMET score, which is the highest among all the submissions.

4 Conclusion

This paper describes LanguageX's translation system for the WMT2022 General MT task. The potential of a single translation model for all domains is explored. We are pleased to argue that, with data mixing and TM-augmented NMT, a versatile machine translation system with all-round translation performance could be built.

Acknowledgments

Thanks to my wife who spends most of her time to take care of our two kids, so that I am able to participate in the contest and complete this paper.

GTCOM Neural Machine Translation Systems for WMT22

Hao Zong, Chao Bei, Conghu Yuan
Global Tone Communication Technology Co., Ltd
{zonghao,yuanconghu}@gtcom.com.cn
chaobei001@gmail.com

Abstract

This paper describes the Global Tone Communication Co., Ltd.'s submission of the WMT22 shared general MT task. We participate in six directions: English to/from Ukrainian, Ukrainian to/from Czech, English to Croatian and English to Chinese. Our submitted systems are unconstrained and focus on backtranslation, multilingual translation model and finetuning. Multilingual translation model focus on X to one and one to X. We also apply rules and language model to filter monolingual, parallel sentences and synthetic sentences.

1 Introduction

We applied fairseq(Ott et al., 2019) as our develop tool and use transformer(Vaswani et al., 2017) as the main architecture. The primary ranking index for submitted systems is BLEU(Papineni et al., 2002), therefore we apply BLEU as the evaluation matrix for our translation system by using sacreBLEU[1].

For data preprocessing, punctuation normalization, tokenization and BPE(byte pair encoding) are applied for all languages. Further, we apply truecase model for English, Ukrainian, Czech and Croatian according to the character of each language. Regarding to the tokenization, we use polyglot as the tokenizer for Ukrainian and Croatian, and mosese tokenizer.perl for English and Czech. Besides, knowledge based rules and language model are also involved to clean parallel data, monolingual data and synthetic data.

This paper is arranged as follows. We firstly describe the task and show the data information, then introduce our baseline and multilingual translation model. After that, we describe the conducted experiments in detail in all directions, including data preprocessing, model architecture, back-translation and multilingual translation model. At last, we analyze the results of experiments and draw the conclusion.

2 Task Description

The task focuses on bilingual text translation and the provided data is shown in Table 1, including parallel data and monolingual data. For the directions between English and Ukrainian, the parallel data is mainly from ParaCrawl v9, WikiMatrix, Tilde MODEL corpus and OPUS, as well as the directions English to Croatian. For the directions between Ukrainian and Czech, the parallel data is mainly from WikiMatrix and OPUS. The monolingual data we used includes: News Crawl in English, Ukrainian, Croatian and Czech; Leipzig Corpora in Croatian, Ukrainian and Czech; News discussions in English. All language directions we participated in are new tasks this year, therefore we only use the provided development set from FLoRes101 dataset for all directions.

Usually, the news translation task will take the human evaluation result as the final ranking index. And this requires each participated team contribute 8 hours of human evaluation for each participating translation direction. For some low resource language directions, it is not very easy for the organizer to employ human translators from the participating team or translation agency. Besides, due to the number of sentences in the test set and the quantity of participating teams, it is not possible to employ human evaluation for all the test sets. Besides, with recent improvements of MT quality, the organizer decided to move away from testing only in the news domain and we are shifting the WMT focus on testing the general capabilities of MT systems.

3 Billingual Baseline Model and Multilingual Translation Model

To set a strong baseline for our multilingual model as a comparison. Our Billingual base-

hr monolingual data	13M
en-uk development set	997
en-hr development set	997
uk-cs development set	997

Table 1: Task Description

line model is different from the transformer base model transformer_wmt_en_de with 6 encoding layers and 6 decoding layers. Instead, we set our bilingual baseline model by using transformer_vaswani_wmt_en_de_big architecture with 12 encoding layers and 4 decoding layers.

The multilingual translation model is almost the same as GTCOM2021(Bei and Zong, 2021), but focuses on one to X and X to one this year. To obtain a better translation quality, we include Russian as the main auxiliary language since Russian and Ukrainian are very similar. We train four multilingual models: 1. ru-en, uk-en and hr-en to translate uk-en; 2. en-ru, en-uk and en-hr to translate en-uk and en-hr; 3. cs-uk, en-uk and ru-uk to translate cs-uk 4. en-uk; uk-cs and en-cs to translate uk-cs and en-cs. We use joint BPE for all languages in the multilingual model separately.

For English to Chinese direction, we just test our online system as a comparison with other participating systems. Therefore we did not conduct data augmentation, finetuning, or any other adaption experiments.

4 Experiment

4.1 Training Step

This section introduces all the experiments we set step by step and Figure 1 shows the whole flow.

- **Date Filtering** The methods of data filtering are mainly the same as we did last year, including human rules, language models, and repeat cleaning.

- **Baseline.** We use big transformer architecture with 24 layers of encoder and 4 layers of decoder to construct our baseline.

model	en2uk	uk2en
baseline	32.43	40.08
back translation	32.58	40.84
joint training	32.97	42.33
deep multilingual translation model	33.72	43.27

Table 2: The BLEU score between English and Ukrainian.

model	uk2cs	cs2uk
baseline	22.52	22.00
back translation	25.51	23.59
joint training	25.72	24.09
deep multilingual translation model	26.14	24.89

Table 3: The BLEU score between Czech and Ukrainian.

- **Back-translation.** We use a multilingual translation model to translate the target sentence to the source side, and clean synthetic data with language model. Here, we translate each language pairs we have added into the multilingual translation model. Mix cleaned back-translation data and parallel sentences and train multilingual translation model.

- **Joint training.** Repeat the back-translation step by the best model, until there is no improvement.

- **Multilingual translation model.** We focus on one to X and X to one model, and each multilingual model has joint BPE and a shared vocabulary. The multilingual translation model setting follows Google's Multilingual Neural Machine Translation System(Johnson et al., 2017).

- **Deep multilingual translation model.** Using bilingual parallel data and synthetic data by the best model, train the multilingual transformer model with 12 encoding layers and 4 decoding layers, then repeat the back-translation step and forward-translation step, until there is no improvement.

- **Ensemble Decoding.** We use GMSE Algorithm (Deng et al., 2018) to select models to obtain the best performance.

Figure 1: The work flow of GTCOM machine translation competition systems

model	en2hr
baseline	30.15
back translation	32.90
joint training	33.80
deep multilingual translation model	34.93

Table 4: The BLEU score for English to Croatian.

5 Result and Analysis

Table 2, Table 3 and Table 4 show the BLEU score we evaluated on development set for English to/from Ukrainian, Czech to/from Ukrainian and English to Croatian respectively. As shown in the above table, back-translation is still the best data augmentation measure to improve translation quality from the data aspect. Joint training and deep multilingual translation model also show solid improvement in all five directions.

We notice that when adding Russian (a very similar language to Ukrainian) into the multilingual corpus, we did not obtain as much improvement as we expect. This is probably because the original English to Ukrainian data is rich enough and decreased the positive impact of adding Russian data into the multilingual model.

6 Conclusion

This paper describes GTCOM's neural machine translation systems for the WMT22 shared general MT task. We applied 3 major techniques to improve the translation quality: back-translation, joint training, and deep multilingual translation model. With these 3 techniques, the final automatic evaluation matrix is shown in Table 5. Besides BLEU, this year the organizer introduce a new evaluation matrix COMET(Rei et al., 2020) to inspect the translation quality. Our system is ranking 1st place in English->Ukrainian and English->Chinese, 2nd place in Ukrainian-English, Czech ->Ukrainian and English->Croatian, 7th place in Ukrainian->Czech with COMET index.

Direction	BLEU	COMET Rank
en2uk	30.8	1
uk2en	43.9	2
cs-uk	36.8	2
uk-cs	31.3	7
en-hr	17.6	2
en-zh	47.7	1

Abstract

This document describes a fine-grained linguistically motivated analysis of 29 machine translation systems submitted at the Shared Task of the 7th Conference of Machine Translation (WMT22). This submission expands the test suite work of previous years by adding the language direction of English–Russian. As a result, evaluation takes place for the language directions of German–English, English–German, and English–Russian. We find that the German–English systems suffer in translating idioms, some tenses of modal verbs, and resultative predicates, the English–German ones in idioms, transitive-past progressive, and middle voice, whereas the English–Russian ones in pseudogapping and idioms.

1 Introduction

Neural Machine Translation has seen enormous progress and reached a quality that is helpful for many everyday use cases. However, several methods for evaluating MT suggest that there is still plenty of room for improvement. An evaluation method for revealing the translation flaws in a more structured way refers to the use of *test suites* or *challenge sets*. Contrary to the classical evaluation, where test sets are drawn from random everyday texts, test suites consist of manually devised or selected sentences that focus on testing the ability of the MT systems to translate a particular phenomenon. Here, we are presenting test suite results while analyzing the state-of-the-art systems with regard to many linguistically-motivated phenomena. The test suites[1] were applied to the MT systems submitted at the 7th Conference of Machine Translation (WMT22) for the language directions German–English, English–German, and English–Russian. The test suites for the first two language directions have also been showcased during the previous years, whereas English–Russian is published for the first time.

This paper is structured as follows: Section 2 goes through related papers, whereas Section 3 explains how the test suite was created and applied. Section 4 outlines the setup of this year's experiment, whose results are detailed in Section 5. Section 6 concludes the paper with an outlook to future research.

2 Related Work

The first test suites were introduced as early as the first MT systems in the 1990s (King and Falkedal, 1990; Way, 1991; Heid and Hildenbrand, 1991). Recent years saw the rise of Deep Learning and the drastic improvement of the quality of MT outputs, which has led to the current revival of test suites. Most of these test suites, however, focus on evaluating specific linguistic phenomena, e.g., Guillou and Hardmeier (2016), or on the comparison of different MT technologies (Isabelle et al., 2017; Burchardt et al., 2017), and Quality Estimation methods (Avramidis et al., 2018).

Over the last few years, several test suites for multiple language directions have emerged as a part of the Conference on Machine Translation test suite track. These test suites, however, focus on one or a few different phenomena, including the works of Popović (2019) Cinkova and Bojar (2018), Bojar et al. (2018), Rysová et al. (2019), Vojtěchová et al. (2019), Kocmi et al. (2020), Zouhar et al. (2020), Burlot et al. (2018), Guillou et al. (2018), Rios et al. (2018), Raganato et al. (2019), Scherrer et al. (2020). Our test suite, on the other hand, performs a systematic evaluation of more than one hundred phenomena per language direction (Macketanz et al., 2022). Similar to our work, the test suite approach and human evaluation are also used to evaluate MT quality metrics (Freitag et al., 2021; Avramidis and Macketanz, 2022).

[1] https://github.com/DFKI-NLP/mt-testsuite

Test set	Test sentences	Categories	Phenomena
De–En	~5,500	14	106
En–De	~4,400	13	110
En–Ru	~300	12	51

Table 1: Metadata of the language pairs in the test suite.

3 Method

We have created a large-scale test suite with the goal of testing and comparing the performance of MT systems. Currently, the test suite covers four different language pairs. We will present three in this paper: German to English, English to German, and English to Russian (the fourth language pair being Portuguese to English). The test suite is based on a number of linguistic categories which are in turn divided into more fine-grained linguistic phenomena. The categories and phenomena are language-specific; however, there is a significant overlap between many of the categories and phenomena across the different language pairs. Each linguistic phenomenon in the test suite is represented by multiple test sentences. All categories, phenomena, and test sentences are the result of extensive research and knowledge of the syntax and morphology of the languages under inspection. The categories and phenomena do not follow a specific linguistic theory, but they were created by linguistic experts who are native speakers or highly proficient speakers of the languages. Furthermore, the set of categories and phenomena was reviewed internally by linguists and experienced translators to achieve objectivity in the classification.

The number of test sentences, categories, and phenomena for each language pair can be found in Table 1. As can be seen in the table, the English–Russian test set is considerably smaller than the other two test sets. This is due to the fact that we started creating the English–Russian test set only recently. However, we are currently working on expanding the test set by creating more phenomena and test sentences.

In order to allow for a semi-automatic evaluation of the test sentences, we have created a set of rules which determine whether a test sentence is translated correctly or incorrectly. The rules consist of hand-crafted regular expressions and fixed strings of translation outputs. They can be applied with the help of an internal evaluation tool (Macketanz et al., 2022). The workflow of the preparation and application of the test suite is depicted in Figure 1.

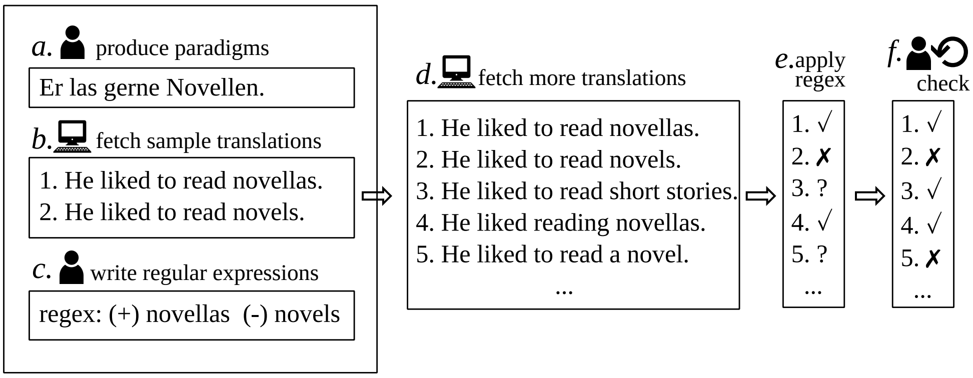
3.1 Application of the test suite

The thorough building and application of the test suite can be found in the previous test suite track papers (Macketanz et al., 2018; Avramidis et al., 2019, 2020; Macketanz et al., 2021). This paper gives a quick overview of the whole system. As shown in Figure 1, the building of the test suite follows steps a to c. Once the test sentences are fed as input to the MT systems, begins the application of the test suite (step d). The MT outputs are then automatically evaluated by the test suite tool with the help of the rules defined earlier by linguists and annotators (step e). The rules combine pre-set regular expressions and fixed strings (correct and incorrect translations from earlier MT system outputs). The rules are designed to evaluate each phenomenon in question's correct and incorrect translations. Note that only the phenomenon under inspection is being evaluated, meaning that all translation errors that are unrelated to the phenomenon are being ignored. The test sentence is marked with a warning if the output cannot be automatically sorted as correct or incorrect with the predefined rules. These warnings are then manually reviewed by human linguist annotators who decide on the translation's correctness and adapt the rules accordingly (step e). After that, the phenomenon-specific translation accuracy is calculated by dividing the number of correctly translated test sentences of a phenomenon by the total number of test sentences of that phenomenon:

$$\text{accuracy} = \frac{\text{correct translations}}{\text{sum of test items}}$$

Since this evaluation aims to compare the systems fairly, only the test items that do not contain any warnings for any systems are included in the calculation. If a test item has an unresolved warning for any MT systems, we exclude them from the calculation. Unfortunately, this reduces the number of test items. We see great importance in the extensive manual evaluation and human annotators designing rules with good coverage.

To define which system(s) perform better for a particular phenomenon (or category), we first identify the best scoring system in each language direction and then compare it to other systems. To do so, we confirm the significance of the comparison with a one-tailed Z-test with $\alpha = 0.95$. The systems that do not differ significantly from the best system are considered in the first performance cluster and indicated with boldface in the tables.



a. produce paradigms
Er las gerne Novellen.
b. fetch sample translations
1. He liked to read novellas.

Figure 1: Example of the preparation and application of the test suite for one test sentence

The boldfaces, therefore, have a meaning only for the respective row of the table.

The average scores are computed in three ways as each category or phenomenon has a different number of test items. Micro-average aggregates the contributions of all test items to compute the average percentages. Category macro-average computes the percentages independently for each category and then averages them (i.e., treating all categories equally). Phenomenon macro-average computes the percentages independently for each phenomenon and then takes the average (i.e., treating all phenomena equally).

4 Experiment Setup

In this paper, we present the evaluation of 29 systems with our test suite. The systems are part of the *news translation task* of the Seventh Conference on Machine Translation (WMT22). The systems cover three different language pairs: nine systems for German–English, nine systems for English–German, and 11 systems for English–Russian.

This year is the second time that the English–German systems are being evaluated and the first time that the English–Russian systems are being evaluated with our test suite. Every year, manual work is involved upon receiving the system translations as there are usually a number of translation outputs that are not yet covered by the existing rules in the database (the warnings). This year, there were on average 7.8 % of warnings for German–English, 9.7 % for English–German, and 20,6 % for English–Russian. It is not surprising that the English–Russian test set had a comparably bigger amount of warnings as this was the first time the test set was evaluated and therefore, the database of evaluation rules for this language pair was still rather small. It was also expected that English–German would have a higher amount of warnings than German–English as the German–English test set has the largest rules database since this language pair has been evaluated five years in a row.

Two annotators with extensive linguistic knowledge of the three languages under investigation conducted the manual evaluation of the warnings. No inter-annotator agreement was calculated; however, problematic cases were discussed with several linguistic experts to exclude subjectivity. The manual evaluation took around four weeks and involved around 50 person-hours. After the manual evaluation, there were on average 1.2 % of warnings left for German–English, 3.2 % for English–German, and 0.7 % for English-Russian.

As mentioned above, test sentences with at least one warning by one system were excluded from the analysis to achieve a fair comparison between the systems under inspection. As a result, our analysis was conducted on 5049 (91 %) test sentences for German–English, 3723 (83 %) test sentences for English–German, and 300 (97 %) test sentences for English–Russian.

5 Results

All result tables can be found in the Appendix.

5.1 System comparison

For **German–English**, two systems have the highest micro-average (85 %), Online-W and Online-A, whereas when considering the macro-average, three more systems also achieve the highest scores (89-90 %), Online-B, Land-Bridge, and JDExplore-Academy.

For **English–German**, two systems have the highest micro-average (97 %), Online-B and Lan-

Bridge. However, on the macro-average, a different system displays the highest score (94 %), JDExploreAcademy. The system with the lowest micro- and macro-average, Online-Y, still achieves scores of 84 % for both averages.

For **English–Russian**, the same four systems achieve the highest scores on both the micro- (78-81 %) and the macro-average (82-85 %), Online-W, Online-G, Online-B, and JDExploreAcademy. The average scores of English–Russian on the category level are comparably smaller than the scores of German–English and English–German. One plausible explanation is that English and Russian are more distant from a typological perspective than English and German.

5.2 Category-level analysis

For **German–English**, the categories with the highest average by all systems (> 90 %) are *composition*, *coordination & ellipses*, *named entity & terminology*, *negation*, and *non-verbal agreement*. The category with the lowest average score (77.2 %) is *false friends*.

For **English–German**, the categories with the highest average scores (> 96 %) are *function words*, *negation*, *non-verbal agreement*, *subordination*, and *verb tense/aspect/mood*. The category with the lowest average score (77.8 %) is *punctuation*.

For **English–Russian**, the category with the highest average score (92 %) is *punctuation*, with seven of the 11 systems achieving 100 % of accuracy, followed by *ambiguity*, *function words*, *negation*, and *subordination* (all > 80 %). The category with the lowest accuracies is *coordination & ellipsis*, followed by *false friends*.

5.3 Phenomenon-level analysis

For **German–English**, there are many phenomena that reach an average of 90-100 %, while the phenomenon macro-average reaches 85 %. Phenomena that reach more than 95 % of accuracy are *gapping*, *sluicing*, *polar question*, *verbal MWE*, *date*, *measuring unit*, *negation*, *internal possessor*, *comma*, *infinitive clause*, *object clause*, several verb tenses in *ditransitive*, *intransitive*, *transitive*, and *modal verbs*, and *passive voice*.

Yet there are some phenomena with a very low accuracy: The phenomena *idiom*, *modal pluperfect*, *modal pluperfect subjunctive II modal negated pluperfect*, *modal negated pluperfect subjunctive II*, and *resultative predicates* are the phenomena with the lowest averages, ranging only between 20-57 % accuracy. This result goes hand in hand with last year's result where the phenomena *modal pluperfect*, *resultative predicates*, and *idioms* reached the lowest accuracy.

Idiom	
Er macht aus einer Mücke immer gleich einen Elefanten.	
It always makes out of a mosquito an elephant.	fail
He always turns a gnat into an elephant.	fail
He always makes a mountain out of a molehill.	pass
Modal negated pluperfect	
Ich hatte nicht lesen sollen.	
I wasn't supposed to read.	fail
I shouldn't have read.	fail
I didn't want to read.	fail
Right node raising	
Lena soll und Tim will den Vertrag kündigen.	
Lena will and Tim will terminate the contract.	fail
L. should and T. want to terminate the contract.	fail
L. should and T. wants to terminate the contract.	pass

Table 2: Examples of German–English linguistic phenomena with passing and failing MT outputs.

Table 2 contains example outputs from three different phenomena for German–English. The first example is from the phenomenon *idiom*. Idioms are multiword expressions whose meaning goes beyond the meaning of their separate elements. This also means that a simple literal translation into another language is usually incorrect. In our example at hand, the German idiom "aus einer Mücke einen Elefanten machen" means "to blow something out of proportion". A literal translation like the first and second outputs leads to an incorrect English meaning. What is further interesting about the incorrect outputs is that while the second one ("turns a gnat into an elephant") is at least grammatically correct, the first one ("makes out of a mosquito an elephant") is also grammatically incorrect. The translation of "Mücke" ("mosquito") as the term "gnat" is also unexpected. Only the third translation "makes a mountain out of a molehill" is a correct translation of this idiom.

The second example contains a *negated modal verb* in the *pluperfect tense*. The German sentence "Ich hatte nicht lesen sollen." can only be correctly translated as "I had not been supposed to read". This year, all systems failed to produce this correct output. Instead, there were different incorrect outputs with incorrect tenses ("I wasn't supposed to read.", "I shouldn't have read.") or incorrect translations of the modal verb ("I didn't want to read.").

The third example sentence contains an elliptical *right node raising construction*. *Right node raising constructions* often consist of parallel coordinate sentences (sentences joined by “and”) in which two conjuncts share some material on the right side of the structure. In the example sentence, the two conjuncts “Lena soll” (“Lena should”) and “Tim will” (“Tim wants to”) are sharing the material “den Vertrag kündigen” (“terminate the contract”) on the right side of the construction. In the first incorrect example, the verbs “soll” and “will” are both translated as “will” which is an incorrect translation for both verbs. In the second incorrect output, the verbs are translated correctly, however, the verb “want” is incorrectly conjugated, missing the third person singular ending. Surprisingly, there were multiple systems that created this incorrectly conjugated translation.

At this point, it is also interesting to mention that there was one system that often incorrectly conjugated the verb “to sleep” in the past tense: Instead of “slept”, the outputs by that particular system often contained the non-existing conjugation “sleeped”.

For **English–German**, the phenomenon-level macro-average is similarly high as for the other language direction with 93 %. The phenomena for which all systems reach 100 % accuracy are *question tag*, *compound*, *prepositional MWE*, *subject clause*, *intransitive - present perfect progressive, present perfect simple, simple present*, and *transitive - future I progressive*.

The phenomena with the lowest accuracies, ranging between 35-61 %, are *idioms*, *transitive - past progressive*, and *middle voice*. These results are more in line with last year’s results, as *idioms* and *middle voice* were also among the lowest accuracy phenomena.

Table 3 contains correct and incorrect translation examples from English–German. The first example contains a *coreference*. While many English nouns are gender-neutral, the same German nouns are in most cases gender specific. This can lead to translation errors if the context of a sentence clarifies the gender in English yet the German translation contains the incorrect gender. The test sentence at hand provides a clear context of the nurse being male. Yet, many systems incorrectly translated “nurse” as the female “Krankenschwester’ instead of the male “Krankenpfleger”. [2]

Coreference	
My brother is a nurse in the local hospital.	
Mein Bruder ist Krankenschwester im örtlichen Krankenhaus.	fail
Mein Bruder ist Krankenpfleger im örtlichen Krankenhaus.	pass
Verbal MWE	
She takes after her mother.	
Sie nimmt nach ihrer Mutter.	fail
Sie hinterlässt ihre Mutter.	fail
Sie kommt nach ihrer Mutter.	pass
Transitive future II progressive	
I will have been playing the piano.	
Ich würde Klavier gespielt haben.	fail
Ich habe Klavier gespielt.	fail
Ich werde Klavier gespielt haben.	pass

Table 3: Examples of English-German linguistic phenomena with passing and failing MT outputs.

The second example contains the *verbal multiword expression* “to take after somebody”. As explained above, multiword expressions cannot be translated literally as their meaning goes beyond their separate elements. The first incorrect output “Sie nimmt nach ihrer Mutter.” is, however, a literal translation of this multiword expression. The second incorrect output “Sie hinterlässt ihre Mutter.” is not a literal translation, yet still incorrect as it means “She leaves her mother behind”. Only the translation “Sie kommt nach ihrer Mutter.”, which is the German equivalent of this multiword expression, is correct.

The third example output contains a *transitive verb* in the tense *future II progressive*. The future II tense was often mistranslated as a conditional II tense “würde gespielt haben” (“would have played”) instead of the correct form “werde”. The second incorrect output contains a completely incorrect tense, the present perfect “habe gespielt” (“have played”).

For **English–Russian**, the phenomenon level macro-average accuracy lies at 76 %. Also for this language pair, there are some phenomena which reach 100 % accuracy for all systems, like *nominal MWE*, *prepositional MWE*, *contact clause*, *indirect speech*, and passive voice. On the other hand, there are quite a few phenomena that reach a very low accuracy, ranging between 30-50 %: *gapping*, *pseudogapping*, *idioms*, *verbal MWE*, *anaphora agreement*, *intransitive verbs*, and *middle voice*. The low accuracies of *idioms* and *verbal MWEs* are

[2] We are aware that genders and their translation are a large topic on their own which we can only scratch on the surface within the scope of our test suite. We would like to point the interested reader to the following research: (Hardmeier et al., 2022)

Collocation	
She is careful to eat light and exercise often.	
Она старается есть легкую пищу и часто занимается спортом.	pass
Она старается есть свет и часто тренируется.	fail
Она осторожно ест легко и часто занимается спортом.	fail
Она следит за тем, чтобы есть мало и часто заниматься спортом.	pass
Pseudogapping	
I don’t know that and don’t think you do.	
Я этого не знаю и не думаю, что вы это делаете.	fail
Я этого не знаю и не думаю, что знаешь.	fail
Я не знаю этого и не думаю, что вы знаете.	pass
Resultative	
He read the children to sleep.	
Он зачитывал детей спать.	fail
Он читал детям спать.	fail
Он читал детям перед сном.	pass

Table 4: Examples of English–Russian linguistic phenomena with passing and failing MT outputs.

not surprising as multiword expressions generally tend to cause translation errors across all language pairs. What is interesting is that the accuracy of *intransitive verbs* is considerably lower than the accuracies of the other verb types. One potential reason might be that in our small-scale English–Russian test suite the intransitives are presented by the verb of motion “to go”, which has a number of equivalents in Russian that can convey various aspects such as tense, frequency, or incompleteness. This ambiguity increases the overall number of equivalents in the training data which could lead to faulty results when analyzing the translations with respect to specific phenomena.

Table 4 covers example translations of some low-accuracy phenomena for English–Russian. The first example contains the *collocation* “to eat light” that does not have an exact equivalent in Russian. The word “light” poses some extra difficulty, as it is lexically and semantically ambiguous in both languages. In different contexts, it could function as an adverb, adjective, or noun. This year, a typical incorrect output is “есть свет” (*est’ svet*) meaning to consume light as in electromagnetic radiation, and “есть/питаться легко” (*est’/pitat’sya legko*), a combination of the verb to eat with an ill-passing adverb. Some possible translations would be Russian equivalents “to eat light food” or “to eat little” that we see in the first and fourth translations.

The second example is taken from the phenomenon of *pseudogapping*. *Pseudogapping* is an ellipsis mechanism in which a part of the verb phrase is omitted. In the example at hand, the non-finite verb part “know” is omitted in the second conjunct of the construction. Instead, the auxiliary verb “do” is used as a substitute for the full verb. Verbal substitution is not common in Russian. Moreover, Russian does not employ auxiliary verbs (such as “to do” or “to be”) to form parallel elliptical constructions standard in English. The verb “does” in the second part of the sentence is translated as “сделает” (*sdelaet*) in the first incorrect Russian translation, leading to an impossible Russian phrasing. The second translation leaves out the subject “you” or “ты” (*ty*) in the conjunct resulting in a syntactically incorrect construction.

The last example contains a *resultative predicate*. *Resultatives* contain a verb with an adjective describing the result of the verb action. *Resultative predicates* usually require a significant construction change to get an equivalent translation in the target language. “He read the children to sleep” would be transformed in Russian as “on chital detyam pered snom” meaning “he read to the children before they were going to bed,” as in the third translation in the table or as “on chital detyam, chtobi oni spali” meaning “he read to the children so that they would sleep”.

5.4 Comparison with previous years

The progress of the systems’ accuracy for particular categories through the last years can be seen in Table 6 for German-English (since 2018) and Table 9 for English-German (since 2021). The calculation has been done based on the common test items without warnings over all these years, which is 4307 items for German-English and 3616 items for English-German. The general trend of this year suggests small but steady improvements for most systems and categories. In a few cases where the accuracies deteriorated, this is only for very few percentage points.

6 Conclusions and Outlook

This paper presents a fine-grained, linguistically motivated test suite to evaluate machine translation outputs. The test suite was applied to evaluate and compare the outputs of 29 machine translation systems in three different language pairs: German–English, English–German, and (for the first time) English–Russian. Altogether, almost 7,000 test sentences, structured in various linguistic categories and phenomena, were evaluated altogether across the three language pairs. Additionally, a comparison to the evaluation in previous years for the language pairs German–English and English–German was drawn.

The average accuracy for most categories and phenomena is relatively high for German–English and English–German, with only about 5 % room for improvement. As compared to last year, this is an improvement of around 5 %. For English–Russian, the average accuracy is not as high, yet still around 80 %.

The high average accuracies do not necessarily mean that the respective categories and phenomena no longer pose difficulties for MT. Instead, it could mean that the difficulty of the test sentences has become too easy over the past few years and should thus be increased. Therefore, we are currently constructing more complex test sentences for German–English and English–German. Further work also includes expanding the English–Russian test suite with more phenomena and more test sentences.

Acknowledgements

This research was supported by the Deutsche Forschungsgemeinschaft (DFG) through the project TextQ, by the German Federal Ministry of Education through the project SocialWear (grant num. 01IW20002) and by the project European Language Grid (ELG), which has received funding from the European Union's Horizon 2020 research and innovation programme (grant agreement no. 825627). We would like to thank Hans Uszkoreit, Aljoscha Burchardt, Ursula Strohriegel, Renlong Ai and He Wang for their prior contributions on the creation of the test suite.

Abstract

The most widely used metrics for machine translation tackle sentence-level evaluation. However, at least for professional domains such as legal texts, it is crucial to measure the consistency of translation of terms throughout the whole text.

This paper introduces an automated metric for term consistency evaluation in machine translation (MT). To demonstrate the metric's performance, we used the Czech-to-English translated texts from the ELITR 2021 agreement corpus and the outputs of the MT systems that took part in WMT21 and WMT22 News Tasks. We show different modes of our evaluation algorithm and try to interpret the differences in the ranking of the translation systems based on standard sentence-level metrics and our approach. We also demonstrate that the proposed metric scores significantly differ from the widespread automated metric scores, and correlate with human assessment.

1 Introduction

Throughout the last decade, the quality of machine translation (MT) has improved significantly, and it is becoming a common phenomenon for various neural MT (NMT) systems to get better scores in manual direct assessment and other metrics than reference human translations (Akhbardeh et al., 2021; Bojar et al., 2018). However, such figures are obtained when the MT outputs are evaluated on the sentence level (i.e., each sentence is assessed separately, without context); in document-level evaluation, human translations typically remain the best, although exceptions exist (Popel et al., 2020). We can explain this situation by the fact that most of the current state-of-the-art NMT systems translate documents sentence by sentence, which thus can provoke inconsistencies in the translation of different linguistic elements – from anaphoric pronouns to named entities and terminology. We focus on the latter.

While term inconsistencies can be tolerable for the general spheres of communication, they are unacceptable for several professional domains, especially legal texts, where the coherent usage of terms is the ultimate characteristic.

In the case of the term translation in the legal domain, the goal of the MT system can be split into several parts:

1. To translate one source term to only one target term (we will call this property "consistency");
2. To ensure that every source term is mapped to a distinct target term (we will call this property "unambiguity");
3. To ensure that the target term is an adequate translation of the source term in general.

In this paper, we present a novel metric that focuses on the consistency and unambiguity of terms, whereas measuring the third parameter, adequacy, is delegated to the mainstream automated metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015). Our proposed metric can be applied automatically, and it needs a small amount of human preprocessing and annotation (for instance, it does not require reference translation of the sentences). However, it can include manually tuned parameters as a variable.

In Section 2, we describe the background in the field of the term consistency in MT; in Section 3 we introduce the algorithm of our metric; in Section 4 we present the data on which the metric is applied; in Section 5 we discuss the results and compare them to the widespread automated metrics in MT. Limitations of our method are highlighted in Section 6.

2 Background

Scholars have been drawing attention to document-level consistency for over a decade. For instance,

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 450 - 457
December 7-8, 2022 ©2022 Association for Computational Linguistics

Hardmeier (2012) presents a number of discourse-related phenomena (such as pronoun use and verb tense modeling) that should be taken into account, as well as an overview of the metrics that were designed to catch the consistency (by that moment, they did not correlate with human judgments much). Since this time, there have been various experiments in enhancing the sentence-level MT models for better consistency, by a variety of means, from hierarchical approaches (Ture et al., 2012) to post-editing the output sentences (Voita et al., 2019b). Notably, the main focus of the proposed systems tends to be on the discourse-related features of texts, such as verb forms, anaphora, ellipsis, named entities, etc. (Voita et al., 2019a), rather than on the terminology consistency.

There has also been progress in designing the evaluation for lexical consistency in domain-specific spheres. For example, the creators of SAO WMT test suite (Vojtěchová et al., 2019) point out that the most accurate evaluation for the audit reports is performed manually by professionals in the field, while neither the automated metrics nor the direct evaluation by non-experts gives valuable information about the ranking of the systems' quality. The same authors in 2020 introduced the concept of the "markables": the linguistic elements to which the human annotators have to pay special attention (Zouhar et al., 2020). In the paper, they considered the domains of Sublease, News, and Audit, and the main markables were the crucial terms in the document. The research reaffirms that the automated metrics such as BLEU are not very informative with respect to term consistency, while the non-professional annotators cannot spot the domain-specific inconsistencies; however, the additional annotation of the "markables" allows even the "lay" annotators to keep in mind the necessary terms, which makes the manual annotation more accurate and informative.

Another notable research by Alam et al. (2021) presents the ideas for automated metrics for the term consistency evaluation, namely, exact match accuracy, window overlap, and TER with bigger penalties for terms. The results of this approach, tested on the domain of medical texts about COVID-19, show a correlation with human professional judgments; however, for most of the metrics, reference translations or at least term dictionaries are necessary. Thus, the relevance of designing more automated metrics in the field is still valid.

3 Metric

Before explaining the metric in detail, we will reiterate our aim. Our first objective is to reward translation consistency (i.e., penalize the one-to-many correspondences in source-to-target term pairs). Secondly, we want translated terms to be unambiguous (i.e., we should penalize the many-to-one correspondences in source-to-target term pairs). Optionally, we also want to include adequacy in our estimation (i.e., penalize the inappropriate translation of the term); otherwise, we will rely on the widely accepted metrics for adequacy. Finally, we want the algorithm to be as automatic as possible, i.e., to avoid the necessity of human annotation on any level. To meet these demands, we introduce the following pipeline.

1. **General preprocessing**: We tokenize the texts. The tokenization needs to be consistent in both source and target texts to run the alignment algorithms (Step 3 below).

2. **Source terms extraction**: We extract "crucial" terms in the source text. The task can be reduced to keyword extraction, which has various approaches. In our study, we used the manual method based on regular expressions: in legal-like texts, the terms relevant for the document are announced uniformly at the beginning of the document (for example, by the phrases "hereinafter referred as..."). We justify this choice in Section 6. As a result of this step, we get a set of the terms that occur in the text (hereinafter: src term set), and, for each sentence, we get a list of terms that appear there.

3. **Term Alignment**: For automation, we suggest using any word alignment algorithm. In this experiment, we used fast-align algorithm introduced by Dyer et al. (2013). Now, for each text separately, we extract the alignments of the source terms obtained in Step 1.[1] At the end of this step, for each document, we have, firstly, lists of aligned target terms in each sentence, secondly, the dictionary of source terms and the counts of their corresponding alignments in this text (hereinafter: src-tgt dict).

[1] To create a better word alignment, we firstly collect all outputs of the same system into one text, apply fast-align to such big texts, and then split the alignments back to the initial document level.

4. **Choosing the “pseudo-reference” translations**: To measure the performance of the MT system, we have to compare the real occurrences of the translations (obtained in Step 3, hereinafter called “candidate” translations) to the translations that we expect to be used throughout the text (we call them “pseudo-reference” translations). Choosing the pseudo-reference translation is the trickiest element of the task. However, we can introduce several solutions to it. On the one hand, we can count the first occurrence of each translated term as the pseudo-reference. This is reasonable in the logic of legal texts, where the terms are “introduced” at the beginning and consistently used afterwards. On the other hand, we can choose the most frequent translation of the term to be the correct translation. In our experiment, we tried both approaches, which are easily done by the src-tgt dict or by the lists of the target terms for each sentence in the text. As a result of this step, we obtain the list of the “pseudo-reference” target terms for each sentence. Notably, the choice of the “pseudo-reference” terminology is calculated separately for each document.
5. **Evaluation**: After the four steps, the final data structure consists of quintuples, where each quintuple consists of the source sentence, the target sentence, and three lists: of the source terms, of the “candidate” occurrences of the translated source terms, and of the “pseudo-reference” translations. We can represent them as a variant of the TORT annotation (term-only reference translation, introduced by Bafna et al., 2021), where for each MT output sentence, there is a list of crucial reference terms instead of the whole text. Such lists of lists of “candidate” and “pseudo-reference” occurrences can be measured by the widespread data science metrics – multi-class precision, recall, true positive rate, etc. For better granularity, we also suggest grouping the lists by the source terms and counting the percentage of the correct occurrences of the exact term (hereinafter we call it "our" or "our own" metric).

Therefore, the main novelty of our approach is not the metric itself but an algorithm for automatizing the data collection for applying the widespread metrics.

4 Data

We used the data from the ELITR agreement test suite to test the metric. The test suite consists of various short agreement documents, namely, 18 purchase agreements, 13 lease and sublease agreements, and two agreements on renting or using the software. All documents have Czech as the source language and English as the target language; only for three files, the reference English translations are provided. As the MT outputs, we used the results of seven MT systems that took part in 2021 and 2022 competitions on this test suite. Detailed information about the systems is presented in Akhbardeh et al. (2021) and **?**, and the test suite texts are available online.[2]

5 Results and Discussion

In this section, we firstly comment on the absolute scores of the different variants of the proposed metric; secondly, we compare the ranking of the MT systems by our metric and by the ones represented in the findings of WMT21 and WMT22.

5.1 Proposed Metric Scores

Speaking about the absolute scores (see Table 1), we can see that for both years, if we fix formula that we use (either F1 or our own metric), the most frequent pseudo-reference initialization is regularly higher than the first-occurrence one (1-3% for F1; 3-5% for our metric). If we fix the pseudo-reference initialization and compare different formulas, the difference is bigger and varies between 7-9%. This can be a reflection of the fact that the NMT models are sentence based. The reason is following: if a model has a pre-trained distribution of translations for each term, then it may tend to choose the same likeliest translation for the term in the majority of the sentences. Thus, such likeliest translations will be most frequent in the src-tgt dicts, and will be chosen as "pseudo-references" in case of the most frequent initialization.

If we take into account the ranking of the algorithms, we can see that the big difference tends to be between the variants with different pseudo-reference choice. Kendall’s tau paired comparisons between the variants support this hypothesis: the most correlating rankings are the F1 and our metric with first-occurrence initialization, next best correlation is between the F1 and our metric with the

Table 1: Scores of different metric variants. The first position in the column name denotes the method for choice of pseudo-reference ("Freq" for "most frequent translation", "1st" for "first occurrence"); the second means the metric ("F1" for F1 score and "Own" for our own metric – averaged percentage of the correct hits per term). The last four columns show the ranking of the systems.

Freq;Own VS DA	.571	N/A

Table 3: Pairwise Kendall's Tau correlations between our metrics and the standard metrics (DA for direct assessment). The columns are arranged the same way as in Table 2; the statistical significance pointed by asterisk is p < 0.05 (for positive tau values only). For 2022 data, we do not have DA scores, thus it is marked "N/A"; also the rankings by BLEU and chrf are same, thus the corresponding cells in 2022 are merged.

same most frequent initialization. The next level of correlation is for the pairs of different initializations with the same metric (F1 or our own, respectively); the lowest correlation is between the most distant variants (such as F1 with the first-occurrence initialization and our metric with the most-frequent initialization). Notably, such a clear trend can be seen only on the results of WMT2021 systems, while on 2022 data, the only clear correlation is between the F1 and our metric with first occurrence initialization. The detailed tau values are shown in Table 2. Looking back at Table 1, we can see that, for 2021 systems, the best ones are Facebook-AI, Online-Y, and Online-B according to any metric variant, and the worst are CUNI-Transformer and Online-G. As for 2022 systems, the best-rated ones are JDExploreAcademy, Lan-Bridge, CUNI-DocTransformer, and Online-B, while the worst-rated ones are CUNI-Transformer ALMAnaCH-Inria, Online-Y, and Online-G.

5.2 Comparison with Standard Automatic Metrics and Direct Assessment

We also wanted to compare our metrics to the traditional manual and automated evaluation approaches for MT. Unfortunately, the only published results of the considered MT systems were based on the evaluation of another dataset of news texts, see Akhbardeh et al. (2021) and the actual scores online.[3] However, they can still give us an approximate idea of the systems' relative performance. For the 2021 news track, we have both automatic scores (BLEU and chrf) and human direct assessment, while for the 2022 track, we only have the automated metrics, the same as for the previous year. To compare the rankings of our metric and the standard ones, we find it logical to use Kendall's tau correlation, as it was applied in previous metrics shared tasks Macháček and Bojar (2014). The results of this comparison can be seen in Table 3. Regarding the WMT2021 outputs, on the one hand, the correlation between any automatic metric and any of our variants is not as high (and the p-values do not show any significance). The correlation with direct assessment scores, on the other hand, is high (more than 0.6 on average), and shows also the statistical significance in 2 out of 4 cases (for F1 with both variants of pseudo-reference initialization).

Unfortunately, we cannot compare the 2022 results with human scores yet. For the 2022 automatic scores, the discrepancy between our metric and automated metrics is even bigger, which is represented by the negative τ value. If we analyze the ranking of the systems by the standard metric and of the proposed metrics, we can see that, for 2021, the tentative clustering into three groups (best-average-worst system) roughly coincides with the automated metrics, while for 2022 the general coincidence remains, but there are counterexamples such as Online-W which is best by BLEU

[3] https://github.com/wmt-conference/wmt22-news-systems

and chrf, and average by our metric. We can interpret the lack of correlation between the automated metrics and our metric the following way: the proposed metrics can give additional information compared to the dominant automated ones; moreover, they tend to correlate with the human document-level judgments, which are, as it has already been mentioned, more sensitive to the inconsistencies in translations on the document level.

5.3 Comparison of 2021 and 2022 Performance

The last notable comparison is the progress of systems that participated in both the 2021 and 2022 competitions; there were six such systems. We subtracted the 2021 scores from the 2022 scores and ranked the differences from the most significant increase to the biggest decrease. We did that both for our metrics and for the standard automatic ones. The first notable difference is that the changes in scores with our metrics are very small compared to BLEU and chrf, they are not bigger than 3% (while the smallest change in BLEU and chrf are 15% and 10%, correspondingly). Based on that, we may hypothesize that our metrics show that the system developers did not aim at increasing the term consistency of the translations. However, to check this hypothesis, we should analyze the architecture of the systems and possibly to compare their performance against the systems intentionally oriented at term preservation, such as Voita et al. (2019a). The detailed comparison of 2021 and 2022 algorithms is shown in Table 4.

6 Limitations and Perspectives

As was stated, we proceed with testing our metrics, both "extensively" (on more data) and "intensively" (by tweaking the inner parameters of the metric itself). Regarding the "extensive" analysis, we firstly should retrieve the automatic metrics obtained for the ELITR agreement corpus and compare them to our findings. Secondly, we should test our method on other language pairs or at least on the opposite English-to-Czech direction.

The second priority covers a more "intensive" analysis of the metric. The method that we suggest is based on several automated (or semi-automated) steps. For each of the steps (keyword extraction, word alignment, manual restriction of the term translations), different approaches and algorithms can be used. So far, we have tested the YAKE Campos et al. (2018) and KeyBERT[4] keyword extractors for the first step. We compared their performance on the legal text outside the main ELITR collection (this means that, for regex-based extractor, we created the templates based on the ELITR connection and applied it to the testing text). Tentative analysis shows that for the considered text, regex term extractor demonstrates the best performance, with 100% precision and 64% recall (7 out of 11 terms). Both YAKE and KeyBERT output an excessive number of false positive results, thus showing a dramatic decrease in precision (best performance – YAKE with 1-token keyword retrieval, 35%). The recall scores for these algorithms decrease as well: the comparable result is performed only by YAKE (54% for 1-token keyword retrieval), while the 2-token length YAKE shows 36% and KeyBERT shows 9%.

This can lead us to the conclusion that the regex term extraction is the best algorithm. However, if we apply these extractors to different texts of a similar domain – audit report (retrieved from another ELITR repository,[5]) we will see that the regex keyword extraction outputs no terms at all. The reason is that the terms in this report are introduced only in parentheses, with no additional explicit hints (such as "hereinafter referred as...") in the legal texts. Both machine learning-based algorithms, in contrast, manage to catch at least some of the necessary terms. This drives us to the conclusion, that for the robustness of the regex-based term extraction, we should take into account different "strategies" of introducing the terms in the document (sometimes – by parentheses, sometimes – by additional phrases). This means that, before evaluating a new collection of the exact text, we still need some human effort to understand the strategy of the term marking there. Another way for a bigger automatization can be using the combination of different keyword extraction algorithms, and choosing the terms through a majority vote or taking the union. Finally, we can look at the problem of the term extraction and alignment from an opposite perspective: if there is no reliable combination of the automated algorithms for these two steps, we can use our metric semi-manually: the steps 2-3 from Section 3 will be completely handed over to human annotators, and their results will be processed automatically

Table 4: Comparison of systems' progress from 2021 to 2022. The columns with the names of metrics (or the variants of our metric) denote the result of subtraction of the 2022 scores from 2021 scores. The "rank" columns sort the systems by their progress in the corresponding metric (1 - biggest increase, 6 - lowest increase/biggest decrease).

by steps 4-5. Of course, such implementation will be more time- and effort-consuming, but, firstly, it should still be faster than other manual evaluation approaches such as MQM, secondly, it will give us a model results of term extraction and alignment, against which we will compare the automated algorithms.

The last notable limitation of the proposed approach is rooted in linguistic issues. Although the legal texts are very consistent in using the same term for the same concept, there regularly appear cases of "legitimate" homonymy, where two terms can denote the same concept. This usually occurs when two or more antecedents can be referred to separately or by one term. The example is the following sentence: *X, hereinafter referred to as "Seller", and Y, hereinafter referred to as "Buyer", together also as "contracting parties"...*. Such ambiguity (when person X can be both referred as "Seller" and as "contracting parties") may cause the problems even within the correct translation, if in the original the chosen formulation would be "the Seller and the Buyer", and in the target language it would be chosen as "contracting parties". The current metric does not have any capacity to capture this feature of the legal language domain.

7 Conclusion

We have presented the metric for evaluating the terminology consistency of the automatically translated texts. Among its main advantages is its ability to be automatized and its relative simplicity of interpretation. We have tested our metric on the texts from the legal domain in the Czech-to-English translation pair, and we have obtained the results that, according to preliminary estimates, correlate with human document-level judgements and statistically differ from those of the automated metrics such as BLEU or chrF. We are continuing our analysis to understand the scope of our metric's functionality and test it on other language pairs.

We publish our code of the project online at the Github page[6] of the Institute of Formal and Applied Linguistics, Charles University. We will appreciate feedback on the current algorithm, and we are open to discussion and suggestions on its improvement.

Test Suite Evaluation: Morphological Challenges and Pronoun Translation

Marion Weller-Di Marco and Alexander Fraser
Center for Information and Language Processing
LMU Munich
{dimarco,fraser}@cis.uni-muenchen.de

Abstract

This paper summarizes the results of our test suite evaluation with a main focus on morphology for the language pairs English to/from German. We look at the translation of morphologically complex words (DE–EN), and evaluate whether English noun phrases are translated as compounds vs. phrases into German. Furthermore, we investigate the preservation of morphological features (gender in EN–DE pronoun translation and number in morpho-syntactically complex structures for DE–EN). Our results indicate that systems are able to interpret linguistic structures to obtain relevant information, but also that translation becomes more challenging with increasing complexity, as seen, for example, when translating words with negation or non-concatenative properties, and for the more complex cases of the pronoun translation task.

1 Introduction

Evaluating MT output is challenging. Document-levels metrics give a rather coarse-grained estimation of the overall translation quality, but cannot determine how well a system operates for particular challenges. Translations do not have a deterministic solution, but there are always several possibilities for a valid translation, making a focused evaluation of particular phenomena difficult.

The annual WMT Shared Task provides the possibility to submit custom test suites to be translated in addition to the regular test sets, which allows the investigation of the translation performance of state-of-the-art systems when presented with particular translation tasks. In this test suite, we focus on morphological challenges for English to/from German translation: For German–English translation, we look at the translation of morphologically complex words, in addition to a small set of sentences where a subtle difference (singular vs. plural) needs to be detected. For English–German, we study how complex noun phrases are translated – as compounds or rather as multi-word phrases. Furthermore, we add a pronoun translation task and evaluate the translation of the English pronoun *it* into its German equivalents *er/sie/es*, depending on the gender of the noun it refers to.

The test suite does not aim at measuring a system's general translation performance – this is already assessed by means of a manual evaluation and various other metrics in the main shared task – but rather at evaluating the translational behaviour for carefully selected words or phrases. As the sentences in the test suite are not parallel, we opt for a semi-automatic approach where translation options for the words in question are manually collected and then matched with the translation output. Thus, only the translation of the relevant word is considered, whereas the rest of the sentence is ignored.

2 Data Creation and Evaluation

In the following, we outline the process of composing and evaluating the test suite.

Selection of words The sets for the analysis of translating morphologically complex words, compound variants and compounds for re-translating into English are mostly based on a word-frequency list from DeWac[1] (Baroni et al., 2009). The words were morphologically analyzed with SMOR (Schmid et al., 2004). Based on this analysis, words for the aforementioned categories were selected:

- Morphologically complex words: Words with a high degree of complexity and properties such as different forms (e.g. with/without *Umlaut*) in stem and derivations; with negation prefixes or particles or verbal components.
- Compound variants: compounds for which both variants NN1 NN2 and NN2 NN1 exist.
- Compounds for re-translation: adjectives and nouns with up to four components.

[1] https://wacky.sslmit.unibo.it/doku.php?id=frequency_lists

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 458 - 468
December 7-8, 2022 ©2022 Association for Computational Linguistics

Sentence selection We manually retrieved sentences containing the selected words, using Google and the search function provided by the corpus platform DWDS (Geyken et al., 2017) with the corpus *Webmonitor*[2] which is daily updated. The search was (mostly) restricted to newspaper entries from this year, in order to obtain "new" data that was not previously seen in the (monolingual) training data.

Evaluation We identified the translation hypotheses of the relevant words using word alignment (Eflomal (Östling and Tiedemann, 2016)), which were then matched with a manually composed lexicon containing translations options. This step is semi-automatic in the sense that yet unseen translation options need to be verified and added to the lexicon. For the verification, we took into account the sentence context. Being mainly interested in adequacy (i.e. reproducing the meaning of the source word) we allowed for some leeway at the level of fluency, which is difficult to determine anyway in sentences that are not always fully grammatical.

3 DE–EN Translation

This section summarized the design and the outcome of the four categories in DE–EN translation.

3.1 Morphologically Complex Words

We are interested in the translation of morphologically complex words that contain interesting morphological properties such as negation, particles, verbal elements or non-concatenative derivation, which often pose a challenge for translation.

Consider, for example, the word *abrissunwillig: abreißen + un + willig* (*tear down + un + willing*: *unwilling to tear down*), which consists of a nominalization (*abreißen*$_\text{V}$ $\rightarrow$ *Abriss*$_\text{N}$), a negation prefix (*un-*) and an adjective (*willig*: *willing*). In addition to being complex, there is also a non-concatenative operation in the derivation, namely the stem change in *abriss-* vs. *abreißen*. This makes it difficult for linguistically uninformed splitting approaches to find a segmentation into meaningful splits that match with, and thus benefit from, other instances of related words with the same stem.

Many of the selected words emerged from creative use of language and are rather low-frequency. This is to challenge the systems to analyze the words rather than having them already memorized. The words can be loosely grouped as follows:

		JDExplore Academy	Lan-Bridge	LT22	Online-A	Online-B	Online-G	Online-W	Online-Y	PROMT
NEGATION	correct	49	51	15	50	55	47	54	51	49
	incorrect	8	6	42	7	2	10	3	6	8
	→ polarity	–	4	9	1	2	4	–	3	1
	→ lex.	8	2	30	6	–	6	3	3	7
	→ untransl.	–	–	3	–	–	–	–	–	–
VERB	correct	12	13	2	12	15	13	14	11	11
	incorrect	4	3	14	4	1	3	2	5	5
UML	correct	50	49	18	48	49	43	50	43	40
	incorrect	2	3	34	4	3	9	2	9	12
NON CONC	correct	43	40	5	28	44	35	36	34	24
	incorrect	8	11	46	23	7	16	15	17	27
PART INF	correct	62	64	24	63	62	64	64	60	58
	incorrect	14	12	52	13	14	12	12	16	18

Table 1: Morphologically complex words.

Negation: words containing the negation morphemes *un-* (*unschmelzbar*: *unmeltable*) or *-los* (*knopflos*: *without buttons*). We are in particular interested how the negation is realized, i.e. as an isomorphic, word-internal negation vs. word-external negation. This group comprises 57 sentences.

Verbal elements: the form of verbal elements in derivations often differs from that of the verb stem (*aufbruchsbereit*: *ready to go*; *aufbrechen*: *to leave*). This group comprises 16 sentences.

Stem change (Umlaut): words containing an *Umlaut* in the derivation but not in the stem: *blümchenbedruckt/Blume* (*printed with little flowers/flower*). This group comprises 52 sentences.

Non-concatenative words: adjectives derived from nouns with non-concatenative properties, e.g. *langwimprig/Wimper*: *long-lashed/lash*. This group comprises 51 sentences.

Complex words: words containing particles, such as *mitzittern* (lit: *tremble-with*; *to sympathize, share somebody's emotions*) and words containing *-zu-* infixes (e.g. *aufzutürmen*: *to stack up*). Words of this group are often difficult to translate directly. This group comprises 76 sentences.

Table 1 gives an overview for all five categories. For words containing **negation**, we find that most systems made between 6 and 10 errors (out of 57), with three systems being much better or worse.

For the errors, we distinguish between *lexically incorrectly* translated and *wrong polarity*[3]. For the lexically bad translations, we found that a majority still contained a negation morpheme (such as

[2] https://www.dwds.de/d/korpora/webmonitor

[3] The negation is incorrectly reproduced in the translation, either through omission or by a word of the opposite meaning.

nuancen**los**	nuanced (3), nuances (1)
manövrier**un**fähige	maneuverable (3),manoeuvrable (1), manoeuvring (1)
familien**un**freundliche	family-friendly (1)
datenschutz**un**freundliche	data protection-friendly (2), data-protection-friendly (1)
keim**un**fähig	viable (1), germinate (2)
kunden**un**freundlichen	client-friendly (1)
klima**un**freundliches	climate-friendly (1)
fahrrad**un**freundlichste	most bicycle-friendly (1)
unverblasst	still faded (1)
unaufgetaut	unfrozen (1)
unadeligen	aristocratic (1)
kalorien**lose**	calories (1)

Table 2: Translations with wrong polarity (all systems).

knopflos (*buttonless*) → *headless*). For translations with wrong polarity, we observed that in particular words with an infix negation morpheme are error-prone, especially when considering that the test set contains only 13 sentences with such words. Table 2 lists the (otherwise lexically correct) translations with wrong polarity.

Among the correct translations, we observe the entire range between no translation variation (e.g. *unwählbar* ↔ *unelectable* and *vorwarnungslos* → *without warning*) and lexical and local structural variation, as shown in table 3.

For words containing **verbal elements** that differ from the lemma of the verb, the systems' performances range from nearly all correct to nearly all incorrect. For this subset, there was no clear trend of error, certainly also due to its small size. One thing that we observed was that for *abrissbedroht* (*threatened by demolition*), *abrissbereit, abrissreife* (*ready to be demolished*), *abrissgeweihten* (*marked for demolition*), *abrisswilligen* (*willing to demolish*) a common mistranslation was just *demolished*, even though the state of being actually demolished is not described by any of these words.

The words with a **stem change (Umlaut)** lead to mixed results; for the words with **non-concatenative properties**, we observe even more errors. Among the incorrectly translated words, there is a tendency that the part with the non-concatenative properties is mistranslated, whereas the other, more easy part, is correct (cf. table 4). Finally, the words containing **particles or infixes** were challenging to translate, even though some words were considerably more difficult. In particular, the set included some verbs that cannot be translated isomorphically. One example is the combination of *kaputt* (*broken*) + *verb*, in analogy to *kaputtmachen* (*to break*, lit. *kaputt-make*): *kaputtsparen* (*to destroy through excessive money saving*) or *kaputtsanieren* (*to destroy through excessive renovating*). With the exception of *kaputtschlägt* and *kaputtzukriegen* (*to break*), they were nearly always translated incorrectly. In particular *kaputtsparen* was often translated as *saved from damage* or similar, the opposite of the intended meaning. In contrast, for *schönreden* (*to gloss over, to sugar coat*, lit: *beautiful* + *talk*), a generally similar construction, about half of the translations were correct.

quittungslos	without receipt (9), without receipts (2), without a receipt (2), receiptless (1), receipt-free (1)
nuancenlos	without nuances (4), nuanceless (3), nuance-free (3),nuance-less (2), unnuanced (1), lacking in nuance (1)
unaufgetaut	unthawed (3), without thawing (1), without defrosting (1), undefrosted (1), before it is thawed (1)
unverblasst	unfaded (2), still vivid (1), not yet faded (1), not faded (1), still fresh (1)

Table 3: Translation variants for words with negation morphemes (only correct translations shown).

sonnenbebrillt	in sun glasses (2), with sunglasses (1), wearing sunglasses (1)	bespectacled by the sun (1), in the sun (1), sunglassed (1)
löwenmähnige	lion-maned (15)	lion-eyed (1) lion-like (1), duel-like (1)

Table 4: Translating non-concatenative words.

3.2 Compound Variations

Compounds are commonly occurring in German and their translational behaviour has been studied extensively. An important aspect in compound translation is to correctly reproduce the relation between the head and modifier in noun-noun compounds, which we aim to investigate in this category by looking at compound pairs that consist of the variants NN1 NN2 and NN2 NN1, such as *Oliven|öl* and *Öl|olive* (*olive oil* vs. *oil olive*) or *Leder|stiefel* and *Stiefel|leder* (*leather boot* vs. *boot leather*).

The compound variants NN1 NN2 and NN2 NN1 have different heads and thus a different meaning (as opposed to variation in hyponymy/hypernymy) and are not generally interchangeable[4]. We thus

[4] We found, however, that in some cases, there is an acceptable one-word translation for both variants, e.g. *Absatzschuh*

	JDExplore Academy	Lan-Bridge	LT22	Online-A	Online-B	Online-G	Online-W	Online-Y	PROMT
correct	57	58	29	59	59	60	59	59	57
wrong order	–	–	2	–	1	–	–	–	–
head missing	1	–	7	–	–	–	–	–	1
mod missing	–	–	5	1	–	–	1	–	–
bad transl.	2	2	17	–	–	–	–	1	2

Table 5: Translation results of compound pairs. *wrong order*: wrong order of head and modifier; *head/mod missing*: only translated head or modifier; *bad transl*: translation was either missing or wrong.

retrieved different sentences for each variant: this means that the compound variants are not analyzed in a minimal pair setting, but each variant is presented in an appropriate and natural context.

This category is somewhat inspired by one of the error types introduced by Sennrich (2017), where translation probabilities for contrastive sentences containing compound variants (a correct vs. a wrong translation consisting of a compound with switched components) are compared.

Table 5 shows the results for 15 compound pairs, with 2 examples per variant in most cases, resulting in 60 sentences total. All systems, with the exception of one, translated most compounds correctly. Furthermore, there is no dominant error type for cases with incorrect translation. This indicates that through most systems, there is a generally good understanding of compound structure and subsequent translation, even in cases such as the high-frequency *Olivenöl* (21M google hits[5]) vs. the low-frequency *Ölolive* (507 google hits).

3.3 Compound Translation

In this section, we look at the translation of compounds consisting of two to four components. This set of compounds[6] also serves as a basis for the experiment in section 4.1 which studies how English noun phrases are translated into German.

This word set contains some "newish" words, i.e. words that are not new per-se, but became considerably more frequent recently, such as *Gasengpass* (*gas bottleneck*) and some Covid-related terms such as *Impfbereitschaft* (*willingness to be vaccinated*). Most words in this set are compositional, and very few are non-compositional compounds, such as *Dornröschendasein* (*Sleeping Beauty existence*).

wrong	5	3	35	3	3	2	3	5	2
missing/copy	–	–	4	–	–	–	1	–	–

Table 6: Results for translating compounds into English.

Table 6 shows the results for translating compounds into English; most systems did quite well. Among the compounds with the most consistent translations are *Sonnenblumenkernöl* (*sunflower seed oil*) and *Haifischflossensuppe* (*shark fin soup*), i.e. compounds with a straightforward literal translation. Similarly, the somewhat new *Testmüdigkeit: test fatigue (17), testing fatigue(1)* (occurrences in two sentences) leads to consistent translations. One of the more difficult words was *distanzlernende (distance learning)*, which 5 of the 9 systems translated correctly. The incorrect translations did not quite capture the meaning and translated into *learning distance*, *learning about distance* and *to dance* (probably due to an incorrect splitting that contained the German "tanz").

3.4 Preserving Morphological Information in Syncretic Forms

Understanding the precise meaning of a word and its function in the sentence is crucial to obtain a good translation. This includes the comprehension of relevant morphological features.

While German is rich in different inflected forms, there is also a certain degree of syncretism (forms with different morphological features sharing the same surface form). For example, *Hund* (*dog*) can be dative, accusative and nominative, *Unternehmen* (*company*) can be singular and plural. Usually, this can be resolved by the context, often by means of the determiner: *dem*$_{\text{DAT}}$/*den*$_{\text{ACC}}$/*der*$_{\text{NOM}}$ *Hund* and *das*$_{\text{SG}}$/*die*$_{\text{PL}}$ *Unternehmen.*

In this experiment, we look at number in non-subject words as (i) number is the only feature of nominal inflection that is shared between German and English, and (ii) there are no further ramifications to the rest of the sentence. We designed a setting in which the disambiguating context, a definite article, is not directly adjacent to the word in question, but separated by an inserted phrase.

→ *heel, heeled shoe* and *Schuhabsatz* → *heel, shoe heel*.

[5] Search of the citation form in double quotes. Numbers reported by Google give only a rough idea of the true frequency on the web, but are sufficient to estimate the order of magnitude.

[6] This set of words is not exactly the same as in section 4.1.

Die Verzögerungen sind auf Engpässe bei **den** mit der Umsetzung beauftragten **Unternehmen** und auf ... zurückzuführen. The delays are to bottlenecks at **the** with the implementation charged **companies** and to ... due
Die Verzögerungen sind auf Engpässe bei **dem** mit der Umsetzung beauftragten **Unternehmen** und auf ... zurückzuführen. The delays are to bottlenecks at **the** with the implementation charged **company** and to ... due
The delays are due to bottlenecks at **the companies/company** charged with the implementation and to ... .

Table 7: Example for minimal sentence pairs.

	JDExplore Academy	Lan-Bridge	LT22	Online-A	Online-B	Online-G	Online-W	Online-Y	PROMT
Correct	15	16	8	15	16	17	17	18	17
Incorrect	3	2	7	3	2	1	1	–	1
NA	–	–	3	–	–	–	–	–	–

Table 8: Preserving number information: *Correct*: the noun in singular and plural was translated correctly. *Incorrect*: for at least one noun, the number was incorrect. *NA*: not translated or otherwise impossible to judge.

We created 18 minimal sentence pairs with the only difference being a singular vs. a plural article, in order to test whether the noun (with identical forms in both sentences) is correctly translated. The sentences contain "nested prepositional phrases" where an inserted prepositional phrase separates the article and the noun, cf. table 7.

Table 8 shows the results for the task of preserving number information: most systems can handle this problem reasonably well, indicating that the systems have the ability to interpret the sentence structure and to identify the relevant context.

4 EN–DE Translation

In this section, we look at re-translating compounds and present a pronoun translation task.

4.1 Compound Creation

To prepare the test set, we translated the German compounds from section 3.3 into English, including structural or lexical variations if possible (cf. table 9 for some examples) and retrieved English sentences with these translations, resulting in a set of 102 sentences. We distinguish between "phrase" (PHR), containing a preposition (such as *interpreter for sign language*) and "compound" (COMP) where the order of the words corresponds to a compound (as in *sign language interpreter*).

The results in table 10 show a tendency to keep the structure, i.e. translating a compound-like structure into a compound, and a phrase into a phrase rather than a compound, even though there are differences depending on the word.

Gebärdensprach-dolmetscher	sign language interpreter interpreter for sign language
Obstbaumschnittkurs	fruit tree pruning workshop workshop on fruit tree pruning
Kleinkläranlagen-betreiber	small wastewater treatment plant operators; operators of small wastewater treatment plants
Kreuzworträtselfrage	crossword question crossword puzzle question

Copied EN	1	1	–	1	–	–	1	–	–

Table 10: Translating English complex phrases.

For example, the variants *wearers of headscarves* and *headscarf wearers* were mostly translated by the compound *Kopftuchträger(innen)*, with only two instances of *Träger von Kopftüchern*. In contrast, both *pacemaker wearer* and *pacemaker carrier* have a more equal distribution of *Träger von Herzschrittmachern* and *(Herz)Schrittmacherträger*. A more complex example, *willingness to get vaccinated*, was translated to the corresponding compound *Impfbereitschaft* (6 times), as *Bereitschaft zur Impfung* (3 times) and *Bereitschaft, sich impfen zu lassen* (9 times). The variant *unwillingness to get vaccinated* proved more problematic: only three systems obtained correct translations: *Impfunwilligkeit* (2) and *Unwilligkeit, sich impfen zu lassen* (1). The translation *Impfunbereitschaft*, while transporting the correct message, is questionable. In the remaining 5 cases, the negation was ignored.

4.2 ContraCat: Translating Pronouns

The translation of pronouns is often more difficult than it seems at a first glance: a translation system requires diverse linguistic information to produce a

1	The mouse ate the cookie and the **bear** drank the milk. **It** drank the milk quickly.
2	The **tiger** ate the ice cream. **It** was happy.
3	The giraffe ate the **steak**. **It** was cooked.

Table 11: Examples for the ContraCat template set.

target-language pronoun with the correct morphological features such as gender, number or case.

To translate the English *it* into German, a translation system needs to identify the noun *it* refers to and to have knowledge about that noun's gender[7] in German, as illustrated below:

... a dog ... it ... → *... ein Hund*$_{\text{MASC}}$ *... er ...*
... a cat ... it ... → *... eine Katze*$_{\text{FEM}}$ *... sie ...*
... a zebra ... it ... → *... ein Zebra*$_{\text{NEUT}}$ *... es ...*

To analyze the translation of pronouns, we make use of the template set *ContraCat* (Stojanovski et al., 2020) which consists of sentence pairs where several nouns are introduced in the first sentence, and a pronoun *it* in the second sentence either refers to one of these nouns, or is generic as in *it is raining*. The sentences are constructed in a way that the relevant noun/context can be derived through either world knowledge or through analyzing the structure of the sentence. Furthermore, the sentences are designed such that the nouns of e.g. the two subjects (mouse and bear in sentence 1 in table 11) have translations into German with different genders (*Maus*$_{\text{FEM}}$ and *Bär*$_{\text{MASC}}$) in order to allow for an unambiguous evaluation.[8] Table 11 shows three examples; an overview of all template categories can be found in table A.

Technically, each sentence consists of two short sentences. As this might be disadvantageous in some system settings, we generated a second version where we joined the two short sentences with "and" into one sentence. In the evaluation, these variants will be referred to as 2S and AND.

In its original form, the template set provides three translation hypotheses, each with a different translation option (male/female/neutrum) for *it*, for which the system's likelihood to produce the correct translation is then measured.

To be used in an actual translation scenario, we adapt the evaluation process: given the template structure, we first identify the antecedent (the noun that is referenced by the pronoun *it*), and then its translation and the translation of the pronoun *it* in the target sentence using word alignment (Eflomal, Östling and Tiedemann (2016)). The translation options of the nouns observed in the different systems' outputs are listed in a manually compiled dictionary[9], alongside their German grammatical gender. With this, the translated pronoun can be automatically matched with the noun's gender.

4.2.1 Test Set Creation

From the original test suite[10], we randomly selected 100 sentences for each of the 20 categories (cf. table A for an overview), with the exception of the category *world knowledge*, for which 200 sentences were selected as this category comprises the scenario of addressing an animate noun (animal) vs. inanimate noun (food). Doubling the sentences for the AND variant results in 4200 sentences total.

4.2.2 Evaluation and Results

Table 12 shows the results of translating pronouns. For the categories *event_** and *pleo_**, where the translation *it* → *es* is always expected, nearly all systems have a perfect score. The other categories where the antecedent needed to be derived from the context are more challenging, however without a clear pattern between the systems. We can observe two tendencies, even though not consistent through all systems: first, the variant AND often leads to better results, probably due to the fact that sentences are often the "standard unit" for translation, whereas the two sentences in variant 2S might be considered separately, depending on the systems' architecture. Second, sentences where the antecedent is the second NP of the first sentence, i.e. closer to the *it*, tend to get better results.

Looking further into the errors, we find that *es*$_{\text{NEUT}}$ is often preferred over a a feminine or masculine form. This might simply be the case because *it* → *es* is the default translation, and also because the generic *es* can oftentimes be considered grammatical, even though a translation into the gender-specific pronoun would be possible.

A general problem with this template approach is the degree of freedom in the translation process: sometimes the pronoun is just not translated (cf. table 13), and in some cases, it is possible to formulate the sentence such that the pronoun *es* leads to

[7] Further features leading to variations at the level of grammatical case and number will be ignored here.

[8] This was guaranteed for the pre-defined translations in the original setting. In actual translations, there can be more variation, for example *deer* → *Hirsch*$_{\text{MASC}}$, *Reh*$_{\text{FEM}}$, *Wild*$_{\text{NEUT}}$.

[9] The dictionary comprises entries for 141 English nouns, with one to four translation options.

Table 12: Results for pronoun translation using the ContraCat template, the number indicates the amount of correct pronoun translations (out of 100 for all except for world_knowledge, which has 200 test sentences). (Note: in JDExploreAcademy–pleo_shame, *it is a shame* is nearly always translated as *"Schade."*, i.e. without a pronoun.)

The mouse ate the cookie and the **sheep**$_{\text{SG/PL}}$ drank$_{\text{SG/PL}}$ the tea. **It**$_{\text{SG}}$ liked the tea.
Die Maus aß den Keks und die **Schafe**$_{\text{PL/NT}}$ tranken$_{\text{PL}}$ den Tee. Er$_{\text{SG/MASC}}$ mochte den Tee.

Table 13: Example for incorrectly passed-on number.

The cow ate and the dog drank. It drank a lot.
Die Kuh aß und der Hund trank viel. *The cow ate and the dog drank a lot.*
The frog ate the fruit and **it** had a sour taste.
Der Frosch aß die Nuss und ∅ hatte einen sauren Geschmack. *The frog ate the fruit and had a sour taste.*

Table 14: Examples for pronoun omission.

a grammatical sentence. For example, *the -animal- liked it* (*it* →*food item*) can be translated as *Dem -Tier- gefiel/schmeckte es*. This is a valid translation, even though not strictly in the sense of the intended meaning as in *dem -Tier- schmeckte er (*→ *Apfel*$_{\text{MASC}}$*)* vs. *dem -Tier- schmeckte sie (*→ *Banane*$_{\text{FEM}}$*)* . For the sake of evaluation, we count a translation only as correct if the pronoun exists and matches in gender with the noun it refers to.

While this experiment only focused on *gender*, we also observed some cases that extended to *number*, namely in a few cases where the English singular and plural forms are the same. In the example in table 13, the number of *sheep* is not directly visible in the first part of the sentence, but can be disambiguated through the singular form *it*. The translation contains *Schafe* in plural, but *er* as translation of *it* is singular/masculine (*Schaf* is neutrum).

5 Related Work

The linguistic and morphological compentence of translation systems is a topic of previous and ongoing research. Isabelle et al. (2017) present a challenge set for English to French translation targeting linguistic divergence between the two language pairs. Their hand-crafted set has a focus on morpho-syntactic, lexico-syntactic and syntactic divergences. Burlot and Yvon (2017) present an analysis of minimal pairs representing a contrast that is expressed syntactically in EN and morphologically in a morphologically rich language (DE, CZ and LV). For a source test sentence (the base), variant(s) containing exactly one difference with the base (e.g. person/number/tense of a verb or number/case of a noun/adjective or polarity) are generated and automatically evaluated, counting a translation as correct if the targeted feature is produced correctly in the target language. The work of Burchardt et al. (2017) and Avramidis et al. (2019) comprises the DFKI test suite for German to English MT. Their test set consists of over 5k sentences to analyze over 100 categories, including negation, composition, function words, subordination, non-verbal agreement, multi-word expressions, verb tense/aspect/mood, lexical ambiguity and punctuation. LingEval97 (Sennrich, 2017) is a large-scale data set of 97000 contrastive English–German translation pairs where errors (on the level of agreement, auxiliaries, verb particles, polarity and swapped compound components) haven been automatically created. It is then measured whether a reference translation is more probable than the corresponding contrastive translation containing an inserted error. An obvious question with this approach is whether forced translation mimics the MT system's "natural behaviour", i.e. whether the presented sentence e is the system's best choice given the source sentence f. This question is addressed in Vamvas and Sennrich (2021) where it is argued that test data should be chosen such that there is minimal discrepancy between the training data and the data to be evaluated. They recommend that test sentences be created from machine generated text rather than using human-written references. The paper proposes an updated version of LingEval97.

6 Conclusion and Future Work

This paper summarizes the results of our WMT22 Test Suite, looking at the translation of morphologically complex words, compounds and a set of minimal pairs to assess the preservation of number. Our evaluation shows that on one side, the translation of morphologically complex words is not without challenges, in particular for low-frequency words and when containing negation. On the other hand, the handling of the (structurally much simpler) compounds NN1 NN2 vs NN2 NN1 and the preservation of the number feature worked quite well. The results for the pronoun translation experiment were mixed.

Our results indicate that the systems have a generally good understanding of linguistic structures, but also that at a certain degree of (morphological) complexity, problems start to arise. For research in MT, this means that modeling morphology, particularly negation and non-concatenative processes, might be worthwhile.

The test suite, with the exception of the pronoun translation task, is based on a manually created set of sentences alongside matching dictionaries. While this has the advantage of presenting the selected words/phrases in a natural context, it comes with a comparatively high amount of manual effort, making it difficult to upscale. In contrast, the artificial data used in the pronoun translation task allows for a comparatively straightforward evaluation, but sounds unnatural and likely differs considerably from the MT training data, which might even bias the results to a certain extent.

For future work, we intend to look into the generation of meaningful sentences with particular properties that allow for a systematic evaluation of MT.

Limitations

There are several limitations to this work: first, the work is obviously limited in terms of data-set size and the small number of language pairs considered. As there is a certain amount of manual selection and annotation required, this is generally a tricky problem to address. As mentioned previously, we plan to work on more sophisticated test data generation as a basis for a more focused evaluation. Another limitation is a lack of generalizability: the presented analyses offer only partial insights and provide but a first glimpse into understanding to what extent morphological information is captured and passed on in machine translation.

Ethics Statement

We have no ethical concerns about the research presented in this paper. The data selection and annotation work was carried out by the first author.

verb_overlap_eatdrinkdrink	The zebra ate and the **bear** drank . **It** drank quickly .
verb_overlap_eatdrinkeat	The **zebra** ate and the lion drank . **It** ate a lot .
world_knowledge world_knowledge	The **tiger** ate the ice cream . **It** was happy . The giraffe ate the **steak** . **It** was cooked .

Table 15: Overview of the different categories of reference in ContraCat. The noun that is referred to by the *it* in question, as well as the *it* itself, are marked in bold face. For the categories *event_** and *pleo_**, the *it* does not refer to a noun.

Robust MT evaluation with Sentence-level Multilingual Augmentation

Abstract

Automatic translations with critical errors may lead to misinterpretations and pose several risks for the user. As such, it is important that Machine Translation Evaluation systems are robust to these errors in order to increase the reliability and safety of the translation process. Here we introduce SMAUG, a novel Sentence-level Multilingual AUGmentation approach for generating translations with critical errors and apply this approach to create a test set to evaluate the robustness of Machine Translation metrics to these errors. We show that current State-of-the-Art methods are improving their capability to distinguish translations with and without critical errors and to penalize the first accordingly. We also show that metrics tend to struggle with errors related to named entities and numbers and that there is a high variance in the robustness of current methods to translations with critical errors.

1 Introduction

In recent years, Machine Translation (MT) systems have been used in diverse real world environments. However, widespread adoption of these systems raises many concerns, namely in the quality of their outputs. Ideally, human translators would evaluate generated translations but this process is expensive and slow. As an alternative, automatic Machine Translation Evaluation relies on external systems to measure the quality of generated translations.

As a crucial aspect of Machine Translation Evaluation, it is vital to ensure that generated sentences do not contain critical errors. As detailed in Specia et al. (2021), translations with such errors deviate in meaning from their source sentence in ways that may lead to misinterpretations and pose health, safety, legal, reputation, religious or financial implications. Specia et al. (2021) group these translations into three categories, based on how their meaning deviates from the source sentence. Mistranslation errors have critical content in the source sentence translated into a different meaning, not translated (the content remains in the source language), or translated into gibberish. Hallucination errors introduce content in the translated sentence that is not present in the source sentence. Deletion errors exclude important content from the source sentence.

In this work, we propose SMAUG[1], a Sentence-level Multilingual AUGmentation framework to generate translations with critical errors, targeting all the aforementioned critical error categories.

We also introduce a novel test set to analyse the robustness of MT Evaluation systems to critical errors. This test set was created with the proposed augmentation framework and submitted to the WMT22 Challenge Sets Sub-task (Freitag et al., 2022).

Finally, we present the results obtained from evaluating metrics submitted to the WMT22 Metrics Shared Task with the developed test set. We show progress of submitted metrics with respect to baseline systems, particularly concerning Quality Estimation systems. Namely, we demonstrate that several metrics are able to correctly distinguish translations with and without critical errors and to penalize the former. Furthermore, we show that current metrics are less sensitive to translations containing errors in named entities and numbers and that there is a high variance in the performance of current SOTA evaluation metrics with respect to identifying and penalizing the occurrence of critical errors.

Metrics for Machine Translation Evaluation produce a quality score for a given hypothesis, based on the source sentence and a possibly empty set

of reference translations. These metrics can be divided into two main groups, given their reference set. Reference based metrics have a non-empty reference set, while reference free metrics have an empty reference set. Reference free evaluation is also denominated by Quality Estimation.

Within reference-based metrics, *n*-gram based metrics, such as BLEU (Papineni et al., 2002) and CHRF (Popović, 2015), measure lexical overlap from the hypothesis to the human references. Rei et al. (2020) advocate that these methods fail to capture semantic similarities beyond the lexical level. Their inability to capture meaning at a sentence level also makes them unfit for the detection of critical errors as they equally penalize the usage of synonyms or the mistranslation of a named entity.

As an alternative to *n*-gram matching, more recent methods leverage word representations to capture semantic similarities beyond the lexical level. As described in Rei et al. (2020), *embedding*-similarity methods, like YISI-1 (Lo, 2019) and BERTSCORE (Zhang et al., 2020), create an alignment between the vector representations of the words in the hypothesis and the reference and then compute a score that captures the semantic similarity between both sentences. As noted by Rei et al. (2020), the main issue with these approaches is that human judgements consider other information beyond semantic similarity, limiting the correlation of these methods with human evaluations.

More recently, learnt methods, such as BLEURT20 (Sellam et al., 2020) and COMET (Rei et al., 2020), address this issue by training to directly maximize correlation with human judgements. Results from the WMT21 Metrics (Freitag et al., 2021) and the WMT21 Quality Estimation (Specia et al., 2021) shared tasks suggest that these methods obtain higher correlations with human judgements, such as Direct Assessments (Graham et al., 2013), Human Translation Edit Rate (HTER) (Snover et al., 2006) or Multi-dimensional Quality Metrics (MQM) (Lommel et al., 2014).

However, as noted by Ribeiro et al. (2020), relying on accuracy on held-out sets can lead to an overestimation on the performance of NLP models. As such, Ribeiro et al. (2020) proposes `CheckList` that relies on data augmentation techniques to create examples that test specific behaviours of NLP systems in various situations. Within the field of Machine Translation Evaluation, as a case study for exploring the sensitivity of learnt metrics to specific phenomena, Amrhein and Sennrich (2022) employed Minimum Bayes Risk decoding with COMET as an utility function to identify good hypotheses. The authors show that hypotheses chosen with COMET are more likely to have errors in Named Entities and Numbers when compared to CHRF, indicating the metric is not sensitive enough to these errors.

Considering multiple metrics, Freitag et al. (2021) tested multiple systems on a challenge set with errors related to negation and sentiment polarity and found that most metrics struggle with these errors. Nonetheless, these examples were chosen from existing MT outputs, which can lead to a major human effort, as these errors are not common.

Regarding reference free evaluation, Kanojia et al. (2021) define multiple perturbations to test the robustness of QE systems in detecting specific errors. The authors show that overall the tested perturbations are well detected but some, such as polarity based perturbations, still pose a challenge to QE systems. However, the list of perturbations is not exhaustive and most rely on transformations that do not necessarily preserve the semantics of the phrases, such as random insertions, substitutions and deletions.

3 SMAUG Framework

In order to create an example of a critical error, the proposed framework receives an existing sentence and perturbs it, inducing one of the linguistic phenomena detailed in the following sections. For each linguistic phenomenon, the perturbation process is separated into two phases: transformation and validation. The first phase generates a candidate sentence by perturbing the original translation. This phase may not produce a candidate, as some perturbations are not applicable to all sentences. The second phase verifies whether the produced candidate meets a set of desirable criteria, discarding it otherwise.

3.1 Deviation in Named Entities

The first perturbation replaces a named entity in the original sentence for a different one that is consistent with the original context. The transformation phase of this perturbation, in Figure 1, starts by detecting all Named Entities in the original sentence with the Named Entity Recognition (NER) System in the Stanza library (Qi et al., 2020). If no entity is detected, the generation process stops. Otherwise, a single one is randomly chosen using an Uniform Distribution. This entity is replaced by employing the mT5 pretrained language model (Xue et al., 2021). For this, the span with the sampled entity is replaced by a single mask token and the model is used to generate the candidate sentence. The decoding strategy for the mT5 model is sampling considering the top 50 elements. When compared with other strategies, such as Beam-Search and Top-P sampling, this approach was empirically found to give realistic examples at a lower computational cost. The mT5 model was chosen for three main reasons: it is multilingual and trained on a massive set of different languages; it can generate multiple words from a single mask token, thus not requiring any special strategy for adding mask tokens in order to avoid only single word entities; and does not change the remainder of the sentence, avoiding unwanted side-effects. Nevertheless, the mT5 model was found to often generate punctuation symbols in the beginning of the sentence. In order to increase the credibility of the generated sentences, these symbols were removed.

John saw a movie with Bob.
Sample and Mask
<mask> saw a movie with Bob.
Candidate
Mike saw a movie with Bob.

Figure 1: Example of the transformation phase for the Deviation in Named Entities phenomenon.

The validation phase for this perturbation encompasses several sub-validations. On the one hand, in order to ensure the mT5 model generates a named entity, the candidate is only accepted if the above NER model detects the same number of entities in both the candidate and the original sentence. On the other hand, the mT5 model can "guess" the correct named entity from the remaining context. As such, the generated sentence can not be equal to the original. Furthermore, to prevent cases where mT5 produces a small variation of the original entity (for example by adding an hyphen between two words or changing the accentuation), candidate sentences may only be accepted if they have a character-level minimum edit distance to the original above a threshold. This procedure can discard many valid candidates and thus, depending on the desired quality and quantity of generated sentences, may be applied or not. Through manual experimentation, a distance greater or equal to 5 was found to produce a good balance between ensuring the generated entities are different without discarding too many valid candidates. Finally, to increase the overall quality of the generated sentences, several sub-validations can be employed. Candidates with words matching the regular expression of the mT5 masking token (`<extra_id_\d{1,2}>`) are discarded, as they represent cases where the model was unable to generate content. This can be extended by considering more generic expressions such as `extra_*`. Furthermore, since named entities do not usually have characters such as `()[]\{\}_`, candidates that have more of these characters than the original can also be removed. As before, these validations can remove valid candidates and they should be adapted to the use case in question.

3.2 Deviation in Numbers

Another perturbation, similar to the deviation in named entities, replaces a number in the original sentence by a different one. The transformation phase for this phenomenon follows the same procedure as the deviation in Named Entities. However, it employs the regular expression `[-+]?\.?(\d+[.,])*\d+` to detect numbers in the original sentence. From the detected numbers, the process to sample a single number and replace it with another one using the mT5 model is the one described above, from masking the span with the chosen number to generating the candidate sentence.

Regarding the validation phase, it also employs a set of sub-validations. As before, the candidate is accepted only if the regular expression to detect numbers is matched the same number of times in both the original and candidate sentences, ensuring a number was generated. Furthermore, the original and candidate sentences must be different to ensure the mT5 model did not "guess" the number by the context. In this perturbation, the minimum edit distance sub-validation was not applied as small variations in numbers mostly lead to critical errors (for example changing the place of a comma within the number). Finally, candidates matching the mT5 masking token (`<extra_id_\d{1,2}>`) or that introduce one of the following characters

( ) [ ] \ { \ } _ are also removed to increase the overall quality of the generated sentences.

3.3 Deviation in Meaning

Concerning deviations in meaning, a phenomenon that either introduces or removes a negation in the original sentence was developed, thus generating a sentence with the opposite meaning.

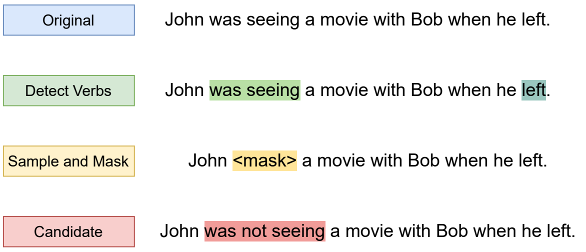
In order to negate the original sentences, this perturbation relies on the POLYJUICE (Wu et al., 2021) model conditioned for negation. POLYJUICE can either negate an entire sentence or a span, by masking the sentence or only the desired text span, respectively. Initial experiments showed that, when trying to negate the entire sentence, the model often forgot some content, specially in longer phrases. Thus, the developed approach, shown in Figure 2, masks a verb in the original sentence, as well as any adjacent auxiliary verbs before it, in order to produce a small perturbation that changes the meaning of the sentence. Specifically, the transform used a Part-of-Speech tagger from the Stanza library (Qi et al., 2020) in the original sentence and recovered all spans with 0 or more AUX tags immediately followed by a VERB tag. If no spans are detected, the generation process stops. Otherwise, one span is sampled using an uniform distribution. Finally, the conditioned POLYJUICE model produces the candidate sentence by negating the original sentence with a mask over the chosen span.

The validation phase for this phenomenon first verifies whether the candidate sentence is equal to the original or if the POLYJUICE model produced its empty token, meaning it was unable to generate a sentence. Furthermore, a RoBERTa (Liu et al., 2019) model trained for Multi-Genre Natural Language Inference (MNLI) corpus was used to verify whether the candidate contradicts the original sentence. This procedure is employed as a proxy for validating whether the generated sentence is a negation over the original.

3.4 Insertion of Content

Regarding the generation of Hallucinated content, a phenomenon to insert new content in the original sentence was devised.

The transformation phase of this perturbation employs a similar strategy to the Named Entities phenomenon. In this case, the masking pattern randomly inserts mask tokens between adjacent words in the original sentence. In order to avoid inserting too much content, a maximum of three mask tokens are introduced. After this step, the masked sentence is fed to the mT5 model, which generates the candidate sentence.



Original
John was seeing a movie with Bob when he left.
Detect Verbs
John was seeing a movie with Bob when he left.
Sample and Mask
John <mask> a movie with Bob when he left.
Candidate
John was not seeing a movie with Bob when he left.

Figure 2: Example of the transformation phase for the Deviation in Meaning phenomenon. Although not shown in this example, the POLYJUICE model receives additional information besides the masked sentence to know the text that was replaced by the mask.

In the validation phase, as in the Named Entities phenomenon, candidate sentences that are equal to the original or that match the regular expression for the mT5 masking pattern (<extra_id_\d{1,2}>) are discarded. Moreover, another sub-validation that ensures the minimum edit distance at a word-level between the candidate and original sentences is above a threshold was applied. As there are only insertions, this sub-validation ensures at least a minimum number of words are introduced in the candidate sentence. Furthermore, higher thresholds increase the likelihood of the candidate sentences having hallucinated content as, with a fixed number of masks (defined in the masking strategy), the model has to generate spans of text with multiple words and it is unlikely that only function words are introduced. Through manual experimentation, a threshold of eight words was found to produce a good balance between ensuring content was added without discarding too many valid candidates.

3.5 Removal of Content

Finally, translations with deletion errors were tackled by a phenomenon that removes a span of text between two punctuation symbols. By considering text spans between adjacent punctuation symbols, this method aims to remove a sub-phrase of the original sentence that likely contains some information, thus generating a sentence which is missing content.

As shown in Figure 3, the transformation phase of this perturbation starts by detecting all instances of the symbols . , ? ! in the original sentence. Then, a span between two adjacent symbols is randomly sampled with an Uniform Distribution. The chosen span, as well as the punctuation symbol after it, are deleted in order to generate the candidate sentence. In order to increase the likelihood of removing content, the deleted span has a minimum number of words. Furthermore, to increase the credibility of the generated sentence, three additional constraints were enforced. First, the first text span was not considered, as translation models are less likely to forget content in the beginning of the sentence. Second, the deleted span has a maximum size, as it is unlikely the translation model drops a large portion of the sentence. Third, if the generated candidate does not end in . ! ? , the final symbol is replaced by a punctuation mark. If no span exists in the previous conditions, the transform does not generate a candidate sentence.

This transform does not require any extra validation, as all verifications are enforced when choosing the text span to delete.

4 Challenge Set

The created test set comprises of records in the format $(s, h_{good}, h_{bad}, r, p)$, where s is a source sentence, h_{good} and h_{bad} are "good" and "bad" hypothesis, r is a reference and p is an identifier for the linguistic phenomenon present in h_{bad}. Three language pairs were considered: English-Portuguese, Spanish-English, Portuguese-English. For each language pair, a data augmentation approach was applied to an existing parallel corpus to generate a the final set of records.

4.1 Parallel Corpora

To create our challenge set we extracted sentences from OPUS (Tiedemann, 2012) ranging several domains such as News and Euro Parliament. To guarantee high-quality references we used Bicleaner tool (Ramírez-Sánchez et al., 2020) with a threshold of 0.85.

4.2 Augmentation Approach

For each language pair, the source side of the respective corpus was considered as source sentences and the target as references. First, the source sentences were translated using an OPUS-MT bilingual model (Tiedemann and Thottingal, 2020)[2]. Second, all the perturbations were applied to the references, generating sentences with at most one critical error. This information was aggregated to create records in the format $(s, h_{good}, h_{bad}, r, p)$, where h_{good} is the translation of the source sentence, h_{bad} is a perturbation of the reference and p is the linguistic phenomenon that was induced. With this approach, multiple records can be created from an original source and reference pair, one for each perturbation applied to the reference. In this case, all the records have the same good hypothesis.

The generated records were then manually filtered and validated to ensure its quality. In this process, we ensured that both the references and the good translations were high quality and that the bad translation contained a critical error. Furthermore, we chose records where h_{good} was different from r to force the metrics to attend to the meaning of the sentence instead of analysing lexical overlap. In the end, around 50 records for each phenomenon and language pair were obtained, as shown in Table 1. The Deviation in Named Entities and Meaning phenomena for the English-Portuguese language pair have 0 records since the Portuguese language is not supported by the NER model in the Stanza library or the POLYJUICE model.

5 Experiments

The developed test set was submitted to the WMT22 Challenge Set Sub-task and the scores for several State-of-the-Art metrics were gathered. The following sections detail the evaluation method for the tested metrics and the obtained results.

5.1 Evaluation Method

We rely on two evaluation methods to assess the robustness of metrics to the developed critical errors.

The first is the official evaluation method for the Shared Task in order to compare the performance of the several metrics. This method used a Kendall-Tau like formulation, defined as:

$$\tau = \frac{Concordant - Discordant}{Concordant + Discordant}, \qquad (1)$$

[2] Available at Hugging Face Transformers (Wolf et al., 2020)

en-pt		pt-en		es-en	
Phenomenon	**Size**	**Phenomenon**	**Size**	**Phenomenon**	**Size**
NE	0	NE	50	NE	48
NUM	49	NUM	48	NUM	50
MEAN	0	MEAN	50	MEAN	48
INS	44	INS	48	INS	50
DEL	48	DEL	50	DEL	49

Table 1: Number of selected records for each phenomenon and language pair. The Deviation in Named Entities and Meaning phenomenon have 0 records for the English-Portuguese language pair as the phenomenon do not support to-Portuguese language pairs.

where $Concordant$ is the number of times the metric assigned a higher score to the good hypothesis and $Discordant$ is the number of times the metric assigned a higher score to the bad hypothesis.

The second method measures the average difference between the scores assigned to h_{good} and h_{bad}, when the score assigned to the h_{good} is higher. For a given set S with pairs of scores, this method is defined as

$$d = \frac{\sum\limits_{(s_{good}, s_{bad}) \in S} \mathbb{I}[s_{good} > s_{bad}](s_{good} - s_{bad})}{\sum\limits_{(s_{good}, s_{bad}) \in S} \mathbb{I}[s_{good} > s_{bad}]} \quad (2)$$

where s_{good} and s_{bad} are respectively the scores for multiple good and bad hypothesis pairs. This formulation is used as a proxy for the confidence of the evaluated metric when it assigns a higher score to the good hypothesis. In order to compare multiple metrics with different scoring intervals, the metric scores are normalized before this evaluation method is applied.

5.2 Baseline Metrics

All the baseline metrics from the Sub-task were considered. These comprise of several State-of-the-Art methods: BLEU and CHRF are *n-gram* based metrics; BERTSCORE and YiSi-1 are *embedding*-similarity methods, and BLEURT20, COMET-20 and COMET-QE are learnt methods.

Figure 4 shows the obtained results for these metrics. For each phenomenon, results show the average Kendall-Tau considering all language pairs and the black bars represent the standard deviation. We observe that the metrics obtain mostly negative correlations, indicating they are assigning higher scores to the bad hypothesis. *n-gram* based metrics show the worst correlations. This result is to be expected as the perturbations create localized changes, such as changing a number, which do not significantly modify the alignments with the reference. Embedding-similarity based metrics exhibit a better performance as contextual embeddings can capture divergence in meaning of the bad hypothesis, but still the obtained correlations are mostly negative. Pretrained models obtain the best results, having positive correlations for the phenomenon Deviation in Meaning, Insertion and Removal of Content. Nevertheless, they still show poor correlations and struggle with Deviation in Named Entities and Numbers.

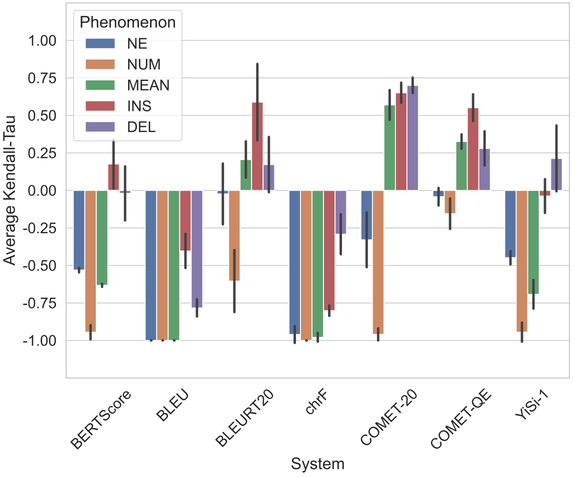

Figure 4: Average Kendall-Tau for baseline metrics discriminated by phenomenon. The coloured bars indicate the average score for all language pairs and the black bars represent the standard deviation.

5.3 Submitted Metrics

The submissions that rely on the reference to predict a score encompass COMET-22 (Rei et al., 2022), metricx_xl_DA_2019[3], MS-COMET-22 (Kocmi et al., 2022) and UniTE (Wan et al., 2022).

[3] Citation was not available.

As depicted in Figure 5, these metrics obtain much higher correlations, when compared to the baselines. The metric metricx_xl_DA_2019 obtains the overall best results, achieving high correlations for all phenomena. Across all metrics, the Deviation in Numbers phenomenon is the one with lowest scores. Furthermore, it is also the one with the highest standard deviation over the several language pairs, showing the uncertainty of these metrics when faced with this perturbation.

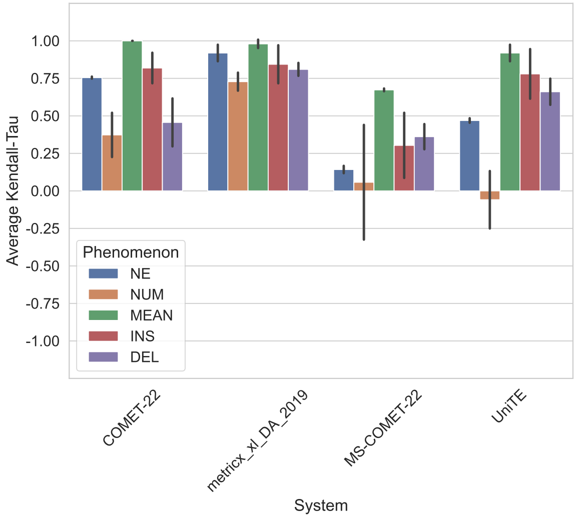

Figure 5: Average Kendall-Tau for submitted reference based metrics discriminated by phenomenon. The coloured bars indicate the average score for all language pairs and the black bars represent the standard deviation.

Regarding reference free metrics, submissions comprise of COMET-Kiwi (Rei et al., 2022), HWTSC-Teacher-Sim (Liu et al., 2022), HWTSC-TLM (Liu et al., 2022), KG-BERTScore (Liu et al., 2022) and MS-COMET-QE-22 (Kocmi et al., 2022). Here, it is important to note that HWTSC-TLM is a system that only receives the hypothesis as input and, as such, it is likely in disadvantage in this task, as the developed bad hypothesis are only critical errors in the context of the source sentence.

As shown in Figure 6, several reference free metrics obtain very high correlations for all linguistic phenomena. The main exception is HWTSC-TLM, which can be attributed to the reasons explained above. KG-BERTScore obtains the best overall results, with almost perfect correlations. Furthermore, we observe that reference free metrics outperform reference based metrics. This result is further discussed in the following section.

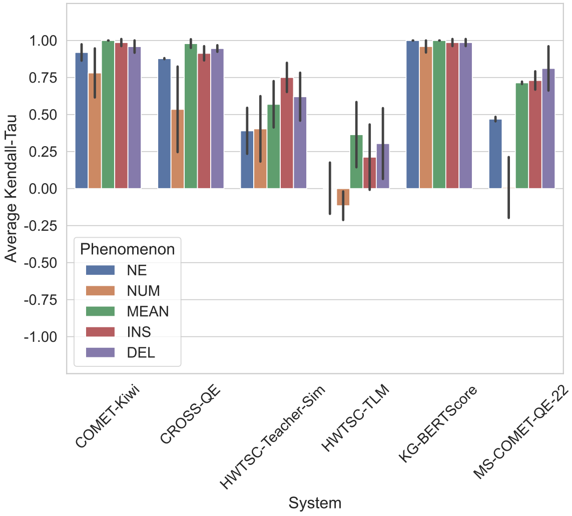

Figure 6: Average Kendall-Tau for submitted reference free metrics discriminated by phenomenon. The coloured bars indicate the average score for all language pairs and the black bars represent the standard deviation.

5.4 Reference based vs Reference free

Figure 7 compares the performance of reference based and reference free metrics across all phenomena. We observe that reference free metrics obtain higher correlations on all perturbations, which can be attributed to the adversarial nature of the bad hypothesis that is specifically generated with a localized perturbation of the reference.

This result reveals the dependency of reference based metrics on the reference and, in particular, on the word overlap of the reference with the hypothesis. Reference-free metrics are forced to attend to the source and compare its meaning with the hypothesis, as there is little word overlap between the two sentences. This issue is particularly visible in the Deviation in Named Entities and Numbers phenomena, where the reference and bad hypothesis differ on a single named entity or number, respectively.

Comparing the performance of metrics for each phenomenon, we verify that both groups of metrics obtain lower correlations for Deviation in Named Entities and Numbers, indicating these phenomena are not well detected by current methods. Moreover, the results show large standard deviations, suggesting an inherent unpredictability on the performance of current methods for all phenomena.

5.5 Penalisation of critical errors

In order to measure whether the metrics penalize the critical errors when they score the bad hypoth-

esis lower, we compare their Kendall-Tau values with their average difference between the scores for good and bad hypothesis, as described in Section 5.1.

In Figure 8, we observe that submitted metrics not only obtain higher correlations but also have a greater difference between the scores attributed to the good and bad hypothesis. Moreover, the two variables follow a linear relationship, obtaining a Pearson Correlation Coefficient of 0.8924. This shows the metrics that correctly distinguish the good from the bad hypothesis also penalize the bad hypothesis accordingly.

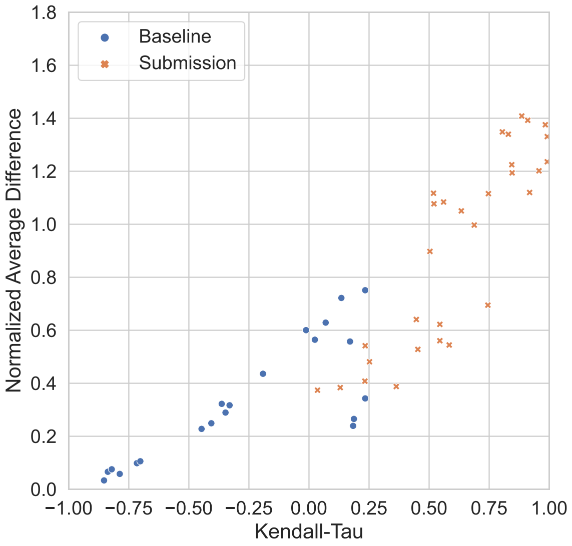

Figure 8: Average Kendall-Tau and Difference for all metrics. Each data point represents a single metric and language pair.

6 Conclusions

Ensuring generated translations do not have critical errors is a crucial aspect of Machine Translation Evaluation, as they can pose various risks. In this work, we propose SMAUG, a multilingual augmentation framework to create translations with critical errors by inducing several linguistic phenomena in existing translations. We also apply these perturbations to create a manually verified test set to assess the robustness of Machine Translation Evaluation systems to critical errors.

With the created test set, we evaluate multiple metrics and show promising progress in current State-of-the-Art methods in both distinguishing translations with and without critical errors and significantly penalizing the occurrence of critical errors in translations. Nevertheless, errors related to named entities and numbers were found to pose a challenge for several tested metrics. Additionally, we observe a high variance in the measured correlations across all the developed phenomena, suggesting an unpredictability on the performance of current methods with respect to detecting critical errors.

One of the challenges in the automatic generation of translations with critical errors is the validation of the output. In this work, we relied on a preliminary automatic validation but also required a manual verification of the outputs. Future work will explore high-precision validation techniques, such as the work of Raunak et al. (2022) that uses very specific detectors to find examples of critical errors in translations.

Furthermore, support for multiple languages is a crucial aspect of this framework. However, several of the devised perturbations support a limited number of languages pairs. For example, the Deviation in Meaning phenomenon only supports to-English language pairs, as the POLYJUICE model is an English only model. A future avenue of research will investigate methods to expanding the number of languages supported by the linguistic phenomena.

Abstract

As machine translation (MT) metrics improve their correlation with human judgement every year, it is crucial to understand the limitations of such metrics at the segment level. Specifically, it is important to investigate metric behaviour when facing accuracy errors in MT because these can have dangerous consequences in certain contexts (*e.g.,* legal, medical). We curate ACES[1], a Translation **A**ccuracy **C**halleng**E** **S**et, consisting of 68 phenomena ranging from simple perturbations at the word/character level to more complex errors based on discourse and real-world knowledge. We use ACES to evaluate a wide range of MT metrics including the submissions to the WMT 2022 metrics shared task and perform several analyses leading to general recommendations for metric developers. We recommend: a) combining metrics with different strengths, b) developing metrics that give more weight to the source and less to surface-level overlap with the reference and c) explicitly modelling additional language-specific information beyond what is available via multilingual embeddings.

1 Introduction

Challenge sets have already been created for measuring the success of systems or metrics on a particular phenomenon of interest for a range of NLP tasks, including but not limited to: Sentiment Analysis[2] (Li et al., 2017; Mahler et al., 2017; Staliūnaitė and Bonfil, 2017), Natural Language Inference (McCoy and Linzen, 2019; Rocchietti et al., 2021), Question Answering (Ravichander et al., 2021), Machine Reading Comprehension (Khashabi et al., 2018), Machine Translation (MT) (King and Falkedal, 1990; Isabelle et al., 2017), and the more specific task of pronoun translation in MT (Guillou and Hardmeier, 2016). They are useful to compare the performance of different systems, or to identify performance improvement/degradation between a modified system and a previous iteration.

In this work, we describe the University of Zurich - University of Edinburgh submission to the *Challenge Sets* subtask of the Conference on Machine Translation (WMT) 2022 Metrics shared task. Our Translation **A**ccuracy **C**halleng**E** **S**et (ACES) consists of 36,476 examples covering 146 language pairs and representing challenges from 68 phenomena (see Appendix A.4 for the distribution of examples across language pairs and Appendix A.5 for the distribution of language pairs across phenomena). We focus on translation accuracy errors and base the phenomena covered in our challenge set on the Multidimensional Quality Metrics (MQM) ontology (Lommel et al., 2014). We include phenomena ranging from simple perturbations involving the omission/addition of characters or tokens, to more complex examples involving mistranslation e.g. ambiguity and hallucinations in translation, untranslated elements of a sentence, discourse-level phenomena, and real-world knowledge. We evaluate the metrics submitted to the WMT 2022 metrics shared task and a range of baseline metrics on ACES. Additionally, we perform an extensive analysis, which aims to reveal:

1. The extent to which reference-based and reference-free metrics take into account the source sentence context.

2. The extent to which reference-based metrics rely on surface-level overlap with the reference.

3. Whether using multilingual embeddings results in better metrics.

[*] Equal contribution by all authors.

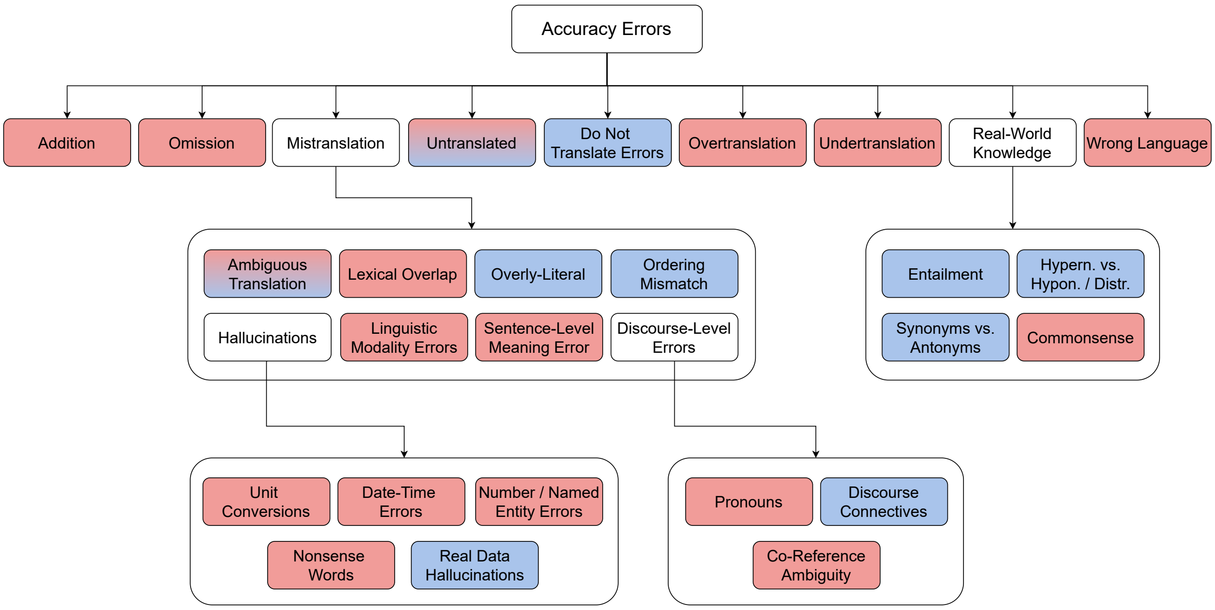

Figure 1: Diagram of the error categories on which our collection of challenge sets is based. Red means challenge sets are created automatically, blue means challenge sets are created manually.

Based on our analysis, we recommend that metric developers consider: a) combining metrics with different strengths, e.g. in the form of ensemble models, b) paying more attention to the source and avoiding reliance on surface-overlap with the reference, and c) explicitly modelling additional language-specific information beyond what is available via multilingual embeddings. We also propose that ACES be used as a benchmark for developing evaluation metrics for MT to monitor which error categories can be identified better, and also whether there are any categories for which metric performance degrades.

2 Motivation

With the advent of neural networks and especially Transformer-based architectures (Vaswani et al., 2017), machine translation outputs have become more and more fluent (Bentivogli et al., 2016; Toral and Sánchez-Cartagena, 2017; Castilho et al., 2017). Fluency errors are also judged less severely than accuracy errors by human evaluators (Freitag et al., 2021a) which reflects the fact that accuracy errors can have dangerous consequences in certain contexts, for example in the medical and legal domains (Vieira et al., 2021).

For these reasons, we decided to build a challenge set focused on accuracy errors. Specifically, we use the hierarchy of errors under the class *Accuracy* from the MQM ontology to design these challenge sets. We extend this ontology by two error classes (translations defying real-world knowledge and translations in the wrong language) and specify several more specific subclasses such as discourse-level errors or ordering mismatches. A full overview of all error classes can be seen in Figure 1. Our challenge set consists of synthetically generated adversarial examples, examples from repurposed contrastive MT test sets (both marked in red), and manually annotated examples (marked in blue). To create the challenge sets, we use test sets from tasks such as adversarial paraphrase detection, Natural Language Inference, and contrastive MT test sets created independently of the WMT shared tasks to avoid overlap with the data that is used to train neural evaluation metrics.

Another aspect we focus on is including a broad range of language pairs in ACES. Whenever possible we create examples for all language pairs covered in a source dataset when we use automatic approaches. For phenomena where we create examples manually, we also aim to cover at least two language pairs per phenomenon, but are of course limited to the languages spoken by the authors.

Finally, we aim to offer a collection of challenge sets covering both easy and hard phenomena. While it may be of interest to the community to continuously test on harder examples to check where machine translation evaluation metrics still break, we believe that easy challenge sets are just as important to ensure that metrics do not suddenly become worse at identifying error types that were previously considered “solved”. Therefore, we take a holistic view when creating ACES and do not filter out individual examples or exclude challenge sets based on baseline metric performance or other factors.

We first discuss previous efforts to create challenge sets (Section 3), before giving a broad overview of the datasets used to construct ACES (Section 4) and discussing the individual challenge sets in more detail (Section 5). We then introduce the metrics that participated in the shared task (Section 6), present an overview of their performance on ACES (Section 7) and detailed analyses (Section 8) that lead to a set of recommendations for future metric development (Section 9).

3 Related Work

Challenge sets are used to study a particular phenomenon of interest rather than the general distribution of phenomena in standard test sets (Popović and Castilho, 2019). The earliest introduction of challenge sets was by King and Falkedal (1990) who probed acceptability of machine translations for different domains. Challenge sets have been prevalent in different fields within NLP such as parsing (Rimell et al., 2009), NLI (McCoy and Linzen, 2019; Rocchietti et al., 2021), question answering (Ravichander et al., 2021), reading comprehension (Khashabi et al., 2018) and sentiment analysis (Li et al., 2017; Mahler et al., 2017; Staliūnaitė and Bonfil, 2017), to name a few. These challenge sets provide insights on whether state-of-the-art models are robust to domain shifts, and whether they have some understanding of linguistic phenomena like negation/commonsense or they simply rely on shallow heuristics. Another line of work under “adversarial datasets” also focuses on creating examples by perturbing the standard test set to fool the model (Smith (2012); Jia and Liang (2017), *inter-alia*).

Challenge sets for evaluating MT systems have focused on the translation models’ ability to generate the correct translation given a phenomenon of interest. These include word sense ambiguity (Vamvas and Sennrich, 2021), gender bias (Rudinger et al., 2017; Zhao et al., 2018; Stanovsky et al., 2019), structural divergence (Isabelle et al., 2017) and discourse level phenomena (Guillou and Hardmeier, 2016; Emelin and Sennrich, 2021).

While such challenge sets focus on evaluating specific machine translation models, it is necessary to identify whether the existing machine translation evaluation metrics also perform well under these and related phenomena. Developing challenge sets for machine translation metric evaluation has gained considerable interest because recently, neural MT evaluation metrics have shown improved correlation with human judgements (Freitag et al., 2021b; Kocmi et al., 2021). However, their weaknesses remain relatively unknown and only a small number of works (e.g. Hanna and Bojar (2021) and Amrhein and Sennrich (2022)) have proposed systematic analyses to uncover them.

Previous challenge sets for metric evaluation focused on negation and sentiment polarity (Specia et al., 2020) and synthetic perturbations such as antonym replacement, word omission, number swapping, punctuation removal, etc. (Freitag et al., 2021b). Avramidis et al. (2018) developed a manually constructed test suite of linguistically motivated perturbations for identifying weaknesses in reference-free evaluation. However, these challenge sets for metrics are only focused on high-resource language pairs such as English↔German and English→Chinese. In this work, we repurpose existing machine translation challenge sets to evaluate machine translation evaluation metrics. We introduce several synthetically generated and manually created challenge sets that broadly focus on translation accuracy errors for 146 language pairs.

4 Datasets

The majority of the examples in our challenge set were based on data extracted from three main datasets: FLORES-101, PAWS-X, and XNLI (with additional translations from XTREME).

The **FLORES-101** evaluation benchmark (Goyal et al., 2022) consists of 3,001 sentences extracted from English Wikipedia and translated into 101 languages by professional translators. **FLORES-200** (NLLB Team et al., 2022) expands the set of languages in FLORES-101. Originally intended for multilingual and low-resource MT evaluation, these datasets have a particular focus on low-resource languages.

PAWS-X (Yang et al., 2019), a cross-lingual dataset for paraphrase identification, consists of pairs of sentences that are labelled as true or adversarial paraphrases. It comprises the Wikipedia portion of the PAWS corpus (Zhang et al., 2019) translated from English into six languages: French, Spanish, German, Chinese, Japanese, and Korean.

The development and test sets (23,659 sentences total) were manually translated by professional translators, and the training set was translated using NMT systems via Google Cloud Translation[3].

XNLI (Conneau et al., 2018) is a multilingual Natural Language Inference (NLI) dataset consisting of 7,500 premise-hypothesis pairs with their corresponding inference label. The English examples were generated by crowd source workers before being manually translated into 14 languages: French, Spanish, German, Greek, Bulgarian, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, Hindi, Swahili and Urdu. In addition, we use the automatic translations from **XTREME** (Hu et al., 2020) of the XNLI test set examples from these 14 languages into English.

For the mistranslation phenomena Gender in Occupation Names and Word Sense Disambiguation, we leveraged the WinoMT and MuCoW datasets. **WinoMT** (Stanovsky et al., 2019), a challenge set developed for analysing gender bias in MT, contains 3,888 English examples extracted from the Winogender (Rudinger et al., 2017) and WinoBias (Zhao et al., 2018) coreference test sets. WinoMT sentences cast participants into non-stereotypical gender roles and the dataset has an equal balance of male and female genders, and of stereotypical and non-stereotypical gender-role assignments (e.g., a female nurse vs. a female doctor). **MuCoW** (Raganato et al., 2019) is a multilingual contrastive, word sense disambiguation test suite for machine translation. The dataset covers 16 language pairs with more than 200,000 contrastive sentence pairs. It was automatically constructed from word-aligned parallel corpora and BabelNet's (Navigli and Ponzetto, 2012) wide-coverage multilingual sense inventory.

For the discourse-level phenomena, we relied on *annotated* resources developed specifically to support work on those phenomena in an MT setting. The **WMT 2018 English-German pronoun translation evaluation test suite** (Guillou et al., 2018) contains 200 examples of the ambiguous English pronouns *it* and *they* extracted from the TED talks portion of ParCorFull (Lapshinova-Koltunski et al., 2018). The example sentences were translated into German by the 16 English-German systems submitted to WMT 2018, and the (German) pronoun translations were manually judged by human annotators as "good/bad". **Wino-X** (Emelin and Sennrich, 2021) is a parallel dataset of German, French, and Russian Winograd schemas, aligned with their English counterparts. It was developed for commonsense reasoning and coreference resolution and used for this purpose to generate examples for Commonsense Co-Reference Disambiguation. The **Europarl ConcoDisco** corpus (Laali and Kosseim, 2017) comprises the English-French parallel texts from Europarl (Koehn, 2005) over which automatic methods were used to perform PDTB-style discourse connective annotation. Discourse connectives are labelled with their sense type and are aligned between the two languages.

5 Challenge Sets

Creating a contrastive challenge set for evaluating a machine translation evaluation metric requires a source sentence, a reference translation, and two translation hypotheses: one which contains an error or phenomenon of interest (the "incorrect" translation) and one which is a correct translation in that respect (the "good" translation). One possible way to create such challenge sets is to start with two alternative references (or two identical copies of the same reference) and insert errors into one of them to form an incorrect translation while the uncorrupted version can be used as the good translation. This limits the full evaluation scope to translation hypotheses that only contain a single error. To create a more realistic setup, we also create many challenge sets where the good translation is not free of errors, but it is a better translation than the incorrect translation. For automatically created challenge sets, we put measures in place to ensure that the incorrect translation is indeed a worse translation than the good translation.

5.1 Addition and Omission

We create a challenge set for addition and omission errors which are defined in the MQM ontology as "target content that includes content not present in the source" and "errors where content is missing from the translation that is present in the source", respectively. We focus on the level of constituents and use an implementation by Vamvas and Sennrich (2022) to create synthetic examples of addition and omission errors.

To generate examples, we use the concatenated dev and devtest sets from the FLORES-101 evaluation benchmark. We focus on the 46 languages

[3] https://cloud.google.com/translate

for which there exists a stanza parser[4] and create datasets for all languages paired with English plus ten additional language pairs that we selected randomly. The script by Vamvas and Sennrich (2022) randomly drops constituents from the source sentence and then generates two translations, one of the full source and one of the partial source without the constituent. Here is an example of two resulting translations:

Full:	For example, castle visits in the Loire Valley, the Rhine Valley, or a cruise **to interesting cities on the Danube** or **a** boat ride along the Erie Canal.
Partial:	For example, castle visits in the Loire Valley, the Rhine Valley, or a cruise or boat ride along the Erie Canal.

Only partial translations that can be constructed by deleting spans from the full translation are considered. For translation, we use the M2M100[5] model with 1.2B parameters (Fan et al., 2021).

We create **omission** examples by taking the original source and reference and using the translation of the full source as a good translation and the translation of the partial source as an incorrect translation. For **addition** errors, we test if the deleted span also occurs in the reference. If it doesn't, we discard the example, if it does, we delete that span from the reference and pair this partial reference with the partial source. Then, the good translation is the translation of the partial source and the incorrect translation is the translation of the full source. For language pairs with a BLEU score of less than 13 between the good translation and the reference, we manually check the examples to ensure the challenge set features appropriate examples of additions and omissions.

5.2 Mistranslation - Ambiguous Translation

This error type is defined in the MQM ontology as a case where "an unambiguous source text is translated ambiguously". For this error type, we create challenge sets where MT metrics are presented with an unambiguous source and an ambiguous reference. The metrics then need to choose between two disambiguated translation hypotheses where only one meaning matches the source sentence. Therefore, these challenge sets test whether metrics consider the source when the reference is not expressive enough to identify the better translation. Since many reference-based metrics, by design, do not include the source to compute evaluation scores, we believe that this presents a challenging test set.

Our method for creating examples is inspired by Vamvas and Sennrich (2021) who score a translation against two versions of the source sentence, one with an added correct disambiguation cue and one with a wrong disambiguation cue to determine whether a translation model produced the correct translation or not. Instead of adding the disambiguation cues to the source, we use an unambiguous source and add disambiguation cues to an ambiguous reference to create two contrasting translation hypotheses.

5.2.1 Ambiguity - Occupation Names Gender

First, we create a challenge set based on WinoMT, where the challenge is to choose either a translation with a "female" or "male" disambiguation cue based on the source sentence:

SRC (de):	Der Manager feuerte **die** Bäcker**in**.
REF (en):	The manager fired the baker.
✓:	The manager fired the **female** baker.
✗:	The manager fired the **male** baker.

We take all English sentences from the WinoMT dataset where either a pro-stereotypical or an anti-stereotypical occupation name occurs. The original sentences in WinoMT contain additional context from which the gender in the English sentence can be inferred. For example, the sentence above exists in the dataset once as "The manager fired the baker because she was too rebellious." from which it is clear that the baker is female, and once as "The manager fired the baker because he was upset." from which it is clear that the manager is male. To make the English sentences ambiguous, we remove the explanatory subordinate clauses using a sequence of regular expressions, so that the sentence becomes "The manager fired the baker." where the gender of the manager and the baker are ambiguous.

We then add the disambiguation cues ("female" or "male") to the ambiguous English sentences and translate them into German, French and Italian which are all languages that mark gender morphologically on most nouns that refer to a person. For translation, we use Google Translate[6] because we find that this system produces gendered occupation

[4] https://stanfordnlp.github.io/stanza/available_models.html

[5] https://huggingface.co/facebook/m2m100_1.2B

[6] https://translate.google.com/

names that are largely faithful to the disambiguation cues. Finally, we remove explicit translations of "female" and "male" from the German, French or Italian output that would help the disambiguation beyond morphological cues. We predict the gender of the occupation names using the scripts provided by Stanovsky et al. (2019) and only keep translation pairs where both the translation of the male-disambiguated source is predicted to be male and the translation of the female-disambiguated source is predicted to be female. We then use either the German, French or Italian translation as the source sentence, the disambiguated English sentences as the translation candidates, and the ambiguous English sentence as the reference, as shown in the example above.

5.2.2 Ambiguity - Word Sense Disambiguation

Second, we create a challenge set based on MuCoW, where the challenge is to choose a translation with a sense-matching disambiguation cue based on the unambiguous source sentence:

SRC (de):	Was heisst "**Brühe**"?
REF (en):	What does "**stock**" mean?
✓:	What does "**vegetable stock**" mean?
✗:	What does "**penny stock**" mean?

We start with disambiguation cues that were automatically extracted by Vamvas and Sennrich (2021) via masked language modelling. Initial screening of the data shows that some disambiguation cues are not sense-specific enough. Therefore, we decide to manually check all disambiguation cues and ensure they are sense-specific and if necessary, replace them with other cues. We generate three pairs of contrasting disambiguation cues per example and use the question "What does X mean?" as a pattern to create the challenge set examples. We decided against using sentences where ambiguous words occur naturally since it may be possible to infer the correct sense from the context of the English sentence rather than by looking at the unambiguous source word. We annotate each example as to whether the correct sense is the more frequent or less frequent sense using frequency counts provided by Vamvas and Sennrich (2021). Following this methodology, we create challenge sets for German into English and Russian into English.

5.2.3 Ambiguity - Discourse Connectives

Third, we create a challenge set where the challenge is to identify a translation with the correct discourse connective based on the unambiguous source sentence:

SRC (fr):	Aucun test de qualité de l'air n'ait été réalisé dans ce bâtiment **depuis** notre élection.
REF (en):	No air quality test has been done on this particular building **since** we were elected.
✓:	No air quality test has been done on this particular building **from the time** we were elected.
✗:	No air quality test has been done on this particular building **because** we were elected.

The English discourse connective "since" can have either causal or temporal meaning, which is expressed explicitly in both French and German. Exploiting this fact, we use the ambiguous "since" in the reference and create two contrastive translations one with "because" for causal meaning and one with "from the time" for temporal meaning. The correct translation is determined by looking at the French or German source sentence where this information is marked explicitly. We use the discourse connective annotations in the Europarl ConcoDisco corpus for this challenge set. We use an automatic-guided search based on the French discourse connective "depuis" (which has temporal meaning) to identify candidate translation pairs. We then manually construct valid contrasting examples for causal and temporal "since" based on the English reference. This results in a challenge set for French-English but we also create a German-English version of the challenge set, where we translate the French source sentences into German and manually correct them.

5.3 Mistranslation - Hallucinations

In this category, we group together several subcategories of mistranslation errors that happen at the word level and could occur due to hallucination by an MT model. Such errors are wrong units, wrong dates or times, wrong numbers or named entities, as well as hallucinations at the subword level that result in nonsensical words. We also present a challenge set of annotated hallucinations in real MT outputs. These challenge sets test whether the machine translation evaluation metrics can reliably identify hallucinations when presented with a correct alternative translation.

5.3.1 Hallucination - Date-Time Errors

We create a challenge set for the category of “date-time errors”. To do this, we collect month names and their abbreviations for several language pairs. We then form a good translation by swapping a month’s name with its abbreviation. The corresponding incorrect translation is generated by swapping the month name with another month name:

SRC (pt): Os manifestantes esperam coletar uma petição de 1,2 milhão de assinaturas para apresentar ao Congresso Nacional em **novembro**.

REF (en): Protesters hope to collect a petition of 1.2 million signatures to present to the National Congress in **November**.

✓: The protesters expect to collect a petition of 1.2 million signatures to be submitted to the National Congress in **Nov.**

✗: The protesters expect to collect a petition of 1.2 million signatures to be submitted to the National Congress in **August**.

To create this dataset, we use the automatic translations of the FLORES-101 dataset from Section 5.1. We choose all pairs with target languages for which we know the abbreviations for months[7] which results in 70 language pairs. As a measure of control, we check that the identified month names in the translation also occur in the reference. If they do not, we exclude the example.

5.3.2 Hallucination - Numbers and Named Entities

We create a challenge set for numbers and named entities where the challenge is to identify translations with incorrect numbers or named entities. Following the analysis by Amrhein and Sennrich (2022), we perform character-level edits (adding, removing or substituting digits in numbers or characters in named entities) as well as word-level edits (substituting whole numbers or named entities). In the 2021 WMT metrics shared task, number differences were not a big issue for most neural metrics (Freitag et al., 2021b). However, we believe that simply changing a number in an alternative translation and using this as an incorrect translation as done by Freitag et al. (2021b) is an overly simplistic setup and does not cover the whole translation hypothesis space.

To address this shortcoming, we propose a three-level evaluation (see examples below). The first, easiest level follows Freitag et al. (2021b) and applies a change to an alternative translation to form an incorrect translation. The second level uses an alternative translation that is lexically very similar to the reference as the good translation and applies a change to the reference to form an incorrect translation. The third, and hardest level, uses an alternative translation that is lexically very different from the reference as the good translation and applies a change to the reference to form an incorrect translation. In this way, our challenge set tests whether number and named entity differences can still be detected as the surface similarity between the two translation candidates decreases and the surface similarity between the incorrect translation and the reference increases.

SRC (es): Sin embargo, Michael Jackson, Prince y **Madonna** fueron influencias para el álbum.

REF (en): Michael Jackson, Prince and **Madonna** were, however, influences on the album.

Level-1 ✓: However, Michael Jackson, Prince, and **Madonna** were influences on the album.

Level-1 ✗: However, Michael Jackson, Prince, and **Garza** were influences on the album.

Level-2 ✓: However, Michael Jackson, Prince, and **Madonna** were influences on the album.

Level-2 ✗: Michael Jackson, Prince and **Garza** were, however, influences on the album.

Level-3 ✓: The record was influenced by **Madonna**, Prince, and Michael Jackson though.

Level-3 ✗: Michael Jackson, Prince and **Garza** were, however, influences on the album.

We use cross-lingual paraphrases from the PAWS-X dataset as a pool of alternative translations to create this challenge set. For levels 2 and 3, we measure surface-level similarity with Levenshtein distance[8] at the character-level and use spacy[9] (Honnibal et al., 2020) for identifying named entities of type “person”. To substitute whole named entities, we make use of the `names`[10] Python library. We only consider language pairs for which we can use a spacy NER model on the target side, which results in 42 language pairs.

[9] `https://spacy.io/`

[10] `https://github.com/treyhunner/names`

5.3.3 Hallucination - Unit Conversion

We create a challenge set for unit conversions where the challenge is to identify the correct unit conversion:

SRC (de):	Auf einem **100 Fuß** langen Teilabschnitt läuft Wasser über den Damm.
REF (en):	Water is spilling over the levee in a section **100 feet** wide.
✓:	On a **30.5 metres** long section, water flows over the dam.
✗:	On a **100 metres** long section, water flows over the dam.

We take all source sentences, reference sentences and translations of the FLORES-101 sets from Section 5.1. We only use the 45 language pairs into English since the Python packages we use for unit conversion only work for English. We first use the Python package `quantulum3`[11] to extract unit mentions from text. We only consider sentences where we identify the same unit mentions in the translation as in the reference and we remove self-disambiguating unit mentions, like "645 miles (1040 km)" from the reference and translation. Then, we use the Python package `pint`[12] to convert unit mentions in the translation into different units. The permitted conversions are listed in Appendix A.2.

The sentence with the converted amount and new unit is considered to be the good translation. Based on this sentence, we construct two incorrect versions, one where the amount matches the reference but the unit is still converted (see example above) and one where the amount is the converted amount but the unit is copied from the reference. We pair each incorrect translation with the good translation and add both examples to the challenge set individually. We are aware that this challenge set lies beyond the ability of current MT systems and evaluation metrics, however, we believe challenge sets such as these incentivise future work on such capabilities which would reduce the workload in post-editing.

5.3.4 Hallucination - Nonsense Words

We also consider more natural hallucinations at the subword level. Because recent MT systems are trained with subwords (Sennrich et al., 2016), an MT model may choose a wrong subword at a specific time step such that the resulting token is not a known word in the target language. With this challenge set, we are interested in how well neural MT evaluation metrics that incorporate subword-level tokenisation can identify such "nonsense" words.

To create this challenge set, we consider tokens which are broken down into at least two subwords and then randomly swap those subwords with other subwords to create nonsense words. In the example below, "mass" is broken down as "mas" and "##s" using subwords and the new word is created by swapping "mas" with "in" while retaining "##s", creating "ins" as the nonsense word. We use the paraphrases from the PAWS-X dataset as good translations and randomly swap one subword in the reference to generate an incorrect translation. This perturbation is language-agnostic. We use the multilingual BERT (Devlin et al., 2019) tokeniser to replace the subwords.

SRC (de):	Die **Massen**produktion von elektronischen und digitalen Filmen war bis zum Aufkommen der pornographischen Videotechnik direkt mit der Mainstream-Filmindustrie verbunden.
REF (en):	The **mas**s production of electronic and digital films was directly linked to the mainstream film industry until the emergence of pornographic video technology.
✓:	Until the advent of pornographic video technology , the mass production of electronic and digital films was tied directly to the mainstream film industry.
✗:	The **in**s production of electronic and digital films was directly linked to the mainstream film industry until the emergence of pornographic video technology.

5.3.5 Hallucination - Real Data Hallucinations

The previously discussed hallucination challenge sets were all created automatically. In addition to these challenge sets, we also create one with real data hallucinations.

For this dataset, we manually check the translations of the FLORES-101 dev and devtest sets for four language pairs: de→en, en→de, fr→de and en→mr. We consider both cases where a more frequent, completely wrong word occurs and cases where the MT model started with the correct subword but then produced random subwords as hallucinations. Translations with a hallucination are used as incorrect translations. We manually replace the hallucination part with its correct translation to form the good translation. If possible, we create one good translation by copying the corresponding

[11] https://github.com/nielstron/quantulum3

[12] https://github.com/hgrecco/pint

token(s) from the reference and one with a synonymous token that does not match the reference:

SRC (de): Es wird angenommen, dass dieser voll gefiederte warmblütige Raubvogel aufrecht auf zwei Beinen lief und **Krallen** wie der Velociraptor hatte.

REF (en): This fully feathered, warm blooded bird of prey was believed to have walked upright on two legs with **claws** like the Velociraptor.

✓ (copy): It is believed that this fully feathered warm-blooded predator ran upright on two legs and had **claws** like the Velociraptor.

✓ (syn.): It is believed that this fully feathered warm-blooded predator ran upright on two legs and had **talons** like the Velociraptor.

✗: It is believed that this fully feathered warm-blooded predator ran upright on two legs and had **crumbs** like the Velociraptor.

5.4 Mistranslation - Lexical Overlap

Language models trained with the masked language modelling objective are successful on downstream tasks because they model higher-order word co-occurrence statistics instead of syntactic structures (Sinha et al., 2021). Although this has been shown for a monolingual English model, we expect that multilingual pre-trained models, as well as MT metrics finetuned on such models, exhibit such behaviour. Similarly, existing surface-level metrics rely on n-gram matching between the hypothesis and the reference. Thus, we are interested in whether MT evaluation metrics can reliably identify the incorrect translation if it shares a high degree of lexical overlap with the reference:

SRC (fr): En 1924, il a été porte-parole invité de l'ICM à Toronto, à Oslo en 1932 et à Zurich en 1936.

REF (en): In 1924 he was an invited spokesman for the ICM in Toronto, in **Oslo in 1932** and in **1936 in Zurich.**

✓: He served as a guest speaker for ICM in 1924, 1932 and 1936 in Toronto, Oslo and Zurich.

✗: He was an invited spokesman for the ICM in Toronto in 1924, in **Zurich in 1932** and in **Oslo in 1936.**

In this example, Oslo and Zurich are swapped in the "incorrect translation" making the sentence factually incorrect. To create such examples, we use the PAWS-X dataset for which adversarial paraphrase examples were constructed by changing the word order and/or the syntactic structure while maintaining a high degree of lexical overlap. We only consider examples in the development set that are adversarial paraphrases.

We automatically translate the first example in a pair (fr→en, en→fr, en→ja) and then manually correct the translations for en, fr, and ja to obtain 100 "good translations" per language. We use the corresponding first paraphrase as the "reference" and the second (adversarial) paraphrase as the "incorrect translation". We then pair these examples with the first paraphrase in the remaining six languages in PAWS-X to obtain the "source". Following this methodology we create examples for each target language (xx→en, xx→fr, xx→ja).

5.5 Mistranslation - Linguistic Modality

Modal auxiliary verbs signal the function of the main verb that they govern. For example, they may be used to denote possibility ("could"), permission ("may"), the giving of advice ("should"), or necessity ("must"). We are interested in whether MT evaluation metrics can identify when modal auxiliary verbs are incorrectly translated:

SRC (de): Mit der Einführung dieser Regelung **könnte** diese Freiheit enden.

REF (en): With this arrangement in place, this freedom **might** end.

✓: With the introduction of this regulation, this freedom **could** end.

✗: With the introduction of this regulation, this freedom **will** end.

We focus on the English modal auxiliary verbs: "must" (necessity), and "may", "might", "could" (possibility). We begin by identifying parallel sentences where there is a modal verb in the German source sentence and one from our list (above) in the English reference. We then translate the source sentence using Google Translate to obtain the "good" translation and manually replace the modal verb with an alternative with the same meaning where necessary (e.g. "have to" denotes necessity as does "must"; also "might", "may" and "could" are considered equivalent). For the incorrect translation, we manually substitute the modal verb that conveys a different meaning or *epistemic strength* e.g. in the example above "might" (possibility) is replaced with "will", which denotes (near) certainty. Instances of "may" with *deontic* meaning (e.g. expressing permission) are excluded from the set, leaving only those with an *epistemic* meaning (expressing probability or prediction). We also construct examples in which the modal verb is omitted from the incorrect translation.

We employ two strategies to create examples: one in which the modal auxiliary is substituted, and another where it is deleted. We use a combination of the FLORES-200 and PAWS-X datasets as the basis of the challenge sets.

5.6 Mistranslation - Overly Literal Translations

MQM defines this error type as translations that are overly literal, for example literal translations of figurative language. Here, we look specifically at idioms and at real-data errors.

5.6.1 Overly Literal - Idioms

Idioms tend to be translated overly literally (Dankers et al., 2022) and it is interesting to see if such translations are also preferred by neural machine translation evaluation metrics, which likely have not seen many idioms during finetuning:

SRC (de):	Er hat versucht, mir die Spielregeln zu erklären, aber **ich verstand nur Bahnhof**.
REF (en):	He tried to explain the rules of the game to me, but **I did not understand them**.
✓:	He tried to explain the rules of the game to me, but **it was all Greek to me**.
✗:	He tried to explain the rules of the game to me, but **I only understood train station**.

We create this challenge set based on the PIE[13] parallel corpus of English idiomatic expressions and literal paraphrases (Zhou et al., 2021). We manually translate 102 parallel sentences into German for which we find a matching idiom that is not a word-by-word translation of the original English idiom. Further, we create an overly-literal translation of the English and German idioms. We use either the German or English original idiom as the source sentence. Then, we either use the correct idiom in the other language as the reference and the literal paraphrase as the good translation, or vice versa. The incorrect translation is always the overly-literal translation of the source idiom.

5.6.2 Overly-Literal - Real Data Errors

We are also interested in overly-literal translations occurring in real data:

SRC (de):	Today, the only insects that cannot fold back their wings are **dragon flies** and mayflies.
REF (en):	Heute sind **Libellen** und Eintagsfliegen die einzigen Insekten, die ihre Flügel nicht zurückklappen können.
✓ (copy) :	Heute sind die einzigen Insekten, die ihre Flügel nicht zurückbrechen können, **Libellen** und Mayflies.
✓ (syn.):	Heute sind die einzigen Insekten, die ihre Flügel nicht zurückbrechen können, **Wasserjungfern** und Mayflies.
✗:	Heute sind die einzigen Insekten, die ihre Flügel nicht zurückbrechen können, **Drachenfliegen** und Mayflies.

For this challenge set, we manually check MT translations of the FLORES-101 datasets. If we find an overly-literal translation, we manually correct it to form the good translation. We create one good translation where we copy the part of the reference that corresponds to the overly-literal part and, if possible, another good translation where we use a synonym of the reference token. This challenge set contains examples for four language pairs: de→en, en→de, fr→de and en→mr.

5.6.3 Mistranslation - Sentence-Level Meaning Error

We also consider a special case of sentence-level semantic error that arises due to the nature of the task of Natural Language Inference (NLI). The task of NLI requires identifying where the given hypothesis is an entailment, contradiction, or neutral, with respect to a given premise. As a result, the premise and hypothesis have substantial overlap but they vary in meaning. We are interested in whether MT evaluation metrics can pick up on such sentence-level meaning changes:

SRC (el):	Ο πραγματικός ϑόρυβος ελκύει τους ηλικιωμένους.
REF (en):	Real noise appeals to the old. (premise)
✓:	The real noise attracts the elderly.
✗:	Real noise appeals to the young and appalls the old. (hypothesis)

We use the XNLI dataset to create such examples. We consider examples where there is at least 0.5 chrF score between the English premise and hypothesis and where the labels are either contradiction or neutral. Examples with an entailment label are excluded as some examples in the dataset are paraphrases of each other and there would be no sentence-level meaning change. We discuss ef-

[13] https://github.com/zhjjn/MWE_PIE

fects of entailment in Section 5.12.1. We use either the premise or the hypothesis as the reference and an automatic translation as the "good translation". The corresponding premise or hypothesis from the remaining 14 languages is used as the source. The "incorrect translation" is either the premise if the reference is the hypothesis, or vice versa.

5.7 Mistranslation - Ordering Mismatch

We also investigate the effects of changing word order in a way that changes meaning:

SRC (de):	Erfülle Dein Zuhause mit einem köstlichem **Kaffee** am Morgen und etwas entspannendem **Kamillentee** am Abend.
REF (en):	Fill your home with a rich **coffee** in the morning and some relaxing **chamomile tea** at night.
✓:	Fill your home with a delicious **coffee** in the morning and some relaxing **chamomile tea** in the evening.
✗:	Fill your home with a delicious **chamomile tea** in the morning and some relaxing **coffee** in the evening.

This challenge set is created manually by changing translations from the FLORES-101 dataset and covers de→en, en→de and fr→de.

5.8 Mistranslation - Discourse-level Errors

We introduce a new subclass of mistranslation errors that specifically cover discourse-level phenomena.

5.8.1 Discourse-level Errors - Pronouns

First, we are interested in how MT evaluation metrics handle various discourse-level phenomena related to pronouns. To create these challenge sets, we use the English-German pronoun translation evaluation test suite from the WMT 2018 shared task as the basis for our examples.

We extract all translations (by the English-German WMT 2018 systems) that were marked as "correct" by the human annotators, for the following six categories derived from the manually annotated pronoun function and attribute labels: pleonastic *it*, anaphoric subject and non-subject position *it*, anaphoric *they*, singular *they*, and group *it/they*. In the case of anaphoric pronouns, we select only the inter-sentential examples (i.e. where the sentence contains both the pronoun and its antecedent). We use the MT translations as the "good" translations and automatically generate "incorrect" translations using one of the following strategies: *omission* - the translated pronoun is deleted from the MT output, *substitution* - the "correct" pronoun is replaced with an "incorrect" form.

For *anaphoric* pronouns, when translated from English into a language with grammatical gender, such as German, the pronoun translation must a) agree in number and gender with the translation of its antecedent, and b) have the correct grammatical case. We propose "incorrect" translations as those for which this agreement does not hold:

SRC (en):	I have a *shopping bag*; ***it*** is red.
REF (de):	Ich habe eine *Einkaufstüte*; ***sie*** ist rot.
✓:	Ich habe einen *Einkaufsbeutel*; ***er*** ist rot.
✗ (subs.):	Ich habe einen *Einkaufsbeutel*; ***sie*** ist rot.
✗ (omit):	Ich habe einen *Einkaufsbeutel*; ***Ø*** ist rot.

Conversely, for *pleonastic* uses of "it" no agreement is required, instead, the correct translation in German requires a simple mapping: "it" → "es". An ‘incorrect" translation of pleonastic ‘it' in German could be "er" (masc. sg.) or "sie" (fem. sg., or pl.). We create, for each "correct" translation a set of possible "incorrect" values and automatically select one at random to replace the "correct" pronoun. For example, in the pleonastic case:

SRC (en):	**It** is raining
REF (de):	**Es** regnet
✓:	**Es** regnet
✗ (subs.):	**Er** regnet
✗ (omit):	**Ø** regnet

5.8.2 Discourse-level Errors - Discourse Connectives

The English discourse connective "while" is ambiguous – it may be used with either a *Comparison.Contrast* or *Temporal.Synchrony* sense – as are two of its possible translations into French: "tandis que" and "alors que". We leverage a corpus of parallel English/French sentences with discourse connectives marked and annotated for sense, and select examples with ambiguity in the French source sentence. We construct the good translation by replacing instances of "while" temporal with "as" or "as long as" and instances of "while" comparison as "whereas" (ensuring grammaticality is preserved). For the incorrect translation, we replace the discourse connective with one with the alternative sense of "while" e.g. we use "whereas" (comparison) where a temporal sense is required:

SRC (fr):	Dans l'UE-10, elles ont progressé de 8% **tandis que** la dette pour l'UE-2 a augmenté de 152%.
REF (en):	In EU-10 they grew by 8% **while** the debt for the EU-2 increased by 152%.
✓:	In the EU-10, they increased by 8% **when** the debt for the EU-2 increased by 152%.
✗:	In the EU-10, they increased by 8% **whereas** the debt for the EU-2 increased by 152%.

We extract our examples from the Europarl ConcoDisco dataset. We automatically selected the sentence pairs that contain an instance of "while" in English and either "alors que" or "tandis que" in French. Our dataset contains examples for both the *Comparison.Contrast* sense and the *Temporal.Synchrony* sense.

This challenge set complements the discourse connectives set in section 5.2.3, in which the English discourse connective "since" is ambiguous, but the corresponding connectives in French and German are not. Note that while in the previous challenge set the correct translation can be identified by looking at the source, here metrics can only rely on context to identify the correct discourse connective.

5.8.3 Discourse-level Errors - Commonsense Co-Reference Disambiguation

One of the greater challenges within computational coreference resolution is referring to the correct antecedent by using commonsense/real-world knowledge. Emelin and Sennrich (2021) construct a benchmark to test whether multilingual language models and neural machine translation models can perform such commonsense coreference resolutions. We are interested in whether such commonsense coreference resolutions pose a challenge for MT evaluation metrics:

SRC (en):	It took longer to clean the fish tank than the dog cage because **it** was dirtier.
REF (de):	Das Reinigen des Aquariums dauerte länger als das des Hundekäfigs, da **es** schmutziger war.
✓:	Das Reinigen des Aquariums dauerte länger als das des Hundekäfigs, da **das Aquarium** schmutziger war.
✗ :	Die Reinigung des Aquariums dauerte länger als die des Hundekäfigs, da **er** schmutziger war.

The English sentences in the Wino-X challenge set were sampled from the Winograd schema. All contain the pronoun *it* and were manually translated into two contrastive translations for de, fr, and ru. Based on this data, we create our challenge sets covering two types of examples: For the first, the good translation contains the pronoun referring to the correct antecedent, while the incorrect translation contains the pronoun referring to the incorrect antecedent. For the second, the correct translation translates the instance of *it* into the correct disambiguating filler, while the second translation contains the pronoun referring to the incorrect antecedent (see example above).

The sentences for en→de were common across both the challenge sets developed by Emelin and Sennrich (2021). Hence, the corresponding correct translations from the two challenge sets were used as the "good" translation for our evaluation setup. For en→ru and en→fr, the source containing the ambiguous pronoun was machine translated and then verified by human annotators to form the "good" translation.

5.9 Untranslated

MQM defines this error type as "errors occurring when a text segment that was intended for translation is left untranslated in the target content". In ACES, we consider both word-level and sentence-level untranslated content.

5.9.1 Untranslated - Word-Level

For word-level untranslated content, we manually annotate translations of the FLORES-101 dev and devtest sets:

SRC (fr):	À l'origine, l'émission mettait en scène des **comédiens de doublage** amateurs, originaires de l'est du Texas.
REF (de):	Die Sendung hatte ursprünglich lokale Amateur**synchronsprecher** aus Ost-Texas.
✓ (copy):	Ursprünglich spielte die Show mit Amateur**synchronsprechern** aus dem Osten von Texas.
✓ (syn.):	Ursprünglich spielte die Show mit Amateur-**Synchron-Schauspielern** aus dem Osten von Texas.
✗:	Ursprünglich spielte die Show mit Amateur-**Doubling-Schauspielern** aus dem Osten von Texas.

We do not only count complete copies as untranslated content but also content that clearly comes from the source language but was only adapted to look more like the target language (as in the example above). If we encounter an untranslated span, we use this translation as the incorrect translation and create a good translation by copying the correct span from the reference and, if possible, a second good translation where we use a synonym for the correct reference span. We manually annotate such untranslated errors for en→de, fr→de, de→en, en→mr.

5.9.2 Untranslated - Full Sentences

In the case of underperforming machine translation models, sometimes the generated output contains a majority of the tokens from the source language to the extent of copying the entire source sentence.[14] We create a challenge set by simply copying the entire source sentence as the incorrect translation. We used a combination of examples from the FLORES-200, XNLI, and PAWS-X datasets to create these examples.

We expect that this challenge set is likely to break embedding-based, reference-free evaluation because the representation of the source and the incorrect translation will be the same, thus leading to a higher score.

5.10 Do Not Translate Errors

This category of errors is defined in MQM as content in the source that should be copied to the output in the source language, but was mistakenly translated into the target language. Common examples of this error type are company names or slogans. Here, we manually create a challenge set based on the PAWS-X data which contains many song titles that should not be translated:

SRC (en):	Dance was one of the inspirations for the exodus - song **"The Toxic Waltz"**, from their 1989 album "Fabulous Disaster".
REF (de):	Dance war eine der Inspirationen für das Exodus-Lied **„The Toxic Waltz"** von ihrem 1989er Album „Fabulous Disaster".
✓:	Der Tanz war eine der Inspirationen für den Exodus-Song **„The Toxic Waltz"**, von ihrem 1989er Album „Fabulous Disaster".
✗:	Der Tanz war eine der Inspirationen für den Exodus-Song **„Der Toxische Walzer"**, von ihrem 1989er Album „Fabulous Disaster".

To construct the challenge set, we use one paraphrase as the good translation and manually translate an English sequence of tokens (e.g. a song title) into German to form the incorrect translation.

5.11 Overtranslation and Undertranslation

Hallucinations from a translation model can often produce a term which is either more generic than the source word or more specific. Within the MQM ontology, the former is referred to as undertranslation while the latter is referred to as overtranslation. For example, "car" may be substituted with "vehicle" (undertranslation) or "BMW" (overtranslation). To automate the generation of such errors, we use Wordnet (Miller, 1994). In our setup a randomly selected noun from the reference translation is replaced by its corresponding hypernym or hyponym to simulate undertranslation or overtranslation errors, respectively:

SRC (de):	Bob und Ted waren Brüder. Ted ist der **Sohn** von John.
REF (en):	Bob and Ted were brothers. Ted is John's **son**.
✓:	Bob and Ted were brothers, and Ted is John's **son**.
✗:	Bob and Ted were brothers. Ted is John 's **male offspring**.

During the implementation, we only replaced the first sense listed in Wordnet for the corresponding noun, which may not be appropriate in the given translation. We constructed this challenge set for hypernyms and hyponyms using the PAWS-X dataset, only considering the language pairs where the target language is English.

5.12 Real-world Knowledge

We manually constructed examples each for en→de and de→en for the first four phenomena described in this section. We used German-English examples from XNLI, plus English translations from XTREME as the basis for our examples. Typically, we select a single sentence, either the premise or hypothesis from XNLI, and manipulate the MT translations.

5.12.1 Real-world Knowledge - Textual Entailment

We test whether the metrics can recognise textual entailment – that is, whether a metric can recognise that the meaning of the source/reference is entailed by the "good" translation. We construct examples for which the good translation entails the meaning of the original sentence (and its reference). For example, we use the entailment *was murdered* → *died* (i.e. if a person is murdered then they must have died) to construct the good translation in the

[14] Through observations of Swahili → English translation; unpublished work

example above. We construct the incorrect translation by replacing the entailed predicate (*died*) with a related but non-entailed predicate (here *was attacked*) – a person may have been murdered without being attacked, i.e. by being poisoned for example. When constructing our examples we focus solely on leveraging *directional entailments*. We specifically exclude paraphrases as these are bidirectional.

In cases where an antonymous predicate is available, we use that predicate in the incorrect translation. For example, if "lost" is in the source/reference, we use "won" in the incorrect translation (lost $\not\Rightarrow$ won).

SRC (de):	Ein Mann **wurde ermordet**.
REF (en):	A man **was murdered**.
✓:	A man **died**.
✗ (omit):	A man **was attacked**.

5.12.2 Real-world Knowledge - Hypernyms and Hyponyms

We consider a translation that contains a *hypernym* of a word to be better than one that contains a *hyponym*. For example, whilst translating "Hund" ("dog") with the broader term "animal" results in some loss of information, this is preferable over hallucinating information by using a more specific term such as "labrador" (i.e. an instance of the hyponym class "dog"):

SRC (de):	..., dass der **Hund** meiner Schwester gehört.
REF (en):	... the **dog** belonged to my sister.
✓ (hypernym):	... the **pet** belonged to my sister.
✗ (hyponym):	... the **labrador** belonged to my sister.

We used Wordnet and WordRel.com[15] (an online dictionary of words' relations) to identify hypernyms and hyponyms of nouns within the reference sentences, and used these as substitutions in the MT output: hypernyms are used in the "good" translations and hyponyms in the "incorrect" translations.

5.12.3 Real-world Knowledge - Hypernyms and Distractors

Similar to the hypernym vs. hyponym examples, we construct examples in which the good translation contains a hypernym (here "pet") of the word in the reference (here "dog"). We form the incorrect translation by replacing the original word in the source/reference with a different member from the same class (here "cat"; both cats and dogs belong to the class of pets). For example:

SRC (de):	..., dass der **Hund** meiner Schwester gehört.
REF (en):	... the **dog** belonged to my sister.
✓ (hypernym):	... the **pet** belonged to my sister.
✗ (hyponym):	... the **cat** belonged to my sister.

As before, we used Wordnet and WordRel.com to identify hypernyms of nouns present in the reference translation.

5.12.4 Real-world Knowledge - Antonyms

Similar to the generation of over- and undertranslations, we also constructed "incorrect" translations by replacing words with their corresponding antonyms from Wordnet. We construct challenge sets for both nouns and verbs.

For nouns, we automatically constructed "incorrect" translations by replacing nouns in the reference with their antonyms. The "good" translation is not amended. This method may result in noisy replacement of nouns with their respective antonyms.

In the case of verbs, we manually constructed a more challenging set of examples intended to be used to assess whether the metrics are able to distinguish between translations that contain a synonym versus an antonym of a given word. We replaced verbs in the reference with a synonym to produce the good translation, and with their antonym to produce the incorrect translation:

SRC (de):	Ich **hasste** jedes Stück der Schule!
REF (en):	I **hated** every bit of school!
✓ (synonym):	I **loathed** every bit of school!
✗ (antonym):	I **loved** every bit of school!

For the verbs challenge set, we consider a translation that contains a synonym of a word in the reference to be a "good" translation, and one that contains an antonym of that word to be "incorrect". As in the example above the use of synonyms preserves the meaning of the original sentence, and the antonyms introduce a polar opposite meaning.

5.12.5 Real-world Knowledge - Commonsense

We are also interested in whether evaluation metrics prefer translations that adhere to common sense. To test this, we remove explanatory subordinate

[15] https://wordrel.com/

clauses from the sources and references in the dataset described in Section 5.8.3. This guarantees that when choosing between the good and incorrect translation, the metric cannot infer the correct answer from looking at the source or the reference:

SRC (en):	Die Luft im Haus war kühler als in der Wohnung.
REF (de):	The air in the house was cooler than in the apartment.
✓:	The air in the house was cooler than in the apartment because **the apartment** had a broken air conditioner.
✗:	The air in the house was cooler than in the apartment because **the house** had a broken air conditioner.

We remove the explanatory subordinate clauses using a sequence of regular expressions. We then pair the shortened source and reference sentences with the full translation that follows commonsense as the good translation and the full translation with the other noun as the incorrect translation.

Since we present several challenge sets in Section 5.2 where the good translation can only be identified by looking at the source sentence, we also create a version of this challenge set where the explanatory subordinate clause is only removed from the reference but not from the source. By comparing this setup with the results from the setup described above, we achieve another way of quantifying how much a metric considers the source.

5.13 Wrong Language

Most of the representations obtained from large multilingual language models do not explicitly use the language identifier (id) as an input while encoding a sentence. Here, we are interested in checking whether sentences which have similar meanings are closer together in the representation space of neural MT evaluation metrics, irrespective of their language. We create a challenge set for embedding-based metrics where the incorrect translation is in a similar language (same typology/same script) to the reference (e.g. a Catalan translation may be used as the incorrect translation if the target language is Spanish). Note that this is also a common error with multilingual machine translation models. We constructed these examples using the FLORES-200 dataset where the "good" translation was the automatic translation and the "incorrect" translation was the reference from a language similar to the target language:

SRC (en):	Cell comes from the Latin word cella which means small room.
REF (es):	El término célula deriva de la palabra latina cella, que quiere decir «cuarto pequeño».
✓ (es):	La célula viene de la palabra latina cella que significa habitación pequeña.
✗ (ca):	Cèl·lula ve de la paraula llatina cella, que vol dir habitació petita.

We construct two categories within this challenge set: one where the target language is a higher-resource language and the incorrect language is a lower-resource language and vice-versa. The languages we consider are (`src-tgt-sim`): en-hi-mr, en-es-ca, en-cs-pl, fr-mr-hi, en-pl-cs, and en-ca-es.

Note that if we were to compare references for different languages and not an automatic translation vs. a reference, this challenge set should be considered unsolvable for reference-free metrics if there is no way to specify the desired target language. But in this case, we expect reference-free metrics to prefer the reference that we use as the "incorrect translation" since there may be translation errors in the automatically translated "good translation".

5.14 Fluency

Although the focus of ACES is on accuracy errors, we also include a small set of fluency errors for the punctuation category. Future work might consider expanding this set to include other categories of fluency errors.

5.14.1 Punctuation

We assess the effect of deleting and substituting punctuation characters. We employ four strategies: 1) deleting all punctuation, 2) deleting only quotation marks (i.e. removing indications of quoted speech), 3) deleting only commas (i.e. removing clause boundary markers), 4) replacing exclamation points with question marks (i.e. statement → question).

In strategies 1 and, especially, 3 and 4, some of the examples may also contain accuracy-related errors. For example, the meaning of the sentence could be changed in the incorrect translation if we remove a comma, e.g. in the (in)famous example "Let's eat, Grandma!" vs. "Let's eat Grandma!". We use the TED Talks from the WMT 2018 English-German pronoun translation evaluation test suite and apply all deletions and substitutions automatically.

6 Evaluation Methodology

We shall now briefly describe the metrics that participated in the challenge set shared task. The organisers of the shared task also provided scores by a number of baseline metrics, as described below.

6.1 Baseline Metrics

BLEU (Papineni et al., 2002) compares the token-level n-grams of the hypothesis with the reference translation and then computes a precision score weighted by a brevity penalty.

spBLEU (Goyal et al., 2022) is BLEU computed over text tokenised with a single language-agnostic SentencePiece subword model. The spBLEU baselines, F101SPBLEU and F200SPBLEU, are named according to whether the SentencePiece tokeniser (Kudo and Richardson, 2018) was trained using data from the FLORES-101 or FLORES-200 languages.

chrF (Popović, 2017) evaluates translation outputs based on a character n-gram F-score by computing overlaps between the hypothesis and the reference.

BERTScore (Zhang et al., 2020) uses contextual embeddings from pre-trained language models to compute the similarity between the tokens in the reference and the generated translation using cosine similarity. The similarity matrix is used to compute precision, recall, and F1-scores.

BLEURT20 (Sellam et al., 2020) is a BERT-based (Devlin et al., 2019) regression model, which is first trained on scores of automatic metrics/similarity of pairs of reference sentences and their corrupted counterparts. It is then fine-tuned on the WMT human evaluation data to produce a score for a hypothesis given a reference translation.

COMET-20 (Rei et al., 2020) uses a cross-lingual encoder (XLM-R (Conneau et al., 2020)) and pooling operations to obtain sentence-level representations of the source, hypothesis, and reference. These sentence embeddings are combined and then passed through a feedforward network to produce a score. COMET is trained on human evaluation scores of machine translation systems submitted to WMT until 2020.

COMET-QE was trained similarly to COMET-20 but as this is a reference-free metric, only the source and the hypothesis are combined to produce a final score.

YiSi-1 (Lo, 2019) measures the semantic similarity between the hypothesis and the reference by using cosine similarity scores of multilingual representations at the lexical level. It optionally uses a semantic role labeller to obtain structural similarity. Finally, a weighted f-score based on structural and lexical similarity is used for scoring the hypothesis against the reference.

6.2 Metrics Submitted to WMT 2022

We list the descriptions provided by the authors of the respective metrics and refer the reader to the relevant system description papers for further details.

COMET-22 (Rei et al., 2022) is an ensemble between a vanilla COMET model trained with Direct Assessment (DA) scores and a Multitask model that is trained on regression (MQM regression) and sequence tagging (OK/BAD word identification from MQM span annotations). These models are ensembled together using a hyperparameter search that weights different features extracted from these two evaluation models and combines them into a single score. The vanilla COMET model is trained with DA's ranging 2017 to 2020 while the Multitask model is trained using DA's ranging from 2017 to 2020 plus MQM annotations from 2020 (except for en-ru that uses TedTalk annotations from 2021).

Metric-X is a massive multi-task metric, which fine tunes large language model checkpoints such as mT5 on a variety of human feedback data such as Direct Assessment, MQM, QE, NLI and Summarization Eval. Scaling up the metric is the key to unlocking quality and makes the model work in difficult settings such as evaluating without a reference, evaluating short queries, distinguishing high quality outputs, and evaluating on other generation tasks such as summarisation. The four metrics are referred to according to the mT5 model variant used (xl or xxl) and the fine-tuning data: METRICX_*_DA_2019 only used 2015-19 Direct Assessment data for fine-tuning, whereas METRICX_*_MQM_2020 used a mixture of Direct Assessment 2015-19 and MQM 2020 data.

MS-COMET-22 and **MS-COMET-QE-22** (Kocmi et al., 2022) are built on top of the COMET (Rei et al., 2020) architecture. They are trained on a several times larger set of human judgements covering 113 languages and covering 15 domains. Furthermore, the authors propose filtering of human judgements with potentially low quality. MS-COMET-22 receives the source, the MT hypothesis and the human reference as input, while MS-COMET-QE calculates scores in a quality estimation fashion with access only to the source segment and the MT hypothesis.

UniTE (Wan et al., 2022), Unified Translation Evaluation, is a metric approach where the model-based metrics can possess the ability of evaluating translation outputs following all three evaluation scenarios, i.e. source-only, reference-only, and source-reference-combined. These are referred to in this paper as UNITE-SRC, UNITE-REF, and UNITE respectively.

COMET-Kiwi (Rei et al., 2022) ensembles two QE models similarly to COMET-22. The first model follows the classic Predictor-Estimator QE architecture where MT and source are encoded together. This model is trained on DAs ranging 2017 to 2019 and then fine-tuned on DAs from MLQE-PE (the official DA from the QE shared task). The second model is the same multitask model used in the COMET-22 submission but without access to a reference translation. This means that this model is a multitask model trained on regression and sequence tagging. Both models are ensembled together using a hyperparameter search that weights different features extracted from these two QE models and combines them into a single score.

Huawei submitted several metrics to the shared task (Liu et al., 2022). **Cross-QE** is a submission based on the COMET-QE architecture. **HWTSC-Teacher-Sim** is a reference-free metric constructed by fine-tuning the multilingual Sentence BERT model: paraphrase-multilingual-mpnet-base-v2 (Reimers and Gurevych, 2019). **HWTSC-TLM** is a reference-free metric which only uses a target-side language model and only uses the system translations as input. **KG-BERTScore** is a reference-free machine translation evaluation metric, which incorporates a multilingual knowledge graph into BERTScore by linearly combining the results of BERTScore and bilingual named entity matching.

MATESE metrics (Perrella et al., 2022) leverage Transformer-based multilingual encoders to identify error spans in translations, and classify their severity between MINOR and MAJOR. The quality score returned for a translation is computed following the MQM error weighting introduced in Freitag et al. (2021a). MATESE is reference-based, while **MATESE-QE** is its reference-free version, with the source sentence used in place of the reference.

MEE (Mukherjee et al., 2020) is an automatic evaluation metric that leverages the similarity between embeddings of words in candidate and reference sentences to assess translation quality, focusing mainly on adequacy. Unigrams are matched based on their surface forms, root forms and meanings which aims to capture lexical, morphological and semantic equivalence. Semantic evaluation is achieved by using pretrained fasttext embeddings provided by Facebook to calculate the word similarity score between the candidate and reference words. MEE computes an evaluation score using three modules namely exact match, root match and synonym match. In each module, fmean-score is calculated using the harmonic mean of precision and recall by assigning more weightage to recall. The final translation score is obtained by taking average of fmean-scores from individual modules.

MEE2 and **MEE4** (Mukherjee and Shrivastava, 2022b) are improved versions of MEE, focusing on computing contextual and syntactic equivalences along with lexical, morphological and semantic similarity. The intent is to capture fluency and context of the MT outputs along with their adequacy. Fluency is captured using syntactic similarity and context is captured using sentence similarity leveraging sentence embeddings. The final sentence translation score is the weighted combination of three similarity scores: a) Syntactic Similarity achieved by modified BLEU score; b) Lexical, Morphological and Semantic Similarity: measured by explicit unigram matching similar to MEE score; c) Contextual Similarity: Sentence similarity scores are calculated by leveraging sentence embeddings of Language-Agnostic BERT models.

REUSE (Mukherjee and Shrivastava, 2022a) is a REference-free UnSupervised quality Estimation Metric. This is a bilingual untrained metric. It estimates the translation quality at chunk-level and sentence-level. Source and target sentence chunks are retrieved by using a multi-lingual chunker. Chunk-level similarity is computed by leveraging BERT contextual word embeddings and sentence similarity scores are calculated by leveraging sentence embeddings of Language-Agnostic BERT models. The final quality estimation score is obtained by mean pooling the chunk-level and sentence-level similarity scores.

6.3 Evaluation of Metrics

For all phenomena in ACES where we generated more than 1,000 examples, we randomly subsample 1,000 examples according to the per language pair distribution to include in the final challenge set to keep the evaluation of new metrics tractable.

We follow the evaluation of the challenge sets from the 2021 edition of the WMT metrics shared task (Freitag et al., 2021b) and report performance with Kendall's tau-like correlation. This metric measures the number of times a metric scores the good translation above the incorrect translation (concordant) and equal to or lower than the incorrect translation (discordant):

$$\tau = \frac{concordant - discordant}{concordant + discordant}$$

Ties are considered as discordant. Note that a higher τ indicates a better performance and that the values can range between -1 and 1.

7 Results

7.1 Phenomena-level Results

We start by providing a broad overview of metric performance on the different categories of phenomena. We compute Kendall's tau-like correlation scores (Section 6) for the 24 metrics which a) provide segment-level scores and b) provide scores for all language pairs and directions in ACES. We first compute the correlation scores for all of the individual phenomena and then take the average score over all phenomena in each of the nine top-level accuracy categories in ACES plus the fluency category punctuation (see Table 1).

The performance of the metrics varies greatly and there is no clear *winner* in terms of performance across all of the categories. There is also a high degree of variation in terms of metric performance when each category is considered in isolation. Whilst each of the categories proves challenging for at least one metric, some categories are more challenging than others. For example, looking at the average scores in the last row of Table 1, and without taking outliers into account, we might conclude that addition, undertranslation, real-world knowledge, and wrong language (all with average Kendall tau-like correlation of < 0.3) present more of a challenge than the other categories. On the other hand, for omission and do not translate (with an average Kendall tau-like correlation of > 0.7) metric performance is generally rather high.

We also observe variation in terms of the performance of metrics belonging to the baseline, reference-based, and reference-free groups. For example, the baseline metrics appear to struggle more on the overtranslation and undertranslation categories than the metrics belonging to the other groups. Reference-based metrics also appear to perform better overall on the untranslated category than the reference-free metrics. This makes sense as a comparison with the reference is likely to highlight tokens that ought to have been translated.

7.2 ACES Score

To analyse general, high-level, performance trends of the metrics on the ACES challenge set, we define a weighted combination of the top-level categories to derive a single score. We call this score the "ACES - Score":

$$\text{ACES} = sum\left\{\begin{array}{r} 5 * \tau_{\text{addition}} \\ 5 * \tau_{\text{omission}} \\ 5 * \tau_{\text{mistranslation}} \\ 1 * \tau_{\text{untranslated}} \\ 1 * \tau_{\text{do not translate}} \\ 5 * \tau_{\text{overtranslation}} \\ 5 * \tau_{\text{undertranslation}} \\ 1 * \tau_{\text{real-world knowledge}} \\ 1 * \tau_{\text{wrong language}} \\ 0.1 * \tau_{\text{punctuation}} \end{array}\right\} \quad (1)$$

The weights correspond to the values under the MQM framework that Freitag et al. (2021a) rec-

Table 1: Average Kendall's tau-like correlation results for the nine top level categories in the ACES ontology, plus the additional fluency category: punctuation. The horizontal lines delimit baseline metrics (top), participating reference-based metrics (middle) and participating reference-free metrics (bottom). The best result for each category is denoted by bold text with a green highlight. Note that *Average* is an average over averages. The last column shows the ACES-Score, a weighted sum of the correlations. The ACES-Score ranges from -29.1 (all phenomena have a correlation of -1) to 29.1 (all phenomena have a correlation of +1).

ommend for major (weight=5), minor (weight=1) and fluency/punctuation errors (weight=0.1). We determined that untranslated, do not translate and wrong language errors should be counted as minor errors because they can be identified automatically with language detection tools and should also be easy to spot in post-editing. We also include real-world knowledge under minor errors since we do not expect that current MT evaluation metrics have any notion of real-world knowledge and we do not want to punish them too severely if they do not perform well on this challenge set.

We caution that our weighting for the ACES-Score is not ideal, as some phenomena within a broad category might be more difficult than others. Still, we believe that an ACES-Score will be helpful to quickly identify changes in performance of a metric (e.g. following modifications), prior to conducting in-depth analyses at the category and sub-category levels. The ACES-Score ranges from -29.1 (all phenomena have a correlation of -1) to 29.1 (all phenomena have a correlation of +1).

The ACES-Score results can be seen in the last column of Table 1. Using the ACES-Score, we can see at a glance that the majority of the metrics submitted to the WMT 2022 shared task outperform the baseline metrics. Interestingly, many reference-free metrics also perform on par with reference-based metrics. The best performing metric is a reference-free metric, namely KG-BERTSCORE, closely followed by the reference-based metric METRICX_XL_DA_2019. Perhaps unsurprisingly, the worst performing metric is BLEU. However, we caution against making strong claims about which metrics perform *best* or *worst* on the challenge set based on this score alone. Instead, we recommend that ACES be used to highlight general trends as to what the outstanding issues are for MT evaluation metrics. More fine-grained analyses are reported in the following sections.

More generally, work on analysing system performance on ACES prompts the question: What is the definition of a good metric? One might consider that a *good* metric exhibits a strong correlation with human judgements on whether a translation is good/bad *and* assigns sufficiently different scores to a good vs. an incorrect translation. The latter criterion would provide evidence of the ability of the metric to discriminate reliably between good and incorrect translations, but it may be difficult to establish what this difference should be, especially without knowing to what degree the translations are good/bad without human judgements and because the scales of different metrics are not comparable. We leave an analysis of metrics' confidence on different error types for future work.

Table 2: Average Kendall's tau-like correlation results for the sub-level categories in mistranslation: **discourse-level**, **hallucination**, and **other** errors. The horizontal lines delimit baseline metrics (top), participating reference-based metrics (middle) and participating reference-free metrics (bottom). The best result for each category is denoted by bold text with a green highlight. Note that *Average* is an average over averages.

7.3 Mistranslation Results

Next, we drill down to the fine-grained categories of the largest category: *mistranslation*. We present metric performance on its sub-level categories in Table 2. Again, we find that performance on the different sub-categories is variable, with no clear *winner* among the metrics. The results suggest that hallucination phenomena are generally more challenging than discourse-level phenomena. Performance on the hallucination sub-category is poor overall, although it appears to be particularly challenging for the baseline metrics. We present additional, more fine-grained, performance analyses for individual phenomena in Section 8.

Table 3: Average Kendall's tau-like correlation results grouped by language pairs: trained language pairs (en-de, en-ru, zh-en), from English (en-x), into English (x-en) and language pairs not involving English (x-y). The horizontal lines delimit baseline metrics (top), all language pairs participating reference-based metrics (second), all language pairs participating reference-free metrics (third) and trained language pairs only metrics (bottom). The best result for each category is denoted by bold text with a green highlight.

Another possible way to evaluate the metrics' performance is not to look at the phenomena but rather at the results on different language pairs. Since ACES covers 146 language pairs and for some of these language pairs we only have very few examples, we decide to split this analysis into four main categories:

- **trained:** language pairs for which this year's WMT metrics shared task provided training material (en-de, en-ru and zh-en). This category also allows us to analyse the metrics that only cover these specific language pairs and not the full set of language pairs in ACES.
- **en-x:** language pairs where the source language is English.
- **x-en:** language pairs where the target language is English.
- **x-y:** all remaining language pairs, where neither the source language nor the target language are English.

Table 3 shows the results for all metrics. It is important to note that the results for different language pair categories cannot be directly compared because the examples and covered phenomena categories are not necessarily the same. However, we can compare metrics on each of the language pair groups individually. First, it can again be observed that most submitted metrics outperform the baseline metrics (first group). This shows that the field is advancing and MT evaluation metrics have improved since last year (i.e. 2021).

Interestingly, the six metrics that only scored the trained language pairs (last group in the table) do not outperform the other metrics on the "trained" category. Note, however, that the MEE* metrics and REUSE are unsupervised metrics and that the MATESE metrics only used MQM training data. Therefore, we cannot comment on creating metrics that are specific to a language pair would result in better metrics. In any case, our findings in Section 8.3.1 suggest that generalisation to unseen language pairs is generally quite good for the multilingual metrics which might be a more desirable property than increased performance on specific language pairs.

8 Analysis

Aside from high-level evaluations of which metrics perform best, we are mostly interested in metric-spanning weaknesses that we can identify using ACES. This section shows an analysis of three general questions that we aim to answer using ACES.

8.1 How sensitive are metrics to the source?

We designed our challenge sets for the type of ambiguous translation in a way that the correct translation candidate given an ambiguous reference can only be identified through the source sentence. Here, we present a targeted evaluation intended to provide some insights into how important the source is for different metrics. We exclude all metrics that do not take the source as input, all metrics

Table 4: Results on the challenge sets where the good translation can only be identified through the source sentence. Upper block: reference-based metrics, lower block: reference-free metrics. Best results for each phenomenon and each group of models is marked in bold and green and the average over all can be seen in the last column.

that do not cover all language pairs, and the smaller versions of METRIC-X (metricx_xl_DA_2019 and metricx_xl_MQM_2020) from this analysis. This leaves us with seven reference-based metrics and seven reference-free metrics. Table 4 shows the detailed results of each metric on the considered phenomena.

The most important finding is that the reference-free metrics generally perform much better on these challenge sets than the reference-based metrics. This indicates that reference-based metrics rely too much on the reference. Interestingly, most of the metrics that seem to ignore the source do not randomly guess the correct translation (which is a valid alternative choice when the correct meaning is not identified via the source) but rather they strongly prefer one phenomenon over the other. For example, several metrics show a gender bias either towards female occupation names (female correlations are high, male low) or male occupation names (vice versa). Likewise, most metrics prefer translations with frequent senses for the word-sense disambiguation challenge sets, although the difference between frequent and infrequent is not as pronounced as for gender.

Only metrics that look at the source and exhibit fewer such preferences can perform well on average on this collection of challenge sets. COMET-22 performs best out of the reference-based metrics and COMET-KIWI performs best of all reference-free metrics. It is noteworthy that there is still a considerable gap between these two models, suggesting that reference-based models should pay more attention to the source when a reference is ambiguous to reach the performance of reference-free metrics.

Table 5: Results on the real-world knowledge commonsense challenge set with reference-based metrics in the upper block and reference-free metrics in the lower block. The numbers are computed as the difference between the correlation with the subordinate clause in the source and the correlation without the subordinate clause in the source. Largest gains are bolded.

This finding is also supported by our real-world knowledge commonsense challenge set. If we compare the scores on the examples where the subor-

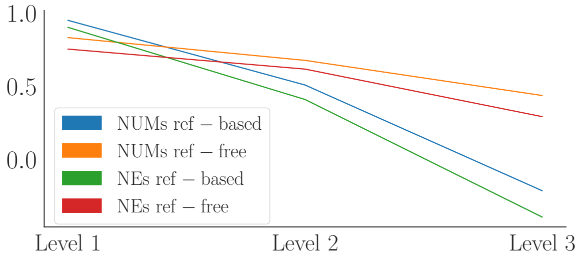

Figure 2: Decrease in correlation for reference-based and reference-free metrics on the named entity and number hallucination challenge sets.

dinate clauses are missing from both the source and the reference to the ones where they are only missing from the reference, we can directly see the effect of disambiguation through the source. The corresponding correlation gains are shown in Table 5. All reference-based model correlation scores improve less than most reference-free correlations when access to the subordinate clause is given through the source. This highlights again that reference-based metrics do not give enough weight to the source sentence.

8.2 How much do metrics rely on surface-overlap with the reference?

Another question we are interested in is whether neural reference-based metrics still rely on surface-level overlap with the reference. For this analysis, we use the dataset we created for hallucinated named entities and numbers. We take the average correlation for all reference-based metrics[16] and the average correlation of all reference-free metrics that cover all languages and plot the decrease in correlation with increasing surface-level similarity of the incorrect translation to the reference. The result can be seen in Figure 2.

We can see that on average reference-based metrics have a much steeper decrease in correlation than the reference-free metrics as the two translation candidates become more and more lexically diverse and the surface overlap between the incorrect translation and the reference increases. This indicates a possible weakness of reference-based metrics: If one translation is lexically similar to the reference but contains a grave error while others are correct but share less surface-level overlap with the reference, the incorrect translation may still be preferred.

	reference-based	reference-free
hallucination	-0.22 ± 0.16	+0.04 ± 0.07
overly-literal	-0.32 ± 0.16	+0.12 ± 0.09
untranslated	-0.44 ± 0.18	+0.03 ± 0.24

Table 6: Average correlation difference and standard deviation between the challenge sets with reference-copied good translations and the challenge sets with the synonymous good translations.

We also show that this is the case for the challenge set where we use an adversarial paraphrase from PAWS-X that shares a high degree of lexical overlap with the reference but does not have the same meaning as an incorrect translation. On average, the reference-based metrics only reach a correlation of 0.05 ± 0.12 on this challenge set, whereas the reference-free metrics reach a correlation of 0.23 ± 0.15. This shows that reference-based metrics are less robust when the incorrect translation has high lexical overlap with the reference.

Finally, we can also see a clear effect of surface-level overlap with the source on three real error challenge sets where we have different versions of the good translation: some where the error was corrected with the corresponding correct token from the reference and some where the error was corrected with a synonym for the correct token from the reference. As seen in Table 6, the reference-based metrics show a much larger difference in correlation between the challenge sets with reference-copied good translations and the challenge sets with the synonymous good translations, than the reference-free metrics. For example, for the hallucination test set, reference-free metrics have very similar average performance when the good translation contains the same word as the reference vs. when it contains a synonym (δ of +0.04). On the other hand, the reference-based metrics lose on average -0.22 in correlation when the good translation contains the synonym rather than the same word as the reference. Based on all of these results, we conclude that even though state-of-the-art reference-based MT evaluation metrics are not only reliant on surface-level overlap anymore, such overlap still considerably influences their predictions.

8.3 Do multilingual embeddings help design better metrics?

As the community moves towards building metrics that use multilingual encoders, we investigate if some (un)desirable properties of multilingual em-

[16] Excluding surface-level baseline metrics: BLEU, SPBLEU and CHRF.

beddings are propagated in these metrics.

8.3.1 Zero-shot Performance

Similar to Kocmi et al. (2021), we investigate whether there is a difference in the performance of metrics on our challenge sets when evaluated on non-WMT language pairs *i.e.* language pairs unseen during the training of the metrics. For this analysis, we include only those metrics for which the training data consisted of some combination of WMT human evaluation data. As different metrics used data from different years, we consider an intersection of languages across these years as WMT language pairs. For a fair comparison, we consider a subset of examples from those phenomena where we have least 100 examples in WMT languages and 100 examples in non-WMT languages, irrespective of the number of examples per individual language pair. We report some of the phenomena in Table 7, where metrics are compared in terms of the correlation difference between the performance on WMT and non-WMT language pairs (see Appendix A.3 for the original WMT and non-WMT correlation scores and the list of language pairs).

Table 7: Correlation difference between the performance of WMT and non-WMT language pairs reported for trained metrics across a subset of examples. $\delta = \tau_{\text{WMT}} - \tau_{\text{non WMT}}$. WMT language pairs consist of a subset of languages seen during training of the metrics, while non-WMT language pairs are unseen. Results show that the metrics are able to generalise to unseen languages.

We draw similar conclusions to Kocmi et al. (2021), namely that trained metrics are not overfitted to the WMT language pairs. We observe that the median difference of τ between WMT and non-WMT language pairs is 0.056, indicating a good generalisation to unseen languages. We still note that performance on the phenomena is variable when we compare the results on WMT language pairs versus non-WMT language pairs. In the case of real-world knowledge commonsense, performance is slightly better on the non-WMT language pairs[17], while the opposite is (generally) true for the antonym replacement and, especially, the nonsense phenomena for certain metrics. Further analysis is required to better understand metric behaviour on zero-shot language pairs, especially considering that some of the analysed non-WMT language pairs have a target language that is also the target language in at least one of the WMT language pairs (e.g. English).

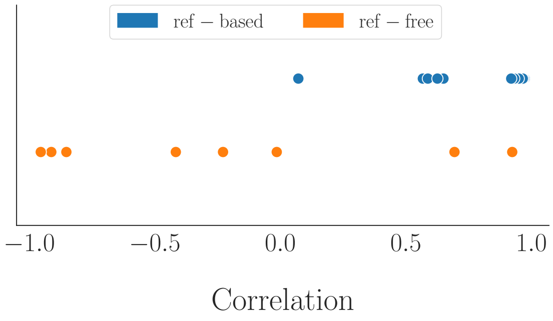

Figure 3: Correlation of reference-based metrics (blue) and reference-free metrics (orange) on the sentence-level untranslated test challenge set.

8.3.2 Language Dependent Representations

Multilingual models often learn cross-lingual representations by abstracting away from language-specific information (Wu and Dredze, 2019). We are interested in whether the representations are still language-dependent in neural MT evaluation metrics which are trained on such models. For this analysis, we look at the sentence-level untranslated text challenge set (see Figure 3) and wrong language phenomena (see Table 1). We only consider metrics that provided scores for examples in all language pairs.

Figure 3 shows the correlations for all reference-based and reference-free metrics. Unsurprisingly, some reference-free metrics struggle considerably on this challenge set and almost always prefer the copied source to the real translation. The representations of the source and the incorrect translation are identical, leading to a higher surface and embedding similarity, and thus a higher score. We do, however, find some exceptions to this trend

[17] We also observe better performance on non-WMT language pairs for the similar language high phenomenon.

- COMET-Kiwi and MS-COMET-QE-22 both have a high correlation on sentence-level untranslated text. This suggests that these metrics could have learnt language-dependent representations.

Most reference-based metrics have good to almost perfect correlation and can identify the copied source quite easily. As reference-based metrics tend to ignore the source (see Section 8.2), the scores are based on the similarity between the reference and the MT output. In this challenge set, the similarity between the good-translation and the reference is likely to be higher than the incorrect-translation and the reference. The former MT output is in the same language as the reference and will have more surface level overlap. We believe the reference here acts as grounding.

However, this grounding property of the reference is only robust when the source and reference languages are dissimilar, as is the case with language pairs in the sentence-level untranslated text challenge set. We find that reference-based metrics struggle on wrong language phenomena (see Table 1) where the setup is similar, but now the incorrect translation and the reference are from similar languages (e.g. one is in Hindi and the other is in Marathi). Naturally, there will be surface level overlap between the reference and both the good-translation and the incorrect-translation. For example, both Marathi and Hindi use named entities with identical surface form, and so these will appear in the reference and also in both the good-translation and the incorrect-translation. Thus, the semantic content drives the similarity scores between the MT outputs and the references. It is possible that the human translation in the similar language (labelled as the incorrect-translation) has a closer representation to the human reference because in the MT output (labelled as the good-translation) some semantic information may be lost. We leave further investigation of this for future work.

While multilingual embeddings help in effective zero-shot transfer to new languages, some properties of the multilingual representation space may need to be altered to suit the task of machine translation evaluation.

9 Recommendations

Based on the metrics results on ACES and our analysis, we derived the following list of recommendations for future MT evaluation metric development:

No metric to rule them all: Both the evaluation on phenomena and on language pair categories in Section 7 showed that there is no single best-performing metric. This divergence is likely to become even larger if we evaluate metrics on different domains. For future work on MT evaluation, it may be worthwhile thinking about how different metrics can be combined to make robust decisions as to which is the best translation. This year's submissions to the metrics shared task already suggest that work in that direction is ongoing as some groups submitted metrics that combined ensembles of models or multiple components (COMET-22, COMET-Kiwi, KG-BERTScore, MEE*, REUSE).

The source matters: Our analysis in Section 8.1 highlighted that many reference-based metrics that take the source as input do not consider it enough. Cases where the correct translation can only be identified through the source are currently better handled by reference-free metrics. This is a serious shortcoming of reference-based metrics and should be addressed in future research, also considering that many reference-based metrics do not even take the source as input.

Surface-overlap still prevails: In Section 8.2, we showed that despite moving beyond only surface-level comparison to the reference, most reference-based metric scores are still considerably influenced by surface-level overlap. We expect future metrics to use more lexically diverse references in their training regime to mitigate this issue.

Multilingual embeddings are not perfect: Some properties of multilingual representations, especially, being language-agnostic, can result in undesirable effects on MT evaluation (Section 8.3). It could be helpful for future metrics to incorporate strategies to explicitly model additional language-specific information.

10 Conclusion

We presented ACES, a translation accuracy challenge set based on the MQM ontology. ACES consists of 36,476 examples covering 146 language pairs and representing challenges from 68 phenomena. We used ACES to evaluate the baseline and submitted metrics from the WMT 2022 metrics shared task. Our overview of metric performance at the phenomena and language levels in Section 7 reveals that there is no single best-performing metric. The more fine-grained analyses in Section 8 highlight that 1) many reference-based metrics that take the source as input do not consider it enough, 2) most reference-based metric scores are still considerably influenced by surface overlap with the reference, and 3) the use of multilingual embeddings can have undesirable effects on MT evaluation.

We recommend that these shortcomings of existing metrics be addressed in future research, and that metric developers should consider a) combining metrics with different strengths, e.g. in the form of ensemble models, b) developing metrics that give more weight to the source and less to surface-level overlap with the reference, and c) incorporating strategies to explicitly model additional language-specific information (rather than simply relying on multilingual embeddings).

We have made ACES publicly available and hope that it will provide a useful benchmark for MT evaluation metric developers in the future.

Limitations

The ACES challenge set exhibits a number of biases. Firstly, there is greater coverage in terms of phenomena and number of examples for the en-de and en-fr language pairs. This is in part due to the manual effort required to construct examples for some phenomena, in particular those belonging to the discourse-level and real-world knowledge categories. Further, our choice of language pairs is also limited to the ones available in XLM-R. Secondly, ACES contains more examples for those phenomena for which examples could be generated automatically, compared to those that required manual construction/filtering. Thirdly, some of the automatically generated examples require external libraries which are only available for a few languages (e.g. Multilingual Wordnet). Fourthly, the focus of the challenge set is on accuracy errors. We leave the development of challenge sets for fluency errors to future work.

As a result of using existing datasets as the basis for many of the examples, errors present in these datasets may be propagated through into ACES. Whilst we acknowledge that this is undesirable, in our methods for constructing the *incorrect translation* we aim to ensure that the quality of the *incorrect translation* is always worse than the corresponding *good translation*.

The results and analyses presented in the paper exclude those metrics submitted to the WMT 2022 metrics shared task that provide only system-level outputs. We focus on metrics that provide segment-level outputs as this enables us to provide a broad overview of metric performance on different phenomenon categories and to conduct fine-grained analyses of performance on individual phenomena. For some of the fine-grained analyses, we apply additional constraints based on the language pairs covered by the metrics, or whether the metrics take the source as input, to address specific questions of interest. As a result of applying some of these additional constraints, our investigations tend to focus more on high and medium-resource languages than on low-resource languages. We hope to address this shortcoming in future work.

Ethics Statement

Some examples within the challenge set exhibit biases, however this is necessary in order to expose the limitations of existing metrics. Wherever external help was required in verifying translations, the annotators were compensated at a rate of £15/hour. Our challenge set is based on publicly available datasets and will be released for future use.

Acknowledgements

We thank the organisers of the WMT 2022 Metrics task for setting up this shared task and for their feedback throughout the process, and the shared task participants for scoring our challenge sets with their systems. We are grateful to Stephanie Droop, Octave Mariotti, and Kenya Murakami for helping us with the annotations. We thank the StatMT group at Edinburgh, especially Alexandra Birch, Barry Haddow, and Ulrich Germann, and the attendees at the MT Marathon 2022 for their valuable feedback. We thank Janis Goldzycher, Mark Steedman, Rico Sennrich, and the anonymous reviewers for their insightful comments and suggestions. This work was supported in part by the UKRI Centre for Doctoral Training in Natural Language Processing, funded by the UKRI (grant EP/S022481/1) and the University of Edinburgh (Moghe), by the Swiss National Science Foundation (project MUTAMUR; no. 176727) (Amrhein) and by the ERC H2020 Advanced Fellowship GA 742137 SEMANTAX (Guillou). We also thank Huawei for their support (Moghe).

A Appendix

A.1 Language Codes

Code	Language	Code	Language
af	Afrikaans	ja	Japanese
ar	Arabic	ko	Korean
be	Belarusian	lt	Lithuanian
bg	Bulgarian	lv	Latvian
ca	Catalan	mr	Marathi
cs	Czech	nl	Dutch
da	Danish	no	Norwegian
de	German	pl	Polish
el	Greek	pt	Portuguese
en	English	ro	Romanian
es	Spanish	ru	Russian
et	Estonian	sk	Slovak
fa	Persian	sl	Slovenian
fi	Finnish	sr	Serbian
fr	French	sv	Swedish
ga	Irish	sw	Swahili
gl	Galician	ta	Tamil
he	Hebrew	th	Thai
hi	Hindi	tr	Turkish
hr	Croatian	uk	Ukranian
hu	Hungarian	ur	Urdu
hy	Armenian	vi	Vietnamese
id	Indonesian	wo	Wolof
it	Italian	zh	Chinese

Table 8: ISO 2-Letter language codes of the languages included in the challenge set

A.2 Permitted Unit Conversions

We allow the following unit conversions for the challenge set that covers such errors:

Distance:

- miles → metres
- kilometres → miles
- kilometres → metres
- metres → feet
- metres → yards
- feet → metres
- feet → yards
- centimetres → inches
- centimetres → millimetres
- inches → centimetres

- inches → millimetres
- millimetres → centimetres
- millimetres → inches
- millimetres → inches

Speed:

- miles per hour → kilometres per hour
- kilometres per hour → miles per hour
- kilometres per second → miles per second
- miles per second → kilometres per second

Time:

- hours → minutes
- minutes → seconds
- seconds → minutes
- days → hours
- months → weeks
- weeks → days

Volume:

- barrels → gallons
- barrels → litres
- gallons → barrels
- gallons → litres

Weight:

- kilograms → grams
- kilograms → pounds
- grams → ounces
- ounces → grams

Area:

- square kilometres → square miles

A.3 Zero Shot Performance Scores

Table 9 contains the Kendall tau-like correlation scores for neural metrics on WMT language pairs (a subset of those seen during training) and non-WMT language pairs (unseen), for three phenomena: antonym replacement, real-world knowledge commonsense, and nonsense. The table contains the complete set of scores, and complements Table 7, which reports only the difference between the non-WMT and WMT correlation scores. See Section 8.3.1 on zero-shot performance. We shall now list the language pairs across the different phenomena:

Antonym Replacement

WMT:	de-en
non-WMT:	ko-en, es-en

Real-world Knowledge - Commonsense

WMT:	de-en, ru-en, en-ru, en-de
non-WMT:	ru-de, fr-ru, ru-fr, de-ru

Nonsense

WMT:	de-en
non-WMT:	fr-ja, ko-ja, en-ko, ko-en

Note that the subset of examples used in this analysis only consists of mid/high resource language pairs; investigation into the performance on low-resource languages is left for future work.

A.4 Distribution of Examples Across Language Pairs

Table 10 contains the total number of examples per language pair in the challenge set. As can be seen in the table, the distribution of examples is variable across language pairs. The dominant language pairs are: en-de, de-en, and fr-en.

A.5 Distribution of Language Pairs Across Phenomena

Table 11 contains the list of language pairs per phenomena in the challenge set. As can be seen in the table, the distribution of language pairs is variable across phenomena. Addition and omission have the highest variety of language pairs. en-de is the most frequent language pair across all phenomena.

	antonym-replacement		real-world knowledge -commonsense		nonsense	
	WMT	Non-WMT	WMT	Non-WMT	WMT	Non-WMT
BERTScore	-0.376	-0.408	0.007	0.060	0.790	-0.678
BLEURT-20	0.024	-0.008	0.396	0.195	-0.273	-0.622

UniTE	0.632	0.552	0.409	0.409	0.441	-0.203
COMETKiwi	0.744	0.696	0.745	0.772	0.510	0.469
Cross-QE	0.680	0.616	0.638	0.450	0.720	0.538
HWTSC-Teacher-Sim	0.504	0.296	0.248	0.168	0.930	0.580
UniTE-src	0.776	0.680	0.651	0.490	0.524	0.552

Table 9: Zero-shot performance of neural metrics on three phenomena to measure the ability of metrics to generalise to new language pairs. WMT language pairs consist of a subset of languages seen during training of the metrics, while non-WMT language pairs are unseen. Results show that the metrics are able to generalise to unseen languages.

Linguistically Motivated Evaluation of Machine Translation Metrics based on a Challenge Set

Eleftherios Avramidis and Vivien Macketanz

Abstract

We employ a linguistically motivated challenge set in order to evaluate the state-of-the-art machine translation metrics submitted to the Metrics Shared Task of the 7th Conference for Machine Translation. The challenge set includes about 20,000 items extracted from 145 MT systems for two language directions (German⇔English), covering more than 100 linguistically-motivated phenomena organized in 14 categories. The best performing metrics are YiSi-1, BERTScore and COMET-22 for German-English, and UniTE, UniTE-ref, MetricX-XL-DA19 and MetricX-XXL-DA19 for English-German. Metrics in both directions are performing worst when it comes to named-entities & terminology and particularly measuring units. Particularly in German-English they are weak at detecting issues at punctuation, polar questions, relative clauses, dates and idioms. In English-German, they perform worst at present progressive of transitive verbs, future II progressive of intransitive verbs, simple present perfect of ditransitive verbs and focus particles.

1 Introduction

Automatic evaluation metrics have been valuable tools for Machine Translation (MT), allowing quick evaluation and suggesting directions for further development. Many metrics have been suggested throughout the years, which in turn sets the requirement for their evaluation.

Whereas MT metrics so far have been evaluated based on the agreement of their scores with human judgments on test sets drawn from broad text, little research has taken place on investigating whether the performance of the metrics generalizes enough when evaluating particular cases. A more target way of evaluating metrics is using *challenge sets*. These are targeted test sets, which have been devised in such a way, so that they benchmark the ability of metrics to score particular translation phenomena.

In this paper we present empirical results on the performance of MT metrics, using an extensive challenge set, which includes thousands of test items aiming to test the performance over more than one hundred linguistically-motivated phenomena in two language directions. It is based on thousands of manually created test items, their translation outputs from dozens of MT systems and semi-automatically evaluated with the supervision of linguists. Through this analysis we attempt to reveal strengths and weaknesses of several state-of-the-art MT metrics considering their background methods with regards to linguistic aspects.

The rest of the paper is structured as follows. In Section 2 related work is briefly described. In Section 3 we describe the construction of the challenge set and the evaluation protocol. The empirical results are outlined in Section 4, followed by a conclusion is Section 5.

2 Related work

The need for a thorough evaluation of Natural Language Processing (NLP) tools has lately received increased interest in the research community, indicated by a big amount of publications, among them several which received best paper awards (Ribeiro et al., 2020; Avelino et al., 2022; Campolungo et al., 2022). When focusing on MT, first efforts were made in the 1990s with the introduction of test suites (King and Falkedal, 1990), which were revived after the latest advances in the field (Guillou and Hardmeier, 2016). To the best of our knowledge, the first efforts relevant to the application of challenge sets on MT metrics was presented as an analysis at the Findings paper of the Metrics shared task of the 6th Conference of Machine Translation (Freitag et al., 2021), based on our test suite (Macketanz et al., 2022) that we are using on this paper.

Hereby we are advancing as to that preliminary analysis by (a) increasing the number of challenge
