items to about 9,000-10,000, including outputs from state-of-the-art systems from 2021, (b) adding a second language direction (English-German) (c) presenting a more fine-grained analysis, not only in the category level but also on the phenomenon level. This way we can get more confident and more generalisable empirical conclusions.

3 Method

3.1 Test suite for MT systems

The challenge set is based on our test suite (Macketanz et al., 2022), a manually devised test suite for MT for German-English and its recently developed extension for English-German (Macketanz et al., 2021).[1] The German-English side consists of 5,540 German test sentences covering 107 linguistically motivated phenomena, organized in 14 categories. The English-German side consists of 4,438 English test sentences covering 105 phenomena, organized in 12 categories.

The chosen phenomena do not follow a particular linguistic theory but their definition has been inspired by observing linguistic aspects which are relevant for MT. Each phenomenon is represented by at least 20 source test sentences to guarantee a balanced test set. The test suite is used to evaluate MT systems with regard to their performance on the phenonmenon-targeting test sentences. The evaluation operates semi-automatically and it occurs based on a set of handwritten rules which contain regular expressions and fixed string tokens.

The above described test suite has been used to evaluate the outputs of 116 German-English and 29 English-German systems, submitted at the translation task of the Conference of Machine Translation (WMT) for four consequent years (2018-2021; Macketanz et al., 2018; Avramidis et al., 2019, 2020; Macketanz et al., 2021), including a preliminary system comparison in 2017 (Burchardt et al., 2017).

3.2 Challenge set for MT metrics

Here we describe how the aforementioned test suite, along with inputs from previous shared tasks, is used in order to evaluate MT metrics. A challenge set for metrics requires contrastive pairs of correct/incorrect translations and a reference, whereas our original test suite contained only source sentences and handwritten rules for the outputs, but no reference translations. We therefore use the collected MT outputs to construct the challenge items for the metrics task in order to create the required challenge sets as following. For every source sentence of the test suite we create a tuple including:

- one correct translation, to be given to the metrics as reference translation; and a pair of
- another correct translation and
- one incorrect translation, the latter two intended to be given to the metrics for scoring.

In order to generate these tuples we perform random combinations of correct and wrong translations from the WMT outputs. Also, before collecting MT outputs, we filter out a part of the original test items, to be reserved for future evaluations.

The above process resulted into a metrics challenge set with 10,402 items for German-English and 8,945 items for English-German. The fact that the correct and incorrect translations have been sampled from real MT system outputs of the last 4 years, implies that these challenge set is closer to the real MT system ecosystem, as compared to artificially created challenge sets, which may contain translations that would never be produced by state-of-the-art MT.

3.3 Evaluation of metrics

As explained, the challenge set consists of subsets of challenge items, where every subset has been deliberately created so that it can detect the metrics' performance to a particular phenomenon. For every challenge item, the two MT outputs (correct/incorrect) are given unlabelled to the metrics as two separate MT hypotheses so that they score them against the aforementioned references and/or the source. The item is considered correctly scored, if the metric gives to the correct MT output a higher score than the incorrect MT output. Then the following statistics are calculated:

Accuracy per phenomenon is given by the ratio of all correctly-scored challenge items per phenomenon to the total number of challenge items for this phenomenon

Accuracy per category is given by the ratio of all correctly-scored challenge items per category to the total number of challenge items for this category (after aggregating the underlying phenomena of this category in one set).

Significant tests for comparisons: the highest metric accuracy for every phenomenon is compared to all other metric accuracies of the same

[1] https://github.com/DFKI-NLP/mt-testsuite

phenomenon. For this, a one-tailed Z-test with $\alpha = 0.95$ is calculated. The metrics whose accuracies that are not significantly worse than the highest accuracy, are considered to share the winning position for this phenomenon. The best accuracies per category are calculated in the same way, after aggregating the challenge items from the underlying phenomena of every category.

Statistics for metric categories: We repeat this significance testing in two levels: one for all metrics participating in the shared task, and then separately for each one of the three metric categories (baseline, QE as a metric, reference-based). The significantly best systems per phenomenon over all metrics are indicated with a gray background, whereas the significantly best systems per metrics category are indicated with boldface.

Finally, we report three kinds of average scores: **Micro-average** treats all items equally, aggregating all test items to compute the average percentages; **Category macro-average** treats all categories equally by computing the percentages independently for each category and then averaging them **Phenomenon macro-average** treats all phenomena equally, by computing the percentages independently for each phenomenon and then averaging them

4 Results

The results are displayed in detail in Tables 1 and 3 in the category level and in Tables 4 and 5 for the phenomenon level, for both language directions German-English and English-German respectively.

4.1 Metric performance analysis

Here we are observing the statistics with a focus on comparing the performance of various metrics on the challenge set.

German-English The best performing metrics for German-English are YiSi-1 (Lo, 2019), BERTScore (Zhang et al., 2020) and COMET-22 (Rei et al., 2022), achieving the significantly highest micro- and macro-average accuracies (84-85%), whereas for the macro-average, UniTE-ref (Wan et al., 2022) is also included in the first significance cluster. The two QE based metrics of HWTSC (Liu et al., 2022) get the lowest accuracies, together with the baseline BLEU (Papineni et al., 2002).

When considering the systems performance with regards to particular categories, one can see that different metrics win in different combinations of categories. Most reference-based metrics perform best for at least four categories, apart from MS-COMET which only gets two.

Interestingly enough, one QE method is outperforming reference-based metrics for one category: HWTSC-TLM is the best performing system for *punctuation*. Additionally, UNITE-src performs equally well to reference-based metrics for coordination and ellipsis.

English-German UniTE and UniTE-ref are the winning metrics based on the macro-average (82%), whereas the former seems to be stronger than the latter, winning 5 categories. MetricX-XL-DA19 and MetricX-xxl-DA19 are the winning metrics when it comes to micro-average (78%). Their average accuracies are close to 80%, which raises concerns, as this indicates that 2 out of 10 challenge items in average are not scored correctly in this language direction, even for the best performing metrics. The lowest scoring metric is MATESE (Perrella et al., 2022) in both QE and reference-based versions, very close to REUSE (Mukherjee and Shrivastava, 2022).

Also in this direction, QE methods manage to outperform submitted reference-based metrics in a few categories. REUSE is the best performing metric for *false friends* and UNITE-src for *function words*. COMET-kiwi (Rei et al., 2022) and UniTE-src are on par with reference-aware metrics when it comes to *subordination* and Cross-QE (Liu et al., 2022) for *verb tense/aspect/mood*.

4.2 Linguistically motivated analysis

Here we are looking closer to the results for particular phenomena or categories.

4.2.1 German-English

Category-level The overall average accuracy of all metrics with regards to the linguistically motivated categories is at 78% for German-English. This indicates that the metrics failed in average to predict properly the scores for about one out of four challenge items that we provided. Even for the best categories, the accuracy achieved by most metrics is considerably below the acceptable limit of 90%.

The best performing category in *negation* with 86% average accuracy. For the rest of the categories, the average accuracy is less than 82%. The worst performing categories in average are *named entity and terminology* and *punctuation* with only 67% accuracy, whereas *subordination* comes next

Table 1: Accuracy of the metrics (%) with regards to the 14 linguistically motivated categories for German-English. The significantly best systems per phenomenon over all metrics are indicated with a gray background, whereas the significantly best systems per metrics category are indicated with boldface.

with 72%. The lowest performing score for all systems and all categories is achieved by MetricX-XL-MQM20, which can only score correctly almost half of the punctuation challenge items (53%).

Phenomenon-level The best accuracy for this language pair is achieved for *Transitive, future I* where the metrics get an accuracy of 95%-100%. Another 13 phenomena score more than 85%. Four of them also refer to the future tenses of the transitive, in particular future I and future II in both the plain and their subjunctive form. Additionally, one can see good performance in *Intransitive-present, Modal-future I, pied-piping, comma, negation, passive voice,* and the *negated modal for future I subjunctive II.*

The lowest accuracy of all metrics in average is given for *polar questions* (61%), followed by *quotation marks* (63%). An average accuracy of less than 65% is given for some more phenomena, such as the ones including *measuring units, relative clauses, dates* and *idioms*.

The lowest phenomenon accuracies are given by QE methods, and particularly when it comes to *idioms*, where HWTSC-TLM achieves the lowest performance of 17%. This is explainable by the fact that idioms require resolving rather rare semantic relations between the source and the MT output (used for QE), but can be easily resolved with lexical matching on the reference (used by reference-aware metrics). Idioms have shown to be a particular challenge for MT systems as well.

4.2.2 English-German

Category-level The overall average accuracy of all metrics (Table 3) with regards to the linguistically motivated categories is at 69-72% for English-German. This is 6% lower than the respective average accuracy for German-English, indicating that the metrics for this MT language direction perform worse.

The category where all metrics perform best in average is *negation* (86%), whereas the one where they perform worse is *Named entity & terminology* (59%). The rest of the categories lie in rather mediocre accuracies, between 66% and 82%. The performance of metrics in English-German is worse than German-English in all categories apart from *function words, punctuation* and *subordination*, although the comparisons between the language directions have to be taken with a grain of salt, due to the fact that the two directions consist of different items.

Phenomenon-level The English-German phenomena, where metrics perform best in average are

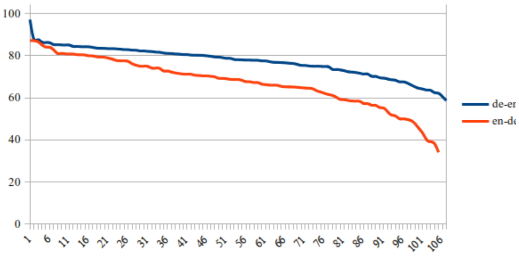

Figure 1: Plot of the accuracy of all phenomena per language direction. The accuracy percentage is shown on the vertical axis and the phenomena on the horizontal

the *Contact clause, Negation, Ditransitive - present progressive* and *question tags*, achieving more than 85% of accuracy. The most difficult phenomena to score are the *Intransitive - future II progressive* and the *Transitive - present progressive*, as they achieve less then 40% average accuracy, followed by *Ditransitive - present perfect simple*, *measuring units* and *focus particles*.

Interestingly enough, in this language direction there are metrics which scored zero accuracies in several phenomena, something that we didn't see in the opposite language direction.[2] These zero accuracies are mostly relevant to rare verb-related phenomena (e.g. intransitive constructions). A comparative plot of the accuracies for all phenomena for both language directions can be seen in Figure 1. It is very clear that English-German lacks considerably, with its lowest scored phenomena having an accuracy at half of the lower-scored phenomena of the opposite direction.

Finally, some examples of incorrectly scored challenge items from the phenomena that have the lowest accuracies can be seen in Table 2. Whereas is hard to know why each metric score in a wrong way, in many cases we may assume that it was misled by a part of the sentence which seemed distant to reference (or the source for QE), but it was correct.

5 Conclusion

In this paper we analyzed the performance of several state-of-the-art metrics with regards to particular linguistically-motivated phenomena for two language pairs, German-English and English-German. The analysis gave a multitude of observations, regarding both the performance of the metrics and the corresponding linguistic observations.

In an effort to draw conclusions after averaging accuracies, we conclude that the best performing metrics are YiSi-1, BERTScore and COMET-22 for German-English, and UniTE, UniTE-ref, MetricX-XL-DA19 and MetricX-xxl-DA19 for English-German.

The metrics are particularly good at scoring the German-English verb tense *Transitive, future I* and the category of *negation*. Concerning English-German, the best performing phenomena are *contact clause* and *negation*.

On the contrary, metrics in both directions are performing worst when it comes to *named-entities & terminology*. Particularly in German-English they are weak at detecting issues at *punctuation (quotation marks), polar questions, measuring units, relative clauses, dates* and *idioms*. In English-German at *present progressive of transitive verbs*, *future II progressive of intransitive verbs*, *present perfect of ditransitive verbs, measuring units* and *focus particles*.

We believe that further investigation on particular phenomena or categories can provide explanations for the relevant observations and possibly lead to suggestions for technical improvements in the development of the metrics in the future. For example, many observations are also relevant to whether the metrics take into account for scoring the reference translation or the source (QE as a metric). Additionally, having seen several low accuracies regarding punctuation, we note that this issue is often handled via pre-processing scripts. The low percentages of scoring punctuation issues, show that the metrics should improve their engineering on that direction.

Abstract

Contextual word embeddings extracted from pre-trained models have become the basis for many downstream NLP tasks, including machine translation automatic evaluations. Metrics that leverage embeddings claim better capture of synonyms and changes in word orders, and thus better correlation with human ratings than surface-form matching metrics (e.g. BLEU). However, few studies have been done to examine robustness of these metrics. This report uses a challenge set to uncover the brittleness of reference-based and reference-free metrics. Our challenge set[1] aims at examining metrics' capability to correlate synonyms in different areas and to discern catastrophic errors at both word- and sentence-levels. The results show that although embedding-based metrics perform relatively well on discerning sentence-level negation/affirmation errors, their performances on relating synonyms are poor. In addition, we find that some metrics are susceptible to text styles so their generalizability compromised.

1 Introduction

Automatic metrics compare machine-translated results with human-translated references or/and sources, and give scores accordingly. Such metrics offer a quick and inexpensive approach for researchers to evaluate model performances. Among these metrics, BLEU (Papineni et al., 2002) has dominated the area for twenty years since its birth in 2002. However, its limitations are obvious: (1) it weighs each word equally but in fact the entropy of each word varies; (2) it only counts n-grams that are exact in the reference and thus synonyms and elaborations are wrongly punished (Smith et al., 2016). Consequently, the correlation between BLEU and human evaluation is relatively low, which sometimes puzzles researchers.

In recent years, embedding-based approaches have been introduced to design new automatic metrics. These metrics, e.g. BERTScore (Zhang et al., 2019), COMET (Rei et al., 2020a), and BLEURT (Sellam et al., 2020a), claim better ability to capture synonyms and changes in word order, and thus better performance than BLEU. Apart from ref-based metrics, researches on quality estimation (QE) have been rising, as QE is an cheaper and more convenient approach considering no need of human-translated references.

In the WMT metric task, correlation with human annotators is the major indicator to evaluate metric performance (Freitag et al., 2021). However, in addition to that, a good metric should meet the following requirements (Banerjee and Lavie, 2005; Koehn, 2009): (1) sensitivity to nuances in quality among systems or outputs of the same system in different stages of its development so it can be used to direct system performance optimization; (2) consistency and reliability of scores; (3) usability in a great range of fields; (4) speed; (5) low cost. We believe the first three aforementioned requirements are crucial for judging metric performance as well. So we build a Zh→En challenge set to evaluate metrics' capability in these regards. Section 2 offers a brief description of metrics to be evaluated. Details of our challenge set are described in Section 3. Section 4 presents experiment results and Section 5 discusses our findings.

2 Metrics To Be Evaluated

2.1 Surface-Form Matching Metrics

Reference-based metrics measure the similarity between MT outputs and human translations, and believe that high similarity means high quality and vice versa. In the pre-neural era, metrics calculate the similarity based on surface forms and word stems. Two examples that fall into this category and used in this task as baselines are BLEU (Papineni

[1] We open-source our challenge set at: https://github.com/HwTsc/Challenge-Set-for-MT-Metrics

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 530 - 540
December 7-8, 2022 ©2022 Association for Computational Linguistics

et al., 2002) and chrF (Popović, 2015).

BLEU BLEU computes precision by comparing the n-gram of hypothesis with n-gram of the reference, coupled with a brevity penalty. In this task, sentence-level BLEU (SENT-BLEU) is used.

chrF chrF computes F1 score based on character-level n-grams instead of word-level n-grams.

2.2 Embedding-based Metrics

In the neural era, by leveraging pre-trained word embeddings, new metrics claim better understanding of sentence meanings and thus fare better in evaluation tasks. Some of the well-known metrics that fall into this category and used as baselines in this task include:

BERTScore BERTScore (Zhang et al., 2019) outputs F1 score by calculating token similarity based on contextual embeddings extracted from BERT.

BLEURT-20 BLEURT (Sellam et al., 2020a) is a BERT-based regression model trained on rating data. BLEURT-20 (Sellam et al., 2020b), which is fine-tuned based on Rebalanced mBERT is used in this task.

COMET-20 COMET (Rei et al., 2020a) employs the estimator-predictor architecture and leverages both source and reference information to assess translation quality. COMET-20 (Rei et al., 2020b), which utilizes XLM-RoBERTa, is used in this task.

Yisi-1 Yisi (Lo, 2019) measures semantic similarity between hypothesis and references. Yisi-1 (Lo, 2020) leverages contextual embeddings extracted from language models to compute the idf-weighted lexical semantic similarities.

2.3 QE as Metrics

Quality estimation approach evaluates machine translation quality totally without human intervention. It scores model outputs by leveraging information in source text. Among the seven baseline metrics, COMET-QE (Rei et al., 2021) is a reference-free version of COMET and thus falls into the QE category.

Table 1 is a summary of the seven baselines.

Metrics	Surface	CWE	Source	Ref	Rating
BLEU	Yes	No	No	Yes	No
chrF	Yes	No	No	Yes	No
BERTScore	No	Yes	No	Yes	No
BLEURT-20	No	Yes	No	Yes	Yes
COMET-20	No	Yes	Yes	Yes	Yes
COMET-QE	No	Yes	Yes	No	Yes
YISI-1	No	Yes	No	Yes	No

Table 1: A comparison of seven baseline metrics from aspects of whether they use surface form (Surface), contextual word embedding (CWE), Source text (Source), Target text (Ref), and human rating data (Rating).

2.4 Participants in WMT22 Metric Task

The challenge set is also used to measure performances of metrics submitted to the WMT22 Metric Task, including twelve reference-based (ref-based) metrics: COMET-22, MATASE, three variants of MEE, four variants of Metricx, ME-COMET-22, two variants of UniTE; and nine QE metrics: COMET-Kiwi, Cross-QE, HWTSC-Teacher-Sim, HWTSC-TLM, KG-BERTScore, MATESE-QE, MS-COMET-QE, REUSE, and UniTE-src.

For details about their implementations, please refer to their system reports and summary report of WMT22 Metrics Task[2].

3 Challenge Set & Method

3.1 Source of the Challenge Set

We build our Zh-En challenge set to evaluate metrics' ability to relate synonyms and identify crucial mistakes. The set is built based on two open-source test sets: Flores 101 (Goyal et al., 2022) En-Zh subset (but used as a Zh-En test set in this task) and WMT21 Zh-En news dev + test sets (Akhbardeh et al., 2021). We particularly pick up an En-Zh test set and a Zh-En test set because neural-based metrics may be style-sensitive (Hanna and Bojar, 2021): the English side of the En-Zh test set is natural language while that of the Zh-En test set is translation results, which may suffer from translationese. In addition, WMT sets focus on news domain while Flores is extracted from Wiki. We try to understand whether reference style and domain might influence metric performance so as to evaluate the generalizability of metrics.

3.2 Challenge Set Description

Our test set has 721 test cases and focuses on five categories of errors: (1) number; (2) date & time (D/T); (3) named-entity & terminology (NE&Term); (4) unit; and (5) affirmation/negation

[2] At the time of writing, we have not received descriptions from every participant.

Phenomenon	Flores	WMT	Overall
Number	183	172	355
D/T	50	90	140
NE&Term	68	42	110
Unit	23	35	58
AFF/NEG	58	0	58
Overall	382	339	721

Table 2: Challenge set composition

(AFF/NEG). Each case contains a source text, a reference, a good translation, a bad translation, a language phenomena label and a source of origin label indicating where the sentence comes from. Table 2 details the set composition. The first four categories focus on word-level crucial errors. If such information is translated wrong, human annotators will assign relatively low scores since the audience will be misled by such mistakes. In addition, the four categories feature rich types of expressions. For instance, a number can be presented in either numeral or number format; unit, named entity and terminology have widely-used abbreviations. We try to analyze whether metrics are able to relate synonyms and punish errors the way human annotators do. The last category – affirmation/negation – deals with phrase- to sentence-level errors and tests whether metrics are able to capture the overall meaning of a sentence.

Since both sets provide only one translation result for each sentence, to generate an additional translation result, we employ a group of six in-house translators to post-edit MT results generated by our in-house model. We adopt List-based Attack (LIST) (Alzantot et al., 2018) to generate adversarial examples. LIST replaces word(s) in a candidate sentence with a list of similar words to construct adversarial examples. We use semi-auto and human-craft approaches to extract related sentences from the original data sets. We replace key words in those sentences to ensure that key information in references and good examples are semantically equal but in different formats, and that in references and adversarial examples are semantically different but in the same "surface" format.

Table 3 shows an example of our challenge set. The test case contains a source sentence, a reference, a good-translation that contains a correct translation for a language phenomenon, and an incorrect-translation with an error accordingly. Phenomenon to be evaluated and source of the sentence are also labelled in our challenge set. In this case, it is number and comes from Flores. For more examples, please see Appendix A.

SRC:	在已知的大约24,000块坠落至地球的陨石中，经核实只有***34***块是来自火星。
REF:	Out of the approximately 24,000 known meteorites to have fallen to Earth, only about ***34*** have been verified to be martian in origin.
GOOD:	Of the roughly 24,000 meteorites known to have fallen to Earth, only ***thirty-four*** have been confirmed to have come from Mars.
BAD:	Of the roughly 24,000 meteorites known to have fallen to Earth, only ***30*** have been confirmed to have come from Mars.

Table 3: A case of number in different formats. GOOD refers to good translation and BAD refers to the adversarial example.

3.3 Measurement

Kendall's tau-like correlation (Freitag et al., 2021) is used to evaluate metric performance. A good translation has higher quality than the corresponding bad one, so a good metric should assign a higher score to the good translation. If a metric does so, we label the metric "Concordant" on the case, and "Discordant" vice versa. The correlation is calculated based on the following formula:

$$\tau = \frac{Concordant - Discordant}{Concordant + Discordant}$$

4 Result

Table 4 presents the results of our challenge set. In general, 20 out of the 28 metrics struggle to discriminate between good and adversarial examples as they fail to achieve a medium correlation (above 0.4) with human annotators. The 8 metrics that manage to achieve medium-level correlation including: BLEURT-20 (baseline), four variants of Metricx (ref-based), HWTSC-Teacher-Sim (QE), KG-BERTScore (QE), and REUSE (QE).

4.1 Comparison across types of metrics

In general, embedding-based metrics perform much better than merely surface-form matching

Table 4: Kendall's tau-like correlation results of each metric on our challenge set. The horizontal lines delimit baseline metrics (top), participating ref-based metrics (middle), and participating QE metrics (bottom).

metrics. Ref-based QE metrics perform slightly better than QE metrics. Regarding the two surface-form matching metrics, character-level chrF performs much better than SENT-BLEU on AFF/NEG, Number and D/T test cases, although slightly worse on the other two categories. The performances of embedding-based metrics vary greatly across both ref-based and QE metrics.

4.2 Comparison across error categories

Embedding-based metrics perform well on AFF/NEG cases as we assumed, as most embedding-based metrics (both ref-based and QE) achieve medium to strong correlations with human ranking. However, regarding the other four categories on word-level crucial errors, performances of some embedding-based metrics deteriorate significantly and only few metrics manage to reach medium-level correlation.

5 Discussion

5.1 Number as A Tough Issue

One of the focuses of our challenge set is number. Numbers are dispersed, rich in format, and semantically similar, making metrics hard to grasp the exact meaning. To analyze how metrics perceive and score numbers, we further divide it into four sub-categories:

- Same Format (SAME): Good and bad exam-

Metric	SAME	DIFF	SWAP	SEP
STEN-BLEU	-0.908	-0.807	-0.333	-0.630
chrF	-0.333	-0.572	-0.286	0.210
BERTScore	0.632	-0.393	-0.476	-0.383
BLEURT-20	0.678	0.490	0.000	0.481
COMET-20	0.011	-0.559	-0.095	0.630
COMET-QE	-0.034	-0.159	0.000	0.531
Yisi-1	0.586	-0.379	-0.476	-0.309
Baseline Avg.	**0.090**	**-0.340**	**-0.238**	**0.076**
COMET-22	0.747	-0.103	-0.143	0.358
MATESE	-0.839	-0.710	-0.857	-0.333
MEE	-0.701	-0.876	-0.810	-0.160
MEE2	0.747	0.283	-0.571	0.086
MEE4	0.816	0.421	-0.571	0.012
metricx_xl_DA	0.954	0.862	0.190	0.605
metricx_xl_MQM	0.770	0.724	0.571	0.580
metricx_xxl_DA	0.977	0.903	0.762	0.531
metricx_xxl_MQM	0.931	0.890	0.905	0.728
MS-COMET-22	0.057	-0.103	-0.190	-0.012
UniTE	0.655	-0.103	-0.381	0.457
UniTE-ref	0.655	-0.076	-0.190	0.556
Ref-based Avg.	**0.481**	**0.176**	**-0.107**	**0.284**
COMETKiwi	0.425	-0.090	0.048	0.457
Cross-QE	0.218	0.145	-0.095	0.630
HWTSC-Teacher-Sim	0.632	0.503	0.000	0.630
HWTSC-TLM	0.448	0.393	0.238	0.556
KG-BERTScore	0.655	0.503	-0.143	0.630
MATESE-QE	-0.839	-0.821	-0.762	-0.457
MS-COMET-QE-22	-0.011	0.034	-0.095	0.259

UniTE-src	0.264	-0.241	-0.143	0.679
QE Avg.	**0.282**	**0.119**	**-0.111**	**0.443**

Table 5: Kendall's tau-like correlation results on our challenge set. The horizontal lines delimit baseline metrics (top), participating reference-based metrics (middle), and participating QE metrics (bottom).

ples use different numbers in the same format (e.g. 1 & 2; three & four).

- Different Format (DIFF): The good examples contain correct numbers in a different format as reference while the bad examples contains an incorrect number in the same format as reference (e.g. 1 & two; 1,000,000 & 1 million).
- Swapped Number (SWAP): When a sentence contains two or more numbers, we swap the numbers to generate the bad translation.
- Thousand Separator (SEP): Thousand separators are not required but help improve readability. Test sets under this category compare numbers without thousand separators with those in wrong formats (e.g. 1 000; 10,00; 1.000).

Table 5 presents results on the number subcategories. According to the table, surface-form matching metrics perform worse under all the four subcategories. Although embedding-based metrics in general perform much better, those metrics still perform worse under the SWAP subcategory.

5.1.1 Numeral vs. Number

In daily usage, there is no strict rule about when to use numerals or numbers. In some cases, numeral and number are just two different symbols to express the same meaning and as a result can be regarded as synonyms. According to table 5, the majority of embedding-based metrics perform relatively well on discerning differences among numerals or among numbers (SAME). To be more specific, if the good and adversarial examples contain different numbers in the same format, even if the format is different from that used in the reference, the possibility for metrics to discern between the correct and incorrect numbers is relatively high.

However, performances of these metrics under the DIFF category deteriorate to varying extents. In other words, if the good example contains a correct number in different format and the adversarial example contains an incorrect number but in the same format as that in the reference, metrics are likely to assign a higher score to the adversarial example.

The result demonstrates that contextual embeddings fail to relate semantically similar numbers and numerals. Instead, they seem to rely more on the "surface similarity". Another example to buttress this assumption is the metrics' performances in the thousand separator category, where there is about 50% of chance that metrics score numbers with wrong separator formats higher than those without separators.

Although neural machine translation models seldom translate numbers wrong, outputs do use different number formats. When these metrics are used to measure model performances, they incline to wrongly penalize sentences using a different number format, thus leading to unfair evaluations.

5.1.2 Does Number Difference Count?

We further conducted two experiments to examine if metrics' capability of distinguishing numbers improves when the difference between the correct and incorrect numbers turns greater. The sentence shown in Table 3 is used for the two experiments.

In the first experiment, we replace the number in the reference (REF in table 3) to its numeral format "thirty-four" and denote the sentence as good-translation x1. Then we replace the number in the reference to other Arabic numbers ranging from 1 to 100 to generate a set of comparative candidates denoted as bad-translations Y{y_1,y_2,...y_{100}}.

In the second experiment, we denote another correct post-edit result as good-translation x2 (GOOD in table 3), and alter the numeral in x2 to Arabic numbers ranging from 1 to 100 (denoted as bad-translations Z{z_1,z_2,..., z_{100}}).

We calculated BERTScore of x1, x2, Y and Z against the reference and the result is presented in figure 1. When there is no other difference between reference and candidates except the number, it seems easier for BERTScore and BLEURT to discern number differences even in different formats. In addition, as the difference between numbers becomes greater, the gap of scores expands. However, when there are other differences between the reference and candidates, it becomes harder for BERTScore to quantify the error, as BERTScore gives the majority of candidates in Z higher scores than x2. And greater difference between numbers seems not help. However, BLEURT remains a good performance in the second experiment, which is consistent with our challenge test results.

5.1.3 Do Metrics Understand Number?

Another interesting finding regarding number is that all metrics perform badly under the SWAP category (only three ref-based metrics managed to achieve medium-level correlation). Swapping two numbers in a sentence causes drastic changes in meaning but metrics lack the capability to identify such changes.

5.2 Is Source/Ref Information Helpful?

In general, QE metrics perform relatively worse than ref-based metrics, but the gap is smaller than we assumed. By just leveraging source-side information, the average of QE metrics almost reaches medium-level correlation. This gives rise to a question: if a metric leverages both source-side and target-side information, will the accuracy improve?

The implementations of COMET-22 and COMET-Kiwi are almost the same but COMET-22 leverages both source-side and target-side text while COMET-Kiwi uses only source-side text. When we compare the performances of the two metrics, we find that COMET-22 outperforms COMET-Kiwi under the Number and D/T categories. However, COMET-Kiwi outperforms COMET-22 under the NE&Term, Unit and AFF/NEG categories.

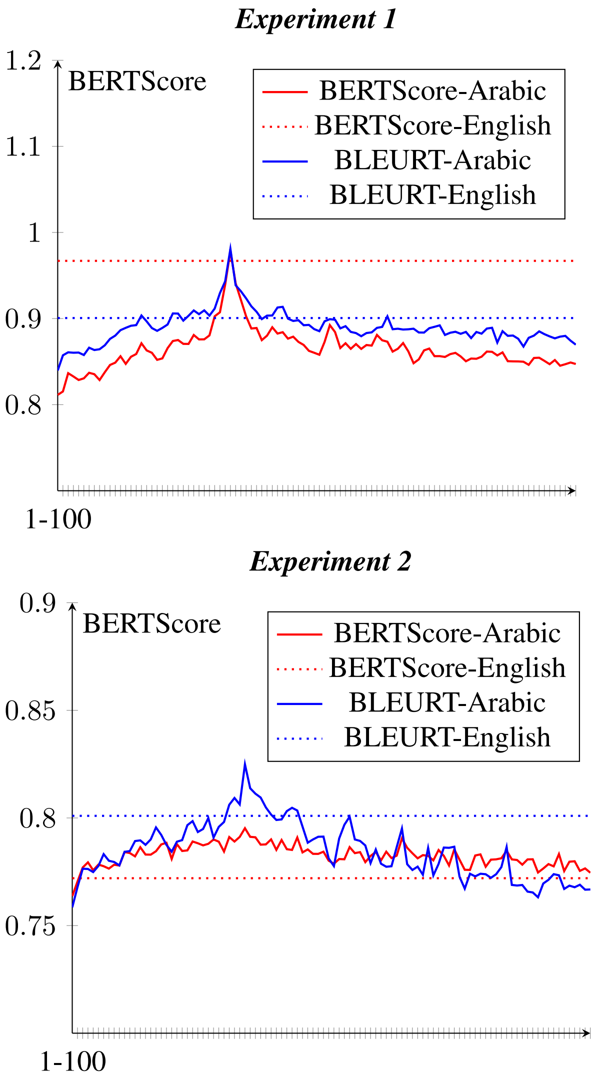

Figure 1: Results for experiment 1 and 2. The dotted lines indicate the scores for x1 and x2, while the solid lines represent the results of Y and Z.

The result indicates that while in some cases, reference-side information helps improve accuracy; in other cases, reference-side information surprisingly causes performance deterioration.

Among all the participating ref-based metrics, although some leverage source-side information while the others do not, their implementations vary. So we are unable to draw a conclusion that whether adding source-side information to a ref-based metric helps improve accuracy. More ablation experiments are required.

5.3 Synonym is Still A Tough Issue

Although embedding-based metrics claim better capture of synonyms, the result shows that there is still a long way to go. Not only numbers, test cases under NE&Term, D/T, and Unit categories all aim at examining metrics' ability to relate different formats of words that express the same meaning. The results show that metric performances vary greatly under these categories. The variations demonstrate that there should be a solution to this problem. However, at the time of writing, we have no detailed information about the implementations of those well-performed metrics. For more details, please refer to WMT Metric summary report and their system reports.

Table 6: A comparison of metric performances on Flores and WMT test cases. The horizontal line delimit baseline metrics (top) and participating reference-based metrics (bottom).

5.4 Do Metrics Suffer from Domain Issue?

We build our challenge set based on two open-source test sets: Flores 101 and WMT21 Zh-En. Hanna and Bojar (2021) claim that when the reference is a post-edit, BERTScore performs poorly as the post-edit may have high lexical overlap with machine translations. In our experiment setting, the candidate sentences are post-edits, which are stylistically similar to references in the WMT21 Zh-En news test sets, as the references are translations provided by professional translators. On the contrary, the Flores 101 En-Zh test set is translated from English to Chinese, so the English side is original and less stylistically similar to post-edits.

We calculate each metric's performance on Flores and WMT test cases (see table 6). Surface-form matching metrics are least influenced by the difference. For both ref-based and ref-free metrics, while some metrics (e.g. Metricx, HWTSC-Teacher-Sim) remain almost same performance on cases from the two sources, some metrics (e.g. COMET-22, UniTE) perform far worse on WMT cases.

The result shows that the generalizability of metrics varies. While good metrics can remain the same performance on test sets in different domains and of different styles, some metrics suffer greatly from domain issues. We assume the reasons for such performance gaps including: 1) WMT test cases are longer than Flores cases in average, making the cases harder to score; 2) big data for training pre-trained models are mostly native monolinguals so these models are better at encoding native languages than "translationese". However, more ablation experiments are required and generalizability should be concerned when developing metrics.

6 Conclusion

This paper presents our submitted challenge set to the WMT22 Metrics Challenge Sets Subtask and various metrics' performances on our set. Our set focuses on five categories of errors and the result shows that while most metrics are able to identify catastrophic sentence-level affirmation/negation errors, some metrics fail at discerning word-level keyword errors and capturing synonyms of such words. The results show that references are not always useful for a metric to identify errors. In addition, generalizability of metrics should be considered as some metrics are susceptible to test sets styles. The majority of metrics fail to meet the requirements (Banerjee and Lavie, 2005; Koehn,

2009) we discuss in the introduction section. They fail to identify nuances in quality and provide reliable scores, and suffer from domain issues as well.

The limitation of this research is that all of the perturbations are human-crafted, and these errors may seldom occur in neural machine translations. To further analyze metric performance in real settings, we will try to annotate and categorize real machine translation errors and evaluate metric performance accordingly.

MS-COMET: More and Better Human Judgements Improve Metric Performance

Tom Kocmi **Hitokazu Matsushita** **Christian Federmann**
Microsoft, 1 Microsoft Way, Redmond, WA 98052, USA
{tomkocmi,himatsus,chrife}@microsoft.com

Abstract

We develop two new metrics that build on top of the COMET architecture. The main contribution is collecting a ten-times larger corpus of human judgements than COMET and investigating how to filter out problematic human judgements. We propose filtering human judgements where human reference is statistically worse than machine translation. Furthermore, we average scores of all equal segments evaluated multiple times. The results comparing automatic metrics on source-based DA and MQM-style human judgement show state-of-the-art performance on a system-level pair-wise system ranking. We release both of our metrics for public use.[1]

1 Introduction

Automatic metrics for machine translation (MT) evaluation are commonly used as the primary tool for comparing the translation quality of MT systems, often without evaluating systems with the human judgement that can be expensive and time-consuming (Marie et al., 2021). Therefore, studying and developing metrics that correlate well with human judgement is critical.

There is an increasing effort in the evaluation of automatic MT metrics, leading with the annual evaluation of metrics at the WMT conference (Freitag et al., 2021b,a; Kocmi et al., 2021; Mathur et al., 2020b). Most research has focused on comparing segment-level or system-level correlations between absolute metric scores and human judgements. However, Mathur et al. (2020a) emphasize that this scenario is not identical to the everyday use of metrics, where instead, researchers and practitioners use automatic scores to compare pairs of systems. For example, when claiming a new state-of-the-art, evaluating different model architectures, and deciding whether to publish results or deploy new production systems.

In this work, we focus on training automatic metric based on COMET architecture (Rei et al., 2020) utilizing a large internal trainset of human segment-level judgements. Additionally, we evaluate the metrics in a pair-wise system-level evaluation against human judgement.

We develop two metrics: *MS-COMET* intended for reference-based evaluating systems, while *MS-COMET-QE* is designed for quality estimation or source-based evaluation. We use the suffix "-22" to differentiate the models from potential future releases.

2 Related work

There are two main categories of automatic MT metrics: (1) string-based metrics and (2) metrics using pretrained models. The former compares the coverage of various substrings between the human-generated reference and MT translations, this group includes metrics such as ChrF (Popović, 2015), BLEU (Papineni et al., 2002), or TER (Snover et al., 2006). String-based methods largely depend on the quality of reference translations. However, their advantage is that their performance is predictable as it can easily diagnose which substrings affect the score the most.

The latter category of pretrained methods consists of metrics that usually use pretrained models to evaluate the quality of MT translations given the source sentence, the human reference, or both. Evaluation metrics from this category includes COMET (Rei et al., 2020), BLEURT (Sellam et al., 2020), or BERTScore (Zhang* et al., 2020). They are not strictly dependent on the reference quality (for example, they can better evaluate synonyms or paraphrases), and many studies (Freitag et al., 2021b; Mathur et al., 2020b; Kocmi et al., 2021) showed their superiority over string-based metrics. On the other hand, their performance is influenced

[1] https://github.com/MicrosoftTranslator/MS-Comet

by the data on which they have been trained, which may introduce bias, and the pretrained models present a black-box problem where it is challenging to diagnose potential unexpected behavior of the metric.

A separate category of automatic metrics is whether they need a human reference for evaluation. Automatic metrics that calculate scores without the need for reference (quality estimation) open the possibility of evaluating monolingual testsets that can be tailored for a specific domain without the need to build expensive human references.

We build our metric with the architecture of COMET (Rei et al., 2020).[2] It uses the Estimator model which uses pretrained language models XLM-RoBERTa to encode source, MT hypothesis and reference in the same cross-lingual space. The model is then fine-tuned on human judgement data. We use the identical hyper-parameters as COMET.

3 Human Judgement Trainset

For training our models, we use a mix of public and internal data that we further denoise by filtering out potentially problematic human judgements.

We use the same human judgments data used to train the COMET model, i.e. WMT 2017-2019 (Barrault et al., 2019; Bojar et al., 2018, 2017). To test the quality of metrics, we use WMT 2020 (Barrault et al., 2020), WMT 2021 (Akhbardeh et al., 2021) and MQM 2021 (Freitag et al., 2021b). Furthermore, we submitted our model to WMT Metrics Shared Task 2022.

In addition to publicly available data, we use a set of internal data, described in Kocmi et al. (2021) plus newer data collected over the last year. All our internal data are collected with the use of expert annotators. We use a mix of human judgement methods: source-based Direct Assessment (srcDA) (Graham et al., 2013; Federmann, 2018), contrastive Direct Assessment (contrDA, which asks users to rate pairs of system outputs), and SQM presented at WMT General MT 2022 (which uses labeled scale). All collected labels are on a scale of 0-100, where the interface structure is the main difference for human annotators.

We use internal testsets for human judgements that have been translated with a tandem of two professional translators, following findings of Freitag et al. (2020) that high-quality reference plays an essential role in automatic evaluation.

	Langs.	Domains	Segments
All available data			6.53 M
Removed low-quality			0.79 M
Removed WMT refDA			0.35 M
Removed by averaging			2.12 M
MS-COMET	111	15	2.06 M
MS-COMET-QE	113	15	3.43 M
COMET	13	1	0.66 M

Table 1: The statistics of the training corpora and the effect of filtering in terms of unique languages on the target side, unique domains, and count of training segments used to train MS-COMET, MS-COMET-QE, and original COMET.

In contrast to publicly available data that uses only the News domain, we use a mix of fifteen domains (news, conversation, legal, medical, social, e-commerce, tech, finance, and others). The news domain is the largest domain utilizing at least half of human judgements. Our collection of human judgement data covers 113 languages in contrast to 13 on which COMET is trained. A complete list of all supported languages and counts of human judgement for the largest translation directions are in Appendix A.

Reference-less metric MS-COMET-QE is trained using all training data and removing reference translations. Additionally, many human judgments are evaluated on data that are missing human reference, which is the reason for having more training data for MS-COMET-QE.

3.1 Using raw scores instead of z-scores

The z-score has been introduced (Graham et al., 2013) to resolve an issue with different strategies annotators may apply when judging systems. For example, an overly strict annotator may harshly penalize a system from which he annotated more segments. We partly avoid this problem in our data via a better sampling technique. We sample uniformly from each evaluated system in a way that each annotator evaluates the same number of sentences from each system. Therefore, different strategies should penalize all systems similarly.

As Knowles (2021) pointed out that z-score standardization of human judgements normalizes away both inter-annotator and system quality differences, and since we do not have a mechanism to avoid normalizing away system quality differences. There-

[2] To differentiate models, we are going to use COMET to reference Rei et al. (2020) models from ours labeled as MS-COMET

fore, we decided to use raw scores (0-100) instead of the z-score standardized counterpart.

Using raw scores has the benefit that it gives final scores some meaning. For low-quality languages, we may expect scores in the lower range (0-50), while for high-quality languages, the scores generally can be higher. Z-scores only do not represent any meaning. However, we do not advocate using our metric in an absolute fashion or comparing quality across languages.

However, we want to point out that we have seen only minor improvement when training metrics using raw scores in contrast to z-scores. Therefore, this decision is mainly on a pragmatic layer.

3.2 Professional annotators only

Freitag et al. (2021a) discuss that the quality of crowd-based human judgement is suboptimal, and human evaluation should focus on expert annotators. Professional annotators collect our internal human labels. However, data from WMT are collected in two different setups when one uses crowd-workers.

The language pairs that are from English or not containing English are collected with semi-professional to professional annotators and using source-based DA, which avoids reference bias. On the other hand, all into English language pairs are collected with crowd-workers with reference-based DA. For this reason, we decided to remove all WMT reference-based DA human judgement from our datasets, and therefore, we use only internal into-English human assessments.

3.3 Averaging same human judgement

In our data, many human judgment campaigns evaluate identical triplets *(source, hypothesis, reference)* in different campaigns. This happens when we compare identical baseline system across different campaigns or when a candidate system from the earlier campaign is later evaluated as a baseline system.

We notice that human scores fluctuate every time each triplet is evaluated. We have decided to average scores for all identical triplets to normalize the noise and balance the trainset. Averaging equal scores improved the performance of the metric.

We also experimented with taking a median of the scores, but the results have been a bit worse than averaging.

3.4 Removing low-quality human judgements

In our human annotation campaigns, we often include human reference translation as another system to measure how close MT systems are to human reference. However, scoring human references can also be used as a sanity check for the quality of campaigns or human references. Whenever we see a campaign where human reference is worse than the MT system, it suggests one of the following three scenarios: human reference contains error translations, human judgement is too noisy or misleading, or the MT system performs better than human translators. If we assume that MT systems are not outperforming human translators, a lower human reference score suggests either broken reference translation or a noisy campaign. Neither of these two outcomes is desirable for fine-tuning automatic metrics.

Therefore, we remove all campaigns containing human reference as an additional system, where any of the systems is statistically significantly better than human translation under the Mann–Whitney U test and alpha threshold of 5%.

4 Evaluation

Evaluation of automatic metrics is a challenging task investigated in a yearly WMT Metrics shared task (Freitag et al., 2021b). However, there is no community-agreed testset or evaluation method for comparing with humans that are considered gold standards.

There are different dimensions how to evaluate automatic MT metrics. Let's summarize the main differing points:

- **Human annotation methods** - source-based direct assessment (DA) (Graham et al., 2013), reference-based DA (Graham et al., 2013), contrastive DA (Akhbardeh et al., 2021), Multidimensional Quality Metrics (MQM) (Freitag et al., 2021a)

- **Granularity of evaluation** - evaluating correlation with human on a segment-level or system-level

- **Correlation method** - correlation of absolute values (Pearson or Kendall-like, Mathur et al., 2020b) or correlations in pairwise approach (pairwise accuracy, Kocmi et al., 2021; Mathur et al., 2020a

- **Usage of unlabeled part of testset** - human judgment often evaluates only a subset of the testset. Metrics can use the remaining unlabelled segments (especially for system-level setup)

- **Normalize human behavior** - use raw human scores or normalize them with z-score standardization

- **Evaluating human reference** - if additional human translated references should be evaluated like one of the systems (Freitag et al., 2021b)

- **Evaluating outlier systems** - absolute value correlations via Pearson are sensitive to outliers, therefore Mathur et al. (2020a) recommends removing outlier systems from evaluation.

The list is incomplete as there are other nuances, such as removing outlier systems, using only statistically significant pairs of systems, underlying quality of human judgement, etc.

Evaluating all combinations of approaches is not reasonable. Therefore we mainly follow the approach defined by Kocmi et al. (2021) and also used by WMT Metrics 2021 (Freitag et al., 2021b). Here is a list of constraints for the evaluation:

- We use only testsets produced by professional annotators as described in Section 3.2. Thus, we do not evaluate over reference-based DA.

- We focus on a system-level pairwise setup as the important use-case for automatic metrics (Kocmi et al., 2021). Thus we do not evaluate absolute value correlations with humans. Furthermore, this avoids the problem with outlier systems.

- We use only segments that have been evaluated by humans (unlabelled segments of testsets are not used).

- We use z-score normalization mainly to be comparable with past work. However, we do not consider z-score as a good standardization approach.

- We do not remove additional human references from the evaluation as metrics should be able to evaluate any translation (not only those produced with current MT systems).

	LPs	System pairs	Method
WMT20	8	565	srcDA
WMT21	9	1000	srcDA
WMT21-contr	3	198	contrDA
MQM21-news	3	301	MQM
MQM21-ted	3	247	MQM

Table 2: The statistics of human judgement sets are used for testing automatic metrics.

4.1 Evaluation methodology

We use system-level pairwise accuracy as introduced by Kocmi et al. (2021), which evaluates how often metric agrees on the ranking of two systems with human rank:

$$\text{Accuracy} = \frac{|\text{sign}(\text{metric}\Delta) \;=\; \text{sign}(\text{human}\Delta)|}{|\text{all system pairs}|}$$

We use implementation by Freitag et al. (2021b); therefore, results on the MQM21 testset agree with their findings. We use bootstrap resampling to calculate which metrics are not significantly outperformed by the winning metric with an alpha threshold of 0.05.

To test automatic metrics, we use publicly available data from different sources. You can find statistics in Table 2.

- **WMT20** and **WMT21** - we use source-based DA from Barrault et al. (2020) and Akhbardeh et al. (2021)

- **WMT21-contr** - we use contrastive DA from Akhbardeh et al. (2021). This is the only source of truly pairwise human judgements, where annotators see the outputs of two systems next to each other. We collect those pairs of systems evaluated to each other.

- **MQM21-news** and **MQM21-ted**- we MQM data from Freitag et al. (2021b), both testsets evaluate same set of systems but over different domains.

Additionally, we combine **all** testsets to calculate pairwise accuracy across all system pairs, simply by counting all system pairs where the metric agrees with human overall evaluated system pairs in all testsets.

4.2 Evaluated automatic metrics

We train two metrics MS-COMET trained with human-produced references and MS-COMET-QE

	All	WMT20	WMT21	WMT21-contr	MQM21-news	MQM21-ted
n	2311 ↓	565	1000	198	301	247
MS-COMET-22	**0.826 (1)**	**0.892 (1)**	**0.864 (1)**	0.722 (2)	0.714 (4)	**0.745 (3)**
MS-COMET-QE-22	**0.821 (2)**	0.873 (2)	0.847 (2)	**0.808 (1)**	0.734 (2)	0.713 (6)
Bleurt	**0.820 (3)**	0.869 (3)	**0.864 (1)**	0.702 (3)	0.718 (3)	**0.749 (2)**
COMET	0.816 (4)	0.869 (3)	**0.864 (1)**	0.677 (5)	0.678 (5)	**0.781 (1)**
COMET-QE	0.800 (5)	0.848 (6)	0.839 (3)	0.692 (4)	**0.774 (1)**	0.652 (7)
BERTScore	0.790 (6)	0.853 (5)	0.836 (4)	0.722 (2)	0.621 (6)	0.721 (5)
chrF	0.770 (7)	0.857 (4)	0.793 (5)	0.702 (3)	0.621 (6)	0.713 (6)
BLEU	0.688 (8)	0.848 (6)	0.622 (7)	0.601 (7)	0.618 (7)	0.741 (4)
TER	0.669 (9)	0.766 (7)	0.657 (6)	0.616 (6)	0.585 (8)	0.636 (8)

Table 3: The main results for pairwise accuracy in a system-level setting. The bold scores represent metrics that are not statistically different from the winning metric with a 0.05 alpha level. The numbers in brackets show the rank of metrics. The "n" represents the number of system pairs in each evaluation.

trained only with sources and MT hypothesis. We use identical hyper-parameters as the original COMET model (Rei et al., 2020), and the models are trained for precisely four epochs.

We compare our metrics to publicly available metrics, and either have the highest correlation with humans - COMET, BLEURT, and BERTScore (Kocmi et al., 2021; Freitag et al., 2021a) or are widely used in MT field (BLEU, ChrF, TER). We use default parameters and models for each of them, specifically:

For BLEU (Papineni et al., 2002), ChrF (Popović, 2015), and TER (Snover et al., 2006), we use SacreBLEU implementation https://github.com/mjpost/sacrebleu/ (Post, 2018) version 2.0.1. We use the "mteval-v13a" tokenizer for all language pairs except for Chinese and Japanese, which use their separate tokenizer, as is recommended.

For BERTScore (Zhang* et al., 2020), we use https://github.com/Tiiiger/bert_score version 0.3.11.

For BLEURT (Sellam et al., 2020), we use the recommended model "bleurt-20" and implementation https://github.com/google-research/bleurt.

For COMET (Rei et al., 2020), we use recommended model "wmt20-comet-da" and for COMET-QE we use "wmt21-comet-qe-mqm". The implementation is https://github.com/Unbabel/COMET in version 1.1.0.

5 Results

The results for the pairwise system-level scenario are in Table 3. The results over 2311 system pairs show that both our metrics outperform all other state-of-the-art metrics, with only Bleurt not being statistically worse than our metrics.

n	23595
MS-COMET-QE-22	**0.597 (1)**
COMET-QE	**0.596 (2)**
MS-COMET-22	**0.594 (3)**
Bleurt	**0.593 (4)**
COMET	0.586 (5)
BERTScore	0.567 (6)
chrF	0.557 (7)
TER	0.536 (8)
sentBLEU	0.535 (9)

Table 4: The results for pairwise accuracy in a segment-level setting over *WMT21-contr* testset. The "n" represent a number of segment pairs used in the evaluation.

The results over individual testsets show that our metrics are ranked among the top-performing metrics. Interestingly, *MQM21-news* domain seems to be easier for Quality Estimation metrics, while *MQM21-ted* shows the opposite direction. These results are interesting as the underlying systems are identical except for additional human reference.

Lastly, our metrics win in the *WMT21-contr* testset. This is the only genuinely pairwise testset where annotators saw systems next to each other while evaluating them.

Although we focus on a system-level evaluation, we evaluate how metrics perform in a segment-level setting for completeness. We use the testset *WMT21-contr* to calculate accuracies in the same fashion as for system-level scenario, but taking pairs of segment annotations instead of system-level scores. The segment-level results in Table 4 show that our metrics, COMET-QE, and Bleurt are in the winning cluster outperforming other metrics.

6 Conclusion

We have investigated the training COMET model with a larger corpus of human judgements covering multiple domains and 113 languages.

We employed several steps of filtering low-quality or repetitive human judgement.

With those data, we trained two metrics: MS-COMET-22 and MS-COMET-QE-22, that outperform other current MT metrics on a pair-wise system-level decision task.

We release the metrics for public use.

A List of languages

Our collection of human judgements covers 113 languages, language variants, or writing systems. Here is the complete list. Note that XLM-Roberta does not support some languages:

Afrikaans, Albanian, Amharic, Arabic, Armenian, Assamese, Azeri, Bangla, Bashkir, Basque, Bosnian, Bulgarian, Burmese, Catalan, Central Kurdish, Chinese (Literary), Chinese (People's Republic of China), Chinese (Taiwan), Chinese Yue, Chuvash, Classic Chinese (Simplified), Croatian, Czech, Danish, Dari, Divehi, Dutch, English, Estonian, Faroese, Fijian, Filipino, Finnish, French, French (Canada), Galician, Georgian, German, Greek, Gujarati, Haitian Creole, Hebrew, Hindi, Hmong, Hungarian, Icelandic, Indonesian, Inuktitut, Inuktitut (Latin), Inuinnaqtun, Irish, isiZulu, Italian, Japanese, Kannada, Kazakh, Khmer, Kiswahili, Korean, Kurdish, Kyrgyz, Lao, Latvian, Lithuanian, Macedonian, Malagasy, Malay, Malay Standard, Malayalam, Maltese, Maori, Marathi, Mongolian, Mongolian (Cyrillic), Nepali, Norwegian, Odia, Otomi, Pashto, Persian, Polish, Portuguese (Brazil), Portuguese (Portugal), Punjabi, Romanian, Russian, Samoan, Serbian (Cyrillic), Serbian (Latin), Slovak, Slovenian, Somali, Spanish, Swedish, Tahitian, Tajik, Tajiki, Tamil, Tatar, Telugu, Thai, Tibetan, Tigrinya, Tongan, Turkish, Turkmen, Ukrainian, Upper Sorbian, Urdu, Uyghur, Uzbek, Vietnamese, Welsh.

Furthermore, our human judgement data are not balanced. In some translation directions, we have more human-labeled data than in others. Table 5 shows the largest forty translation directions in our training data corpus.

Abstract

In this paper, we present the contribution of HW-TSC to WMT 2022 Metrics Shared Task. We propose one reference-based metric, HWTSC-EE-BERTScore*, and four reference-free metrics including HWTSC-Teacher-Sim, HWTSC-TLM, KG-BERTScore and CROSS-QE. Among these metrics, HWTSC-Teacher-Sim and CROSS-QE are supervised, whereas HWTSC-EE-BERTScore*, HWTSC-TLM and KG-BERTScore are unsupervised. We use these metrics in the segment-level and system-level tracks. Overall, our systems achieve strong results for all language pairs on previous test sets and a new state-of-the-art in many sys-level case sets.

1 Introduction

Due to the expensive cost of manual evaluation, automatically evaluating the outputs of translation systems is critically important in the field of machine translation (MT) (Freitag et al., 2021a). Therefore, a lot of automatic metrics have been proposed to approach this task. According to whether the reference sentences are required or not, the metrics are categorized into two classes: (1) reference-based metrics like BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007), BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020), which evaluate the hypothesis by referring to the golden reference; (2) reference-free metrics like YiSi-2 (Lo, 2019) and COMET-QE (Rei et al., 2020, 2021), which are also referred as quality estimation (QE). These metrics estimate the quality of hypothesis only based one source sentences without using references.

In this paper, we present the contribution of HW-TSC to the WMT 2022 Shared Task on Metrics. We participated in the segment-level and system-level tracks with 1 reference-based metric (HWTSC-EE-BERTScore*) and 4 reference-free metrics (HWTSC-Teacher-Sim, HWTSC-TLM, KG-BERTScore and CROSS-QE). Details of our metrics are illustrated in Table 1.

HWTSC-EE-BERTScore* (Entropy Enhanced Metrics)is built upon existing metrics, aiming to achieve a more balanced system-level rating by assigning weights to segment-level scores produced by backbone metrics. The weights are determined by the difficulty of a segment, which is related to the entropy of a hypothesis-reference pair. A translation hypothesis with a significantly high entropy value is considered difficult and receives a large weight in aggregation of EE-Metrics' system-level scores.

HWTSC-Teacher-Sim is a supervised reference-free metric with the framework of BERTScore (Zhang et al., 2020), which is obtained by fineturning the multilingual Sentence-BERT model (Reimers and Gurevych, 2019, 2020a). Both the unsupervised TearcherSim (Yang et al., 2022b,a) and the implicit multilingual word embedding alignment (Zhang et al., 2022b) have shown that the pretained multilingual Sentence-BERT model is very effective for both reference-based and reference-free MT evaluations on WMT DA (Direct Assessment) data. However, its performance on WMT MQM (Multidimensional Quality Metrics) data is poor. We propose an effective training strategy for the pretrained multilingual Sentence-BERT and a novel normalization method for the DA and MQM scores.

HWTSC-TLM (Zhang et al., 2022a) is an unsupervised reference-free metric which only uses the system translations as input and calculates the scores by a target-side language model. Although source sentences are not considered, the results of this metric with XLM-R (Conneau et al., 2020) on WMT19 are very promising.

KG-BERTScore (Wu et al., 2022) is an unsupervised reference-free metric, which incorporates multilingual knowledge graph into BERTScore

Table 1: Description of 5 metrics participated in WMT 2022 Shared Task. ✓and ✗respectively indicate whether the metric participates the corresponding track or not.

(Zhang et al., 2020). The score of this metric is calculated by linearly combining the results of BERTScore and bilingual named entity matching.

CROSS-QE is an application of "QE as a metric". Based on our previous work (Yang et al., 2020; Wang et al., 2020; Chen et al., 2021), we propose a reference-free metric, like COMET-QE architecture.

2 Metrics

This section introduces our metrics for WMT Metrics 2022 Shared Task including Reference-based and reference-free.

2.1 Reference-based

This year, entropy-enhanced BERTScore (HWTSC-EE-BERTScore, or referred as EE-BERTScore in short) was used in the general tests of the system-level track. EE-BERTScore, built upon standard BERTScore (Zhang et al., 2019), is within one of the EE metrics proposed earlier (Liu et al., 2022). The main idea of EE metrics is to challenge the standard way of acquiring system-level scores that outputs a simple arithmetic average of scores on segments in the evaluation set, and to provide a framework that enhances existing MT metrics by assigning higher weights to the difficult samples in the evaluation set. The motivation is simple: for MT evaluation, it is not likely that human raters treat every source-reference pair equally. Those simple samples can be easily translated, leading to similar human scores given to different hypotheses, while the more challenging part in an evaluation set often distinguishes top candidates from inferior systems. Like different weights are assigned to questions in real-world examinations based on variant difficulties, MT evaluation metrics should also encourage systems that perform better on relatively difficult samples. In the preliminary experiment, we find that using only the difficult segments (usually counting for less than 5% of all segments in the whole evaluation set) to evaluate MT systems, doesn't lead the automatic metrics to give incorrect ratings for MT systems, and sometimes even improves the performances of metrics in terms of correlation with human DA scores. Thus, we proposed EE metrics, which emphasize the translation qualities of relatively difficult ones among all hypotheses given by a system and assign high weights to these hypotheses in the aggregation of system-level scores.

2.1.1 Working Process of EE Metrics

Currently, EE metrics determine the difficulty of a segment via the average qualities of hypotheses. The qualities are measured by the translation entropy (or chunk entropy) (Yu et al., 2015) between the reference and the hypothesis. For a human reference and a hypothesis given by an MT system, a high chunk entropy suggests high uncertainty of the translation (the more linguistically matched parts between the hypothesis and the reference is, the lower the uncertainty of the translation is) and a low entropy indicates good confidence of the given hypothesis in expressing the meaning of the source segment. For example, if a hypothesis is perfectly matched with a reference, then the entropy of the translation is zero, and if there is no matching token between the hypothesis and the reference, the chunk entropy is positive infinity, indicating a total uncertainty and disorderness of the translation.

Fig. 1 illustrates how EE metrics assign different weights to the segments in the evaluation set based on the computed entropy. Firstly, segments in the evaluation set are divided into two groups: easy samples and difficult samples. If the entropy of a hypothesis is higher than the threshold h, it is considered in the difficult group and vice versa. Then, hypotheses are assigned weights in the aggregation of final score based on the groups they belong to. Specifically, samples in the easy group receive a weight of w/N_e and samples in the difficult group

receive a weight of $(1 - w)/N_d$, where N_e, N_d are the sizes of easy and difficult group, respectively, and w is a balance coefficient that, in our earlier version of EE metrics, may vary for different language pairs and evaluation datasets. Since the number of easy hypothesis is much larger than the number of difficult hypothesis for a given MT system, the weight of easy samples is much lower than the weight of difficult samples.

2.1.2 EE Metrics 2.0 vs. EE Metrics 1.0

The earlier version of EE metrics (denoted as EE metrics 1.0) has two hyper-parameters: h and w, involving in the selection of difficult samples and the determination of weights assigned to each group, respectively. The existence of such hyper-parameters hinders the application of EE metrics. What's worse, the hyper-parameters often alter for different language pairs and evaluation datasets (*e.g.*, we use up to 10 different parameters in our preliminary experiment, involving WMT 19 evaluation set), making it hard to estimate a feasible combination of parameters in the actual scenario. To alleviate such undesirable pain, we propose EE metrics 2.0 for this year's WMT metrics shared tasks. EE metrics 2.0 aims to reduce the hyper-parameters involved in the computation of system-level score as much as possible and offers a lightweight approach of computing weights for each segment. Specifically, EE metrics 2.0 doesn't require specifying h anymore, but automatically estimates thresholds based on a normal distribution fitting of average translation qualities (the average entropy) over all segments, aiming to find the threshold value of entropy where a sample has a significantly higher entropy than those of other samples in the datasets. Moreover, the estimation of w is simplified to a single value, instead of a series of different values for different language pairs. EE metrics 1.0 provides a formula to estimate w for every language pair, which is acquired based on the fitting of WMT 19 results. In contrast, the value of w doesn't change across different language pairs in EE metrics 2.0. Our submissions in WMT 2022 Metrics Shared Task contain three different configurations of values of w: 0.3, 0.5 and 0.8, which stand for different degrees of balance of weights received between difficult groups and easy groups.

2.2 Reference-free

In this section, we would introduce the four reference-free metrics.

2.2.1 HWTSC-Teacher-Sim

HWTSC-Teacher-Sim proposed by (Zhang et al., 2022b), is a Reference-free metric used for machine translation evalation by achieving cross-lingual word embedding alignment thrpugh multilingual knowledge distillation (MKD) (Reimers and Gurevych, 2020b). The procedure of multilingual knowleage distillation is described in the Figure 2. The teacher model is monolingual SBERT (Reimers and Gurevych, 2019) which achieves state-of-the-art performance for various sentence embedding tasks, and the student model is a multilingual pretrained model like mBERT or XLM-R before distillation. After MKD, the similarity score of sentence pairs in MT evaluation on the language

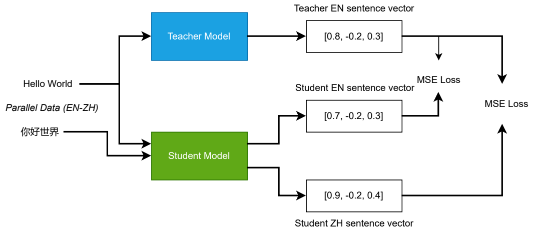

Figure 2: Multilingual knowledge distillation

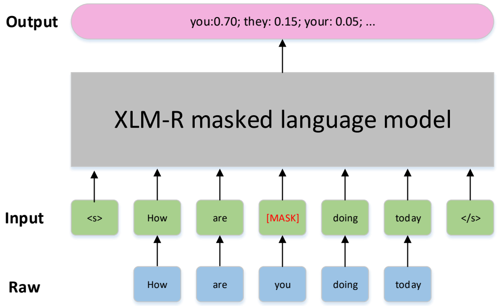
model should be as high as possible. Based on this feature, embeddings of sentences are used to calculate the similarity score as a metric. And we achieve strong results using language models to calculate the similarity between sentence pairs in an supervised manner in MQM data.

2.2.2 HWTSC-TLM

HWTSC-TLM proposed by Zhang et al. (2022a) utilizes a pretrained multilingual model XLM-R (Conneau et al., 2020) to score the system translations, which is a zero-shot unsupervised metric for MT evaluation.



Output

Figure 3: An example of HWTSC-TLM metric calculation for a given sentence

For a given sentence $\boldsymbol{s} = (w_1, \ldots, w_m)$ with m tokens, the score is defined as:

$$SEG\_LM(\boldsymbol{s}) = \frac{1}{m}\sum_{i=1}^{m} \log \frac{1}{P(w_i|\boldsymbol{s} - w_i)}, \quad (1)$$

where $P(w_i|\boldsymbol{s} - w_i)$ the probability of w_i predicted by the masked language model when w_i is replaced by `[MASK]`, as shown in Figure 3. And this score is used for segment-level MT evaluation.

For system-level evaluation where a set of system translation sentences S is provided, the score is defined as:

$$SYS\_LM(S) = \frac{1}{|S|}\sum_{\boldsymbol{s}\in S} SEG\_LM(\boldsymbol{s}), \quad (2)$$

which is the mean value of SEG_LM scores on each sentence in S.

2.2.3 CrossQE

CrossQE showed as figure 4 has used pre-trained Cross-lingual XLM-Roberta large(Lample and Conneau, 2019; Conneau et al., 2019) as predictor instead of RNN-based model in the two-stage Predictor-Estimator architecture (Kim et al., 2017), and uses regressor as quality estimator, and multitasks are trained at the same time. The Cross-lingual XLM-Roberta large model is pre-trained from large-scale parallel corpora which source and target tokens are concatenated by MLM task. Shuffling those tokens and predicting those tokens' index by the pre-trained model as a additional pre-training task can improve CrossQE's effect. CrossQE is build on the COMET architecture[1] by exploring adapter layers (Houlsby et al., 2019) for quality estimation to eliminate the overfitting problem while instead of fine-tuning the whole base pre-trained model for different NLP tasks (He et al., 2021). At training step, the Mean Teacher loss(Baek et al., 2021) is added to improve model's over-fitting problem. Data augmentation method based on Monte Carlo (MC) dropout (Gal and Ghahramani, 2016) is added to enhance the performance in sentence quality score prediction.

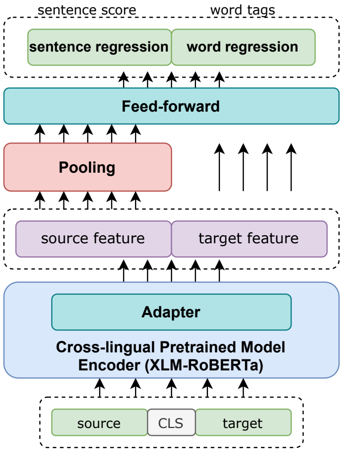

Figure 4: Cross QE architecture

2.2.4 KG-BERTScore

KG-BERTScore metric proposed by Wu et al. (2022), incorporates multilingual knowledge graph into BERTScore for reference-free MT evaluation. The evaluation process in WMT22 metrics shared task is shown in Algorithm 1:

[1] https://github.com/Unbabel/COMET

Firstly, we employ a reference-free BERTScore metric to calculate F_{BERT} score of each MT sentence. For the WMT22 metrics shared task, we use HWTSC-Teacher-Sim metric to calculate F_{BERT} so that the score is more relevant to the MQM.

Secondly, we utilize model (NER) named entity recognition to identify named entities in the sentences, and retrieve the corresponding entity IDs in multilingual knowledge graph. We then calculate F_{KG} scores based on entity matching degree. Since the same named entities in different languages share the same entity ID in multilingual knowledge graph, we can check whether they can be matched by entity IDs. For the WMT22 metrics shared task, the NER model we use is spacy[2], and the multilingual knowledge graph we use is Google Knowledge Graph Search API[3].

Finally, we combine to obtain a segment-level $F_{KG-BERT}$ score, and the $F_{KG-BERT}$ score of all MT sentences are averaged to obtain a system-level score. For the WMT 2022 metrics shared task, we set α to 0.5, and if there is no entity in the source, F_{KG} score is 1.

In addition, due to limited access to the Google Knowledge Graph Search API, we only use KG-BERTScore metric to score the three language directions zh-en, en-ru, and en-de on the WMT22 metrics shared task. The scores for other language directions in our submissions are simply populated with the F_{BERT} score based on the paraphrase-multilingual-mpnet-base-v2 model[4].

Algorithm 1: KG-BERTScore evaluation process

```
Input  : all source sentences $s_k \in S$ and
         machine translations $t_k \in T$ of
         $n$ sentence pairs
Output : a system-level score $F$
for each sentence pair $\{s_k, t_k\} \in \{S, T\}$ do
    // $x_i$, $x_j$, $\hat{x}_i$, $\hat{x}_j$ is the word embedding.
    $R_k = \frac{1}{|s_k|} \sum_{x_i \in s_k} \max_{\hat{x}_j \in t_k} x_i^T \hat{x}_j$
    $P_k = \frac{1}{|t_k|} \sum_{\hat{x}_i \in t_k} \max_{x_j \in s_k} \hat{x}_i^T x_j$
    $F_{BERT_k} = 2\frac{P_k \cdot R_k}{P_k + R_k}$
    // $entities(s_k)$, $entities(t_k)$ is the number of entities.
    if $entities(s_k) \neq 0$ then
        $F_{KG_k} = \frac{matches(entities(s_k), entities(t_k))}{entities(s_k)}$
    else
        $F_{KG_k} = 1$
    end
    // $\alpha$ is an adjustable hyperparameter.
    $F_{KG-BERT_k} = \alpha \cdot F_{KG_k} + (1 - \alpha) \cdot F_{BERT_k}$
end
$F = \frac{\sum_{k=1}^{n} F_{KG-BERT_k}}{n}$
```

3 Experiments

3.1 Experiments of Reference-based

To verify the feasibility of EE metrics 2.0, we conduct experiments mainly on WMT 20 and WMT 21 using MQM (Lommel et al., 2014) as the ground truth. To investigate the difference between when human translations are used as a system and when they are not used, we display the results computed on two sets of systems for each language pair. We report three coefficients: Pearson's correlation r, Kendall's τ and Spearman's ρ, to validate system-level correlations with human evaluations.

Table 2 displays performance comparison between EE-BERTScore and standard BERTScore, where EE-BERTScore achieves overall higher correlations with human MQM than standard BERTScore. We experiment with EE-BERTScore under different values of w, suggesting different relative weights between easy groups and difficult groups in the computation of system-level scores. We find that each setting of w is able to improve the performance of standard BERTScore, and has their best performances on a certain dataset. For example, EE-BERTScore-0.3 and EE-BERTScore-0.5 achieve a strong result on news test of WMT 20 and WMT 21, while on WMT 21 tedtalks, best performance is achieved when w is 0.8.

Since EE metrics evaluate a system relying on not only the single system, but also other participated systems, the existence of human translations may have an impact on the performances of EE metrics. As shown in Table 2, correlations with MQM drop sharply for EE-BERTScore-$*$ when human translations are included as, which is in accordance

Table 2: Correlations with system-level human MQM scores on datasets of WMT 20 news, WMT 21 news and WMT 21 tedtalks. EE-BERTScore-∗ represents EE-BERTScore with different w values. **With Human** indicates evaluation on MT systems and human traslations, and **w/o Human** indicates MT systems only. Best correlations are marked in bold.

with the conclusion from (Freitag et al., 2021b) that most metrics struggle to correctly score translations that are different from MT systems. However, we still see EE-BERTScore-∗ improves the correlations with human for BERTScore in some cases (En→ De in WMT 21 datasets), while there are cases where EE-BERTScore-∗ hardly has a difference with BERTScore in terms of the correlations (Zh→ En in WMT 20 news). Overall, when human translations participate as additional outputs, EE metrics bring a less significant improvement to the standard metrics.

3.2 Experiments of Reference-free

This section introduces the experimental results of our four reference-free metrics.

3.2.1 HWTSC-Teacher-Sim

We choose paraphrase-multilingual-mpnet-base-v2[4] as the model for generating sentence embeddings. Triplets were build with source, MT, and the scores of MT - the scores of MT were normalized. The MT with a higher score is closer to the source in the vector space. With TripletEvaluator, we achieve the alignment of embeddings of source and MT in the space vector. In en-de and zh-en, we use MQM data of WMT2020 and WMT2021 as train set and test set respectively. Since en-ru only has MQMdata of WMT2021, the experimental results of en-ru are missing. COMET-QE-DA_2021-src (Rei et al., 2020) is chosen as the state-of-the-art reference-free metric for comparison. And sentBLEU and BLEU (Koehn et al., 2007) are selected as the state-of-the-art reference-based metrics.

Metrics	**en-de**	**zh-en**
sentBLEU	0.083	0.176
COMET-QE-DA_2021-src	0.244	0.305
HWTSC-Teacher-Sim	0.205	0.355

Table 3: Segment-level Kendall correlations for language pairs of WMT21 MQM data

Metrics	**en-de**	**zh-en**
BLEU	0.937	0.310
COMET-QE-DA_2021-src	0.847	0.453
HWTSC-Teacher-Sim	0.863	0.596

Table 4: System-level Pearson correlations for language pairs of WMT21 MQM data

The experimental results show that the introduction of multilingual knowledge distillation is more helpful to the system level scoring accuracy of reference-free HWTSC-Teacher-Sim.

3.2.2 HWTSC-TLM

XLM-R[5] is selected as the masked language model for our metric HWTSC-TLM. The segment-level and system-level results on the 8 from-English language pairs of WMT19 are reported in Table 5 and Table 6 respectively. YiSi-2 (Lo, 2019) and Prism-src (Thompson and Post, 2020) are chosen as the state-of-the-art unsupervised reference-free metrics for comparison, and reference-based metrics sentBLEU and BLEU (Koehn et al., 2007) are selected for reference. More experimental results of HWTSC-TLM on WMT19 could be found in (Zhang et al., 2022a).

From the results in Table 5 and Table 6, it could be seen that HWTSC-TLM is much better than

[5] https://huggingface.co/xlm-roberta-base

Metrics	**en-cs**	**en-de**	**en-fi**	**en-gu**	**en-kk**	**en-lt**	**en-ru**	**en-zh**	**Avg**

HWTSC-TLM	0.896	0.978	0.941	0.683	0.897	0.919	0.819	0.959	0.886

Table 6: System-level metric results for from-English language pairs of WMT19: absolute Pearson correlation of system-level metric scores with DA.

YiSi-2, and is very competitive with Prism-src, which is a very strong baseline in unsupervised reference-free metrics, although only system translations are used in HWTSC-TLM.

3.2.3 CrossQE

Experiments and results of CrossQE could be found in WMT 2022 QE task report (Su et al., 2022).

3.2.4 KG-BERTScore

The ninth layer of XLM-R[5] is selected for word embedding to calculate F_{BERT} scores in our metric KG-BERTScore. The segment-level and system-level results on the 7 into-English language pairs of WMT19 are reported in Table 7 and Table 8 respectively. YiSi-2 (Lo, 2019) and reference-free BERTScore are chosen as unsupervised reference-free metrics for comparison, and reference-based metrics sentBLEU and BLEU (Koehn et al., 2007) are selected for reference. The experimental results show that the introduction of multilingual knowledge graph is more helpful to the system level scoring accuracy of reference-free BERTScore.

Metrics	de-en	fi-en	gu-en	kk-en	lt-en	ru-en	zh-en	mean
sentBLEU	0.056	0.233	0.188	0.377	0.262	0.125	0.323	0.223
YiSi-2	**0.068**	0.126	-0.001	0.096	0.075	0.053	**0.253**	0.096
BERTScore	0.036	**0.234**	**0.171**	0.310	**0.211**	0.089	0.196	**0.178**
KG-BERTScore	0.039	0.191	0.165	**0.313**	0.177	**0.095**	0.213	0.170

Table 7: Segment-level metric results for into-English language pairs of WMT19: absolute Kendall's Tau correlation of segment-level metric scores with DA.

4 Conclusions

Metrics	de-en	fi-en	gu-en	kk-en	lt-en	ru-en	zh-en	mean

BERTScore	0.785	**0.866**	-0.007	0.117	0.657	-0.372	0.728	0.396
KG-BERTScore	**0.862**	0.733	**0.764**	**0.936**	**0.688**	**0.918**	0.908	**0.830**

Table 8: System-level metric results for into-English language pairs of WMT19: absolute Pearson correlation of system-level metric scores with DA.

In this paper, we present one reference-based metric and four reference-free metrics. We apply the methods of entropy-enhance, multilingual knowledge distillation, multilingual knowledge graph, and quality evaluation in MT to WMT 2022 Metrics Shared Task. The experimental results show great effectiveness of our research direction and the superiority of our metrics.

Abstract

In this paper, we describe our submission to the WMT22 metrics shared task. Our metric focuses on computing contextual and syntactic equivalences along with lexical, morphological and semantic similarity. The intent is to capture fluency and context of the MT outputs along with their adequacy. Fluency is captured using syntactic similarity and context is captured using sentence similarity leveraging sentence embeddings. The final sentence translation score is the weighted combination of three similarity scores: a) Syntactic Similarity b) Lexical, Morphological and Semantic Similarity and c) Contextual Similarity. This paper outlines two improved versions of MEE i.e., MEE2 and MEE4. Additionally, we perform our experiments on language pairs of en-de, en-ru and zh-en from WMT17-19 testset and further report the correlation with human assessments. Our submission will be made available at https://github.com/AnanyaCoder/WMT22Submission.

1 Introduction

Neural Machine Translation (NMT) systems have emerged with an increased research interest in recent times and significantly enhanced the MT quality. However, the MT research community still relies mainly on antiquated metrics and no new, universally adopted standard metric has emerged. In the last few years, research in Machine Translation (MT) evaluation has made significant progress. A metrics-shared task is held annually at the WMT conference, where new evaluation metrics are proposed and those which correlates highly with human judgements are presented from the pool of newly defined metrics. Neural-based metrics largely dominated the last two years of the WMT Metrics Task (Freitag et al., 2021; Mathur et al., 2020; Ma et al., 2019). Nevertheless, n-gram based or lexical-based metrics remain popular as automatic MT evaluation metric due to their agile and light-weighted nature. Traditionally, automatic metrics for evaluating MT quality have relied on estimating the similarity between machine outputs and reference sentences in the target language. However, advanced NMT methods yield high-quality translations that might have lexical, morphological, syntactic variations and different word choices having similar meanings. Typically, the machine output diverges from monotonic lexical transfer between the source and target languages. Widely used evaluation metrics rely on basic, lexical-level features as they calculate the surface similarity between the hypothesis and reference sentences by counting the number of matching n-grams (Papineni et al., 2002; Doddington, 2002). Metrics relying on n-gram overlap cannot appropriately capture morphological, syntactic and semantic variations as they are sensitive to only lexical variations. METEOR (Denkowski and Lavie, 2014; Gupta et al., 2010; Lavie and Denkowski, 2009; Lavie and Agarwal, 2007; Banerjee and Lavie, 2005) captures semantic variations but it is highly dependent on language specific tools . Hence, there is huge requirement for a robust, understandable, easy to use automatic MT evaluation metric which captures all the linguistic features to evaluate like humans. The better evaluation metric will be highly helpful to the development of better MT systems (Liu et al., 2011).

In this paper, we present our submission to the WMT2022 metrics shared task. We evaluate the translations of English-German (en-de), English-Russian (en-ru) and Chinese-English (zh-en) language pairs. However, the proposed metric is language independent and supports 100+ languages. Here, our submission includes scores of three metrics MEE (Mukherjee et al., 2020), MEE2 and MEE4 (MEE2 and MEE4 are extended versions of MEE). We have evaluated the testsets of WMT17 (Bojar et al., 2017), WMT18 (Bojar et al., 2018) and WMT19 (Bojar et al., 2019a,b,c), for the same

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 558 - 563
December 7-8, 2022 ©2022 Association for Computational Linguistics

language pairs (en-de, en-ru and zh-en) and reported the correlation with human assessments. The empirical results conclude that MEE4 shows better agreement with humans.

2 *M*etric for *E*valuation using *E*mbeddings (MEE)

2.1 MEE

MEE (Mukherjee et al., 2020) is an automatic evaluation metric that leverages the similarity between embeddings of words in candidate and reference sentences to assess translation quality focusing mainly on adequacy. Unigrams are matched based on their surface forms, root forms and meanings which aids to capture lexical, morphological and semantic equivalence. Semantic evaluation is achieved by using pretrained fasttext embeddings (Grave et al., 2018) provided by Facebook to calculate the word similarity score between the candidate and the reference words. MEE computes evaluation score using three modules namely exact match, root match and synonym match. In each module, fmean-score is calculated using harmonic mean of precision and recall by assigning more weightage to recall. Final translation score is obtained by taking average of fmean-scores from individual modules.

2.2 MEE2, MEE4

MEE2 and MEE4 are improved versions of MEE that capture lexical, morphological, semantic, contextual and syntactic similarity. These linguistic aspects are captured in different modules and the final sentence translation score is the weighted pool of these individual modules. Unlike MEE, these metrics capture fluency and sentence semantics. **Contextual similarity** (or sentence semantics) is obtained by computing a cosine similarity between sentence embeddings of reference sentence and system output. Whereas fluency is captured by performing **Syntactic Similarity** which is computed by using a modified BLEU score. **Lexical, Morphological and Semantic**[1] **Similarity** is measured by explicit unigram matching similar to MEE.

Figure 1 illustrates the segment-level computation of final translation score of based on a reference sentence.

2.2.1 Syntactic Similarity

Our approach assesses fluency by capturing the syntactic similarity between the reference and the hypothesis using BLEU (Papineni et al., 2002) since it follows the notion that longer n-gram scores account for the fluency of the translation. However, the length with the "highest correlation with monolingual human judgements" was found to be four (BLEU-4). Our experiments adopt the concept of BLEU with a slight variation i.e., dynamic n-gram (n depends on the sentence length). Here, while evaluating a hypothesis, the order of n-gram is based on the corresponding reference sentence length.

2.2.2 Lexical, Morphological and Semantic Similarity

In our work, *lexical, morphological and semantic* equivalence score is computed in similar to MEE metric [2]. MEE (Metric for Evaluation using Embeddings) contains three modules, namely *Exact Match, Root Match, and Synonym Match* which accounts for *lexical, morphological and semantic* features of the translation (Mukherjee et al., 2020).

2.2.3 Contextual Similarity

Contextual Similarity Score is computed by measuring the distance between the hypothesis sentence embedding and reference sentence embedding. Sentence Embedding models map text/sentences to a vector space, implying that related or similar sentences lie closer to each other in this embedding space. Sentence embedding captures the intention of the sentence. Our work is based on the assumption that contextual information of a given sentence can be captured from its vector (or embedding). We determine the context equivalence of two sentences by computing a cosine similarity (Foreman, 2014) between the embeddings of reference and hypothesis. Contextual equivalence is calculated by computing cosine similarity between the sentences embedded using LaBSE by Google AI. Out of several existing Language-Agnostic models, LaBSE (Feng et al., 2020), LASER (Artetxe and Schwenk, 2018), and Indic-Bert (Kakwani et al., 2020) we prefered to use LaBSE to embed the sentences as it is a multilingual BERT embedding model trained using MLM and TLM pre-training, resulting in a model that is effective even on low-resource languages

[1] word-level semantic similarity

[2] https://github.com/AnanyaCoder/MEE_WMT2021

for which there is no data available during training. Also, it produces language-agnostic cross-lingual sentence embeddings for 109 languages.

2.3 Score Computation

The segment-level evaluation score is computed as follows. Based on number of matched unigrams in candidate and reference sentence, individual fmean scores are computed at lexical, morphological and semantic levels. These fmean scores are achieved by parameterized harmonic mean (Sasaki, 2007) of precision and recall as per Equation 3. Ulitmately, MEE score is computed by averaging the individual fmean scores of three modules.

$$precision(P) = \frac{\#matched\_unigrams}{Total\#unigrams\_in\_hypothesis} \quad (1)$$

$$recall(R) = \frac{\#matched\_unigrams}{Total\#unigrams\_in\_reference} \quad (2)$$

$$f_\beta = \frac{(\beta^2+1)PR}{\beta^2 P + R} \quad (3)$$

MEE2 and MEE4 is computed using Equation 4 where LMS score is same as the MEE score (Mukherjee et al., 2020) i.e., $\beta = 3$ in Equation 3. Syn and Cxt are Syntax Simlarity score and Contextual Similarity score of reference and translation. The parameters in Equation 4 are manually tuned for computing MEE2 and MEE4 scores[3]. For MEE2: $\alpha = 2, \gamma = 1, \delta = 1, \epsilon = 1$ and for MEE4: $\alpha = 2, \gamma = 1, \delta = 1, \epsilon = 3$

$$score = \frac{\delta * \frac{\alpha * LMS + \gamma * Syn}{\alpha + \gamma} + \epsilon * Cxt}{\delta + \epsilon} \quad (4)$$

3 Experiments and Results

3.1 Results on WMT17-19 testset

Each year, the WMT Translation shared task organisers collect human judgements in the form of Direct Assessments. Those assessments are then used in the Metrics task to measure the correlation between metrics and therefore decide which metric works best. Therefore, we evaluated a total of 9K sentences from the testset of WMT17, WMT18, WMT19 for en-ru, en-de, zh-en language pairs and computed the pearson correlation (Benesty et al., 2009) of MEE, MEE2, MEE4 with human assessments. The segment level correlation scores are mentioned in Table 1. It is clearly evident that MEE4 correlates better with humans i.e., across the different testsets and language pairs, MEE4 demonstrates higher agreement with human judgements.

3.2 WMT22 task submission

During our experiments, we tested several techniques: averaging the module scores with different weights. Based on the agreement with humans on the WMT17-19 testset (refer Table 1, we decided to report the scores of MEE, MEE2 and MEE4 for the current WMT22 metric shared task submission. Table 2 shows the WMT22 test-set details we have experimented on.

3.2.1 Segment Level Evaluation

For Segment-level task, we submitted the sentence level scores obtained by our reference based metrics MEE2 and MEE4 for en-ru, en-de and zh-en language pairs.

3.2.2 System Level Evaluation

For the System-level task we compute the system-level score for each system by averaging the segment-level scores obtained. We observe an equivalent approach used to compute system-level scores based on segment-level human annotations such as DA's and MQM, implying that a metric that achieves a solid segment-level correlation should also gain strong system-level performances.

4 Conclusion and Future Work

In this paper, we present our participation to the WMT22 Metrics Shared Task. Our submission includes segment-level and system-level scores for sentences of three language pairs Chinese-English (zh-en), English-Russian (en-ru) and English-German (en-de). We evaluate this year's test set using our **unsupervised, reference-based** metrics: MEE2 and MEE4. Both the metrics are extended versions of MEE with improved correlation. From the last year's findings, it was evident that MEE2 was one among the better performing metrics as it was highlighted in the top significant cluster (Freitag et al., 2021). However, this year we present MEE4 along with MEE2 and MEE4 has proved to perform better in terms of correlation with humans when evaluated on testsets of WMT17, WMT18 and WMT19. We observe that this improvement in agreement to human experts level judgements is due to assigning more weightage to context information (sentence level semantics) when compared

Abstract

This paper describes our submission to the WMT2022 shared metrics task. Our unsupervised metric estimates the translation quality at chunk-level and sentence-level. Source and target sentence chunks are retrieved by using a multi-lingual chunker. Chunk-level similarity is computed by leveraging BERT contextual word embeddings and sentence similarity scores are calculated by leveraging sentence embeddings of Language-Agnostic BERT models. The final quality estimation score is obtained by mean pooling the chunk-level and sentence-level similarity scores. This paper outlines our experiments and also reports the correlation with human judgements for en-de, en-ru and zh-en language pairs of WMT17, WMT18 and WMT19 testsets. Our submission will be made available at https://github.com/AnanyaCoder/WMT22Submission_REUSE

1 Introduction

Quality Estimation (QE) is an essential component of the machine translation workflow as it assesses the quality of the translated output without conferring reference translations (Specia et al., 2009; Blatz et al., 2004). High quality reference translations are often hard to find, QE helps to evaluate the translation quality based on the source sentences. Recently QE has emerged as an alternative evaluation approach for NMT systems (Specia et al., 2018). Recently, many researchers have been working on QE, as a part of Quality Estimation Shared Task, several QE systems (Zerva et al., 2021; Lim et al., 2021; Chowdhury et al., 2021; Geigle et al., 2021) were evaluated in WMT conference (Barrault et al., 2021). However, most of the quality estimation systems are supervised i.e., the model regresses on the human judgements. Often, human assessments are not available and it is very difficult to procure high quality human judgements. This motivated our research to emerge with an *Unsupervised Quality Estimation System*. Also, QE is usually performed at different granularity (e.g., word, sentence, document) (Kepler et al., 2019); in this work, we focus on the chunk-level and sentence-level similarity. The final QE score of the target sentence is obtained by mean pooling the chunk similarity scores and sentence similarity scores. Overall, our main contribution is as follows:

- We propose a concept of chunk level similarity i.e., matching the source and target chunks by leveraging multilingual BERT embeddings.
- We release a multilingual chunking model which returns meaningful word group boundaries.
- We present our unsupervised reference free QE metric (REUSE) that estimates the quality of translation by doing a chunk-level and sentence-level comparison with the source.

1.1 Motivation to use chunks

Usually, the words in translated output might not always follow the word sequence of the source text. However, it is observed that few word-groups often occur together irrespective of the order in source.

Figure 1 illustrates two example pairs: English-German (en-de) pair and English-Hindi (en-hi) pair. In the first example pair, the words sequence is not highly altered as English and German belong to the same language family (West Germanic), whereas in en-hi pair we can see a drastic change in the word order as Hindi belongs to a different language family (Indo-Aryan). However, we can observe that few word groups (here we refer as chunk) always occur *together* in both source and target. This phenomenon has motivated our research in the direction of chunk level assessment.

2 REUSE

We propose REUSE, a **RE**ference-free **U**n**S**upervised quality **E**stimation Metric that

evaluates a machine translated output based on the corresponding source sentence regardless of the reference. Figure 2 depicts the high-level architecture of our model. The chunks of source and hypothesis are acquired from the multilingual chunking model. Further chunk-wise subword contextual BERT embeddings are mean-pooled to obtain the chunk-level embeddings. Meanwhile, LaBSE model (Feng et al., 2020) is used for the sentence-level embeddings. Using these embeddings, we compute chunk-level similarity and sentence-level similarity, finally combine them by averaging chunk- and sentence-level similarity scores[1]. We discuss the working details of our system in the following sections.

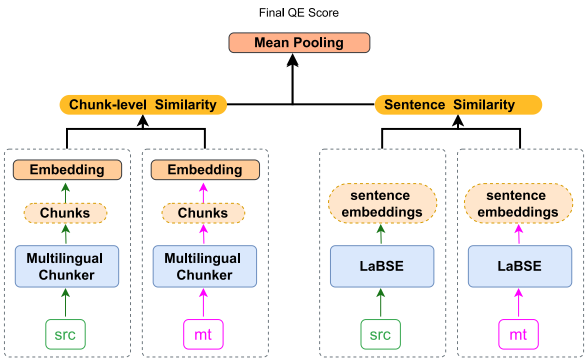

Figure 2: High-level architecture of REUSE model.

2.1 Chunk-level Similarity

We measure the number of matches between source chunks and hypothesis chunks. These matches are obtained by computing a cosine similarity (Foreman, 2014) of the individual chunk embeddings (refer 2.1.2) of source and translation sentence. An all-pair comparison is done to determine the best chunk match. Based on these matches, we compute precision and recall i.e, precision is *count of matches / length of hypothesis* and recall is *count of matches / length of source*. Ultimately, the chunk-level similarity score is calculated as the parameterized harmonic mean (Sasaki, 2007) of precision and recall, assigning more weightage to recall ($\beta = 3$).

2.1.1 Multilingual Chunker

The fundamental innovation in recent neural models lie in learning the contextualized representations by pre-training a language modeling task. Multilingual BERT is one such transformer-based masked language model that is pre-trained on monolingual Wikipedia corpora of 104 languages with a shared word-piece vocabulary. Training the pre-trained mBERT model for a supervised downstream task (finetuning) has dominated performance across a broad spectrum of NLP tasks (Devlin et al., 2018). We leverage this finetuning capability of BERT so as to create a *Multilingual Chunker* model that inputs a sentence and returns a set of divided chunks (word-groups).

[1] REUSE score ranges between 0-1.

We use **BertForTokenClassification** which has BERT (Bidirectional Encoder Representations from Transformers) as its base architecture, with a token classification head on top, allowing it to make predictions at the token level, rather than the sequence level. We use this BertForTokenClassification model and load it with the pretrained weights of "bert-base-multilingual-cased"[2]. We train the token classification head, together with the pretrained weights, using our labelled dataset (chunk annotated data). We employ Cross Entropy as the loss function and Adam optimizer (Kingma and Ba, 2014) with a learning rate of 1e-05.

2.1.2 Chunk Embeddings

Currently, we have word embedding models and sentence embedding models, but there is no specific chunk-level embedding models. Therefore, we embed the chunks leveraging the BERT embeddings by loading the weights of "distiluse-base-multilingual-cased"[3]. For a given sentence, this model return embeddings at a subword-level. To obtain the desired *chunk embeddings*, we perform a chunk to subword mapping and mean-pool the subword embeddings belonging to each chunk.

2.2 Sentence Similarity

To compute similarity at the sentence level, we find the cosine similarity (Foreman, 2014) of source sentence embedding and translation sentence embedding. We use LaBSE (Language Agnostic BERT Sentence Embedding) model to obtain the sentence embeddings. LaBSE model (Feng et al., 2020) is built on BERT architecture and trained on filtered and processed monolingual (for dictionaries) and bilingual training data. The resulting sentence embeddings achieve excellent performance on measures of sentence embedding quality, such as the semantic textual similarity (STS) benchmark and sentence embedding-based transfer learning (Feng et al., 2020).

3 Experiments and Results

3.1 Results on WMT17-19 testset

Each year, the WMT Translation shared task organisers collect human judgements in the form of Direct Assessments. Those assessments are then used in the Metrics task to measure the correlation between metrics and therefore decide which metric works best. Therefore, we estimated the translation quality of about 9K translations from the testset of WMT17 (Bojar et al., 2017), WMT18 (Bojar et al., 2018), WMT19 (Bojar et al., 2019a,b,c) for en-ru, en-de, zh-en language pairs and computed the pearson correlation (Benesty et al., 2009) of human judgements with Chunk-level Similarity scores, Sentence-level Similarity scores and their combination (REUSE). The segment level correlation scores are mentioned in Table 2. It is clearly evident from the correlations that the ensemble of Chunk Similarity model and Sentence Similarity model outperforms the individual models.

3.2 WMT22 QE-as-a-metric task submission

Table 1 shows the WMT22 QE-as-a-metric task test-set details for the language pairs we have experimented on.

Language Pair	#Sentences	#Systems
en-ru	36723	88
en-de	82356	91
zh-en	41127	103

Table 1: Data statistics of WMT22 QE-as-a-metric task testset for en-ru, en-de and zh-en pairs.

3.2.1 Segment Level Evaluation

For Segment-level task, we submitted the sentence level scores obtained by our reference free quality estimation metric (REUSE) for en-ru, en-de and zh-en language pairs.

3.2.2 System Level Evaluation

We compute the system-level score for each system by averaging the segment-level scores obtained. A similar method is also used to compute system-level scores based on segment-level human annotations such as DA's and MQM, implying that a metric with a high segment-level correlation should also demonstrate high system-level correlation.

4 Conclusion

In this paper, we describe our submission to the WMT22 Metrics Shared Task (QE-as-a-metric). Our submission includes segment-level and system-level quality estimation scores for sentences of three language pairs Chinese-English (zh-en), English-Russian (en-ru) and English-German (en-de). We evaluate this year's test set using our **unsupervised, reference-free** metric - REUSE, that

	en-de	0.254	0.131	0.251

Table 2: Correlation with Human Judgements on WMT17, WMT18 and WMT19 testset.

provides a quality estimation score by evaluating a hypothesis against the source sentence. REUSE estimates the translation quality by combining chunk-level similarity score and sentence-level similarity score, leveraging multilingual BERT embeddings. We performed our experiments on testsets of WMT17, WMT18, WMT19 and it has been empericaly observed that the combination of *chunk- and sentence-level* similarity scores performed better in terms of agreement with human assessments.

Potential research directions definitely include improving the multilingual chunking model. As part of future work, we aim to further experiment and emerge with such effortless efficient unsupervised approach to estimate the translation quality and exhibit higher agreement with humans.

Abstract

Starting from last year, WMT human evaluation has been performed within the Multidimensional Quality Metrics (MQM) framework, where human annotators are asked to identify error spans in translations, alongside an error category and a severity. In this paper, we describe our submission to the WMT 2022 Metrics Shared Task, where we propose using the same paradigm for automatic evaluation: we present the MaTESe metrics, which reframe machine translation evaluation as a sequence tagging problem. Our submission also includes a reference-free metric, denominated MaTESe-QE. Despite the paucity of the openly available MQM data, our metrics obtain promising results, showing high levels of correlation with human judgements, while also enabling an evaluation that is interpretable. Moreover, MaTESe-QE can also be employed in settings where it is infeasible to curate reference translations manually.

1 Introduction and Related Work

For many years, Machine Translation (MT) has mainly been evaluated using untrained evaluation techniques, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and chrF (Popović, 2015), which rely heavily on lexical-level matching of either token, or character, n-grams. Unfortunately, these metrics present two major drawbacks: i) it is not possible to carry out the evaluation without manually-curated references and, most importantly, ii) the evaluation is too dependent on the surface form of the translation, and its reference. More recently, attempts have been made to address these problems using machine-learned metrics, which have shown better correlations with human judgements (Mathur et al., 2020). More specifically, last year's WMT Metrics Shared Task saw C-SPEC$_{\text{PN}}$ (Takahashi et al., 2021), BLEURT-20[1] and COMET-MQM_2021 (Rei et al., 2021) emerge as distinctly better than the other participants (Freitag et al., 2021b). These metrics consist of regression models trained to mimic human annotators by directly assigning quality scalar scores to candidate translations. In detail, COMET-MQM_2021 is based on the Estimator architecture introduced by Rei et al. (2020), where features extracted from the embeddings of the source sentence, candidate translation, and reference translation are passed to a feed-forward regressor; C-SPEC first concatenates the embeddings derived from paired inputs of candidate-source and candidate-reference, and then passes the resulting vector to a multi-layer perceptron; BLEURT, instead, feeds the candidate translation and its reference to Rebalanced mBERT (Chung et al., 2021), and regresses on the representation provided by the [CLS] token. Moreover, BLEURT and C-SPEC add automatically-generated negative pairs to the standard training data: BLEURT applies random token perturbations, while C-SPEC uses Word Attribute Transfer to replace words in the translations. Although undoubtedly effective, regression metrics have the major drawback of not being interpretable, meaning that users are not able to gauge the quality of assessments that are returned, which is of paramount importance for an evaluation metric.

Recently, Freitag et al. (2021a) have proposed a shift in the standard practices for human machine translation evaluation, employing the Multidimensional Quality Metrics framework (Lommel et al., 2014, MQM), and moving away from Direct Assessments (Graham et al., 2013, DA), which were computed via requiring (even non-expert) annotators to assign a scalar value to a candidate translation, given a reference. Furthermore, Freitag et al. (2021a) pointed out the limitations of non-professional Direct Assessments, also show-

[1] BLEURT-20 is the retrained version of the previous year's BLEURT submission (Sellam et al., 2020).

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 569 - 577
December 7-8, 2022 ©2022 Association for Computational Linguistics

ing their unreliability compared to MQM. Indeed, differently from Direct Assessments, annotators who follow the MQM guidelines look at the source sentence rather than the reference, and are expected to tag the spans of the candidate translations that contain errors,[2] together with their error category (e.g., `Fluency/Grammar`, `Fluency/Punctuation` or `Style/Awkward`) and severity (e.g., `Major` or `Minor`), which, combined, determine the score associated with the error span. Finally, a scalar quality score for the entire sentence is derived from the various annotated spans.

In this work, we introduce the MATESE and MATESE-QE metrics, reframing the evaluation of machine-translated text as a sequence tagging problem based on the MQM framework, in an attempt to develop metrics that are interpretable, while also displaying high levels of correlation with human judgements.

2 MATESE Metrics

Inspired by the novel MQM evaluation framework, our work aims at employing a similar paradigm for automatic evaluation. We propose the MATESE metrics which, given a candidate translation and its reference (or source, for MATESE-QE), assign a label to each token of the candidate. These labels identify error spans, together with their severity, chosen among `Major` and `Minor`. Finally, in order to associate a score with the entire tagged sentence, we follow a weighting scheme similar to the one presented by Freitag et al. (2021a) for MQM-based human evaluation: we assign a score to an entire error span based on its severity, i.e., -5 and -1 for `Major` and `Minor`, respectively. The score assigned to a translation is the sum of the scores assigned to its error spans, with a minimum total score of -25. Following Freitag et al. (2021a), we compute a corpus-level score by averaging the scores of the sentences in the corpus. Although human MQM annotators are asked to report a maximum of 5 errors per translation,[3] we decided to let our metrics detect as many errors as they can find; nevertheless, in order to keep our scores in the same range as those computed on gold MQM annotations, we set a minimum score of -25, which is equal to the sum of 5 `Major` errors. Figure 1 shows an example of the annotations returned by our metrics.

Candidate
In the square team, this song is the motto of every team member.

Figure 1: Example of the annotation returned by the MATESE metrics, given a candidate translation and its reference. The final score of the translation is -6, that is the sum of -5 and -1, assigned to the `Major` and `Minor` errors, respectively.

2.1 Data pre-processing

According to the MQM guidelines, mistranslated spans are tagged with an error category and a severity. To reduce the granularity of the annotations, we apply some transformations to the original data, which we report below:

1. We discard annotations of the `Non-translation` category, since they are weighted -25 by Freitag et al. (2021a), and would have required a special treatment, but are too scarce ($< 0.1\%$ of the whole data) for the model to learn how to assign them;
2. We discard annotations referring to either `Accuracy/Omission` or `Source error` categories, since in these cases the annotation might be in the source sentence, while our models are trained to tag the candidate translation only;
3. We discard annotations of errors with `Neutral` severity, since they are highly subjective and do not participate in the computation of the final quality score (Freitag et al., 2021a);
4. We replace `Critical` severity labels with `Major`, in order to make the English→Russian dataset conform to the rest of the data;
5. We discard all the MQM error categories, leaving only information about error severity. While we believe error categorization to

[2] In a few cases, the source sentence might also be annotated. An example of this is with omission errors, where annotators report the spans of the source sentence which are missing from the candidate translation.

[3] This holds only for the MQM guidelines released by Freitag et al. (2021a).

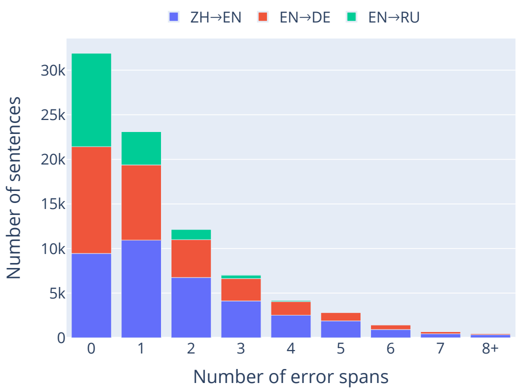

Figure 2: Distribution of the number of error spans over sentences in both training and test data of WMT 2021 Metrics Shared Task, after the pre-processing we described in Section 2.1.

be of great importance, we decided to remove it because of the limited availability of training data and to avoid making the classification problem too sparse.

Furthermore, in the MQM data released by Freitag et al. (2021a), every sentence has been annotated 3 times, each one by a different rater. In order to yield a single sample per sentence and maximize the number of annotations, we merge the annotations of the different raters into a single annotated sentence;[4] in the case when there is even only a partial overlap between two annotated spans, we discard the one associated with the `Minor` error in favor of the `Major`, or pick one or the other randomly if they have the same severity. We decided to keep `Majors` over `Minors` because Freitag et al. (2021a) obtained almost the same ranking of MT systems when considering only `Major` errors, compared to the full MQM score.

2.2 Hypothesis and Target Span Hit metrics

Typically, MT evaluation metrics' quality is assessed through their correlations with human judgements. Nevertheless, our novel formulation of MT evaluation as a sequence tagging problem allows us to estimate the quality of our metrics also via the produced error spans. Specifically, we are interested in determining how well our metrics are able to flag, even partially, a true error span, regardless of its severity or length. However, existing span-level metrics, such as Span Precision, Span Recall and Span F1, focus on exact overlaps between predicted spans and target ones. Moreover, correlations with MQM scores paint only a partial picture, since the final score assigned to a translation depends only on the number of error spans (with their severity), but not on their position in the sentence. For instance, if a system flagged a span as a `Major` error, but the target annotation had a different span tagged as `Major`, the MQM scores would be identical despite the tagging error.

In the square team, this song is the motto of every team member

Figure 3: An example of evaluation with the Hypothesis and Target Span Hit metrics. The **turquoise line —** (below) and **amber line —** (above) represent the hypothesis and target annotation, respectively. HSH $= 2/3$ (2 out of 3 spans are *hit*), TSH $= 2/2$ (2 out of 2 spans are *hit*).

To address these issues, we introduce the Hypothesis Span Hit (HSH) and Target Span Hit (TSH) metrics: HSH represents the percentage of predicted error spans that are also, at least partially, true; instead, TSH represents the percentage of true error spans that the metric has predicted, even partially. An example of their assessments is given in Figure 3.

Formal definition Let us consider a candidate translation $\boldsymbol{c}$ as a sequence of tokens $(c_1, c_2, \dots, c_n)$; moreover, let us define an error span s as a set of contiguous tokens in $\boldsymbol{c}$, e.g., $\{c_1, c_2, c_3\}$, and an error annotation A as a set of disjoint error spans, i.e., that satisfies $\bigcap_{s' \in A} s' = \emptyset$. Furthermore, we define the Span Hit Indicator as

$$\mathrm{SHI}(s, A) = \mathbb{I}(s \cap \sigma(A) \neq \emptyset)$$

where $\sigma(A) = \bigcup_{s' \in A} s'$, i.e., the set of all tokens in annotation A. In simpler terms, $\mathrm{SHI}(s, A)$ is 1 if at least one of the tokens in s belongs to the set of all tokens of the error spans in A.

Finally, let us take two error annotations: A_h represents the hypothesis spans produced by a model, while A_t represents the target spans that $\boldsymbol{c}$ was originally annotated with. We define the Hypothesis Span Hit and Target Span Hit metrics as follows:

$$\mathrm{HSH}(A_h, A_t) = \frac{\sum_{s_h \in A_h} \mathrm{SHI}(s_h, A_t)}{|A_h|}$$

$$\mathrm{TSH}(A_t, A_h) = \frac{\sum_{s_t \in A_t} \mathrm{SHI}(s_t, A_h)}{|A_t|}$$

[4] Therefore, in our merged sentences the number of error spans per translation can be greater than 5. Figure 2 reports the distribution of error spans in our entire data.

Both metrics are defined as the average number of span hits of one error annotation with respect to the other. To compute the metrics for an entire dataset we employ micro-averaging, i.e., we concatenate all hypotheses into a single one, do the same for the targets, and then measure Span Hit metrics on the newly-created pair of hypothesis and target. We avoid averaging the single results because the number of spans varies widely across samples (Figure 2).

3 Experimental Setup

In this Section, we describe the different architectures we experiment with, the data for training and evaluation, and the metrics we use to measure performances.

3.1 Architectures

Since it is rather convenient to have a single model capable of evaluating text in multiple languages, we leverage multilingual pre-trained models like XLM-RoBERTa (Conneau et al., 2020) and mBART (Liu et al., 2020). In order to compare the performances of multilingual models with their English-only counterparts, we also experiment with RoBERTa (Liu et al., 2019).[5]

Encoder-only models XLM-RoBERTa and RoBERTa models consist of only the encoder part of the standard Transformer architecture (Vaswani et al., 2017). The input we provide to the encoder models is the concatenation of the candidate translation and its reference (or source, for MATESE-QE), separated by a </s> token. Furthermore, we add two randomly-initialized encoder layers on top of the last layer, as well as a classification head. Due to computational constraints, we keep the embedding layer frozen.

Encoder-decoder model When experimenting with mBART, we feed the reference translation (or the source, for MATESE-QE) to the encoder, and the candidate to the decoder, so as to maintain similarity with the pre-training process. We highlight that we do not use the decoder autoregressively; instead, following the standard practice for sequence classification with encoder-decoder models, we force the candidate to be processed all at once, and collect the contextualized embeddings at the last layer. On top of the decoder, we add two randomly-initialized encoder layers, and a classification head. As with the encoder-only models, due to computational constraints the embedding layer is frozen.

3.2 Training and validation data

In order to perform our experiments employing all the existing MQM data, we experiment using a 90/10 training/validation split of the concatenation of the training set (which is the MQM data released by Freitag et al. (2021a)) and the test sets of WMT 2021 Metrics Shared Task (Freitag et al., 2021b).

Moreover, to make a fair comparison between the MATESE metrics and the ones submitted to the aforementioned Shared Task, we also retrain our systems using only the above-mentioned training set, with the same split. We dub these systems MATESE^{21} and MATESE-QE^{21}.

In both settings, we use only English→German and Chinese→English data. Moreover, we point out that the split is performed on *unique source sentences*: since each source sentence is translated by multiple systems, our split avoids having translations of the same source sentence be present in both the training and validation splits.

WMT Submission Training Split For our final submission to the WMT 2022 Metrics Shared Task, we include English→Russian data to the concatenation of the training and test sets of the WMT 2021 Metrics Shared Task. We split the whole data 5 times, each time taking 90% for training and 10% for validation, and train 5 different systems (10 if we also consider MATESE-QE). In our submission, each score is the median prediction of the systems trained on the 5 different data splits.

3.3 Evaluation metrics

The MATESE metrics tag the spans of a candidate translation that contain an error. Following the BIO scheme (Ramshaw and Marcus, 1995), we assign to each token a label in $L = \{$`O`, `B-Minor`, `I-Minor`, `B-Major`, `I-Major`$\}$; a final score for the annotated sentence is then obtained as the sum of the individual spans' scores. We can evaluate the performances of our metrics according to the final scores, as well as in terms of the produced annotations: indeed, we use the scalar scores to rank translations and measure the correlations with human judgements, and we measure the tagging accuracy with respect to the gold annotations. In the latter

[5] RoBERTa can be employed only for reference-based evaluation, and with language pairs that have English as target language: in our case, this is only Chinese→English.

XLM-R$^{\text{LARGE}}$	47.38	**38.40**	**41.72**	57.73	**46.08**
XLM-R$^{\text{BASE}}$	46.64	34.12	37.93	**58.01**	38.70
mBART	**47.97**	31.94	36.01	55.85	32.66

Table 2: Comparison of different architectures in terms of Precision, Recall and F1-score in their macro versions; HSH and TSH are Hypothesis Span Hit and Target Span Hit metrics.

case, we rely on the standard classification metrics of Precision, Recall and F1-score, computed using TorchMetrics[6] modules. More specifically, given that our data is highly imbalanced (see Table 1), we employ macro versions of these metrics and, in particular, use the macro-F1 score to select the best checkpoint of the models on the validation set. Furthermore, in order to assess the span-level error detection capabilities of our systems, we employ the Hypothesis and Target Span Hit metrics as defined in Section 2.2.

4 Results

In this Section, we show the results obtained by our metrics. Unless explicitly specified, all experiments have been performed using reference-based systems.

4.1 Architectures comparison

We can see the results of comparing the aforementioned architectures in Table 2. The best performing architecture is XLM-R$^{\text{LARGE}}$, which attains the highest F1-score, as a consequence of achieving the best Recall. Considering the complexity of the task, and the imbalance of the data, we conjecture that the other architectures obtain high Precision and low Recall scores because they are able to predict only the errors that are easier to detect, while assigning `O`s more frequently. This is also confirmed by the TSH score which, ruling `O` labels out of the computation, exacerbates the difference between different architectures, with XLM-R$^{\text{BASE}}$ and mBART clearly failing to detect a higher number of errors of the target annotation compared to XLM-R$^{\text{LARGE}}$. An additional interesting fact that emerges from this comparison is that XLM-R architectures perform better than mBART, with XLM-R$^{\text{BASE}}$ outperforming it despite having less than half of its parameters.

4.2 Monolingual-multilingual comparison

Table 3 reports the results of training the same XLM-R model using a single language pair at a time, or both. Moreover, we test whether an English language model like RoBERTa outperforms XLM-R, when dealing with English-only data. Our results show that training on the whole data is beneficial to the task, with XLM-R$^{\text{ALL}}$ obtaining a higher Recall and Target Span Hit in both language pairs, and an F1-score that is higher, or on par with, its variants. Similarly to what happens with different architectures, we hypothesize that training on more data enables the models to detect a wider range of errors, even if the additional data is in a different language. We do not record significant differences in the results obtained by RoBERTa, compared to XLM-R$^{\text{MONO}}$ on Chinese→English data.

4.3 MaTESe-QE

A desirable feature of evaluation metrics is to function both in the presence and the absence of humanly-curated references. To achieve this, we investigate whether it is feasible to tag the errors in the candidate translation by looking at the source sentence only. Table 4 reports the results obtained by the best architecture, i.e., XLM-R$^{\text{LARGE}}$, trained on both English→German and Chinese→English, both when disposing of the reference sentence, and not.

MaTESe outperforms MaTESe-QE in terms of Recall, F1-score and Target Span Hit metrics. Clearly, the information found in the reference is easier to exploit, and the reference-based system is able to detect a much wider range of errors. At the same time, MaTESe-QE proves to be a viable alternative in the absence of manually-curated references: it displays high levels of Precision and Hypothesis Span Hit, which means that it outputs predictions that are more accurate than those of MaTESe, even if only for the range of errors that it is able to detect.

XLM-R$^{\text{MONO}}$	**43.98**	30.64	33.52	**56.56**	39.67	50.85	38.51	**42.77**	63.51	44.38
RoBERTa	–	–	–	–	–	**51.49**	37.91	42.41	**64.33**	42.81

Table 3: Model performances on monolingual and multilingual settings. XLM-R$^{\text{ALL}}$ is trained and evaluated on the concatenation of English→German (EN→DE) and Chinese→English (ZH→EN) datasets, while XLM-R$^{\text{MONO}}$ stands for two different models, each one trained and evaluated on a single dataset. RoBERTa is an English language model, and therefore can deal with ZH→EN data only.

	P	R	F1	HSH	TSH
MaTESe	47.38	**38.40**	**41.72**	57.73	**46.08**
MaTESe-QE	**49.34**	34.53	38.89	**59.89**	36.84

Table 4: Comparison of our reference-based and reference-free systems, i.e., MaTESe and MaTESe-QE, respectively. The only difference between the two is that MaTESe-QE uses the source sentence in place of the reference.

4.4 Correlations with Human Judgements

Tables 5a and 5b report the correlations with human judgements that our metrics attained on `newstest2021` (in-domain) and `TED` (out-of-domain) test sets of last year's WMT Metrics Shared Task: `w/ HT` means that manually-curated references have been scored together with system outputs, while `w/o HT` means that those references have been kept out of the evaluation. Aside from our systems, i.e., MaTESe^{21} and MaTESe-QE^{21}, we also report two additional baselines: #1 WMT and #2 WMT. These are the top-1 and top-2 results reported by Freitag et al. (2021b) in the corresponding tables (Tables 23, 24, 27 and 28). Since those positions are held by different systems, we assign each submission a unique symbol and report the mapping in Appendix A.

Generally speaking, for in-domain settings, we observe that, on English→German, MaTESe^{21} and MaTESe-QE^{21} achieve correlations on par or better than the top-2 WMT 2021 submissions, while on Chinese→English the results are slightly worse. Interestingly, in out-of-domain settings, we observe a sizeable drop in correlation on both translation directions. We attribute this drop to the very limited amount of training data, which probably hinders proper generalization capabilities to out-of-domain settings. Finally, we observe that MaTESe-QE^{21} lags behind MaTESe^{21} by a relatively small margin.

(b) Segment-level Kendall correlations.

Table 5: System- and segment-level correlations with human judgements as measured in WMT 2021 Metrics Shared Task (Freitag et al., 2021b). MaTESe^{21} and MaTESe-QE^{21} are MaTESe metrics that have been re-trained using only the training set of the Shared Task. A legend of the other symbols is found in Appendix A.

5 Conclusions

In this paper, we described our submission to the WMT 2022 Metrics Shared Task: we presented the MaTESe metrics, a new way of automatically assessing the quality of translations, putting forward evaluation techniques that are interpretable, while at the same time displaying high levels of correlation with human judgements. Scores are in the same ballpark of the best performing metrics proposed in the WMT 2021 Metrics Shared Task. Furthermore, the MaTESe metrics can also be used in the absence of humanly-curated references, with MaTESe-QE being slightly less accurate than its reference-based counterpart, but still presenting encouraging levels of correlation with human judgements. In future work, we plan to improve the MaTESe metrics to also detect the type of errors, and not only their severity, in order to approximate even better the MQM annotation process.

Limitations

Poor generalization We expect the MaTESe metrics' generalization capabilities to be hindered by the narrow range of errors that they are trained upon. Indeed, while the number of samples in the datasets is relatively large (around 80K annotated sentences), the number of unique sources is much smaller (around 6K), because the annotations are performed on the same source sentences translated by multiple MT systems. In fact, we observe a drop in performance in the out-of-domain setting, i.e., the TED dataset.

Computational requirements The MaTESe metrics require a non-negligible computational budget, especially when compared to their untrained alternatives, such as BLEU, METEOR or chrF. Given that the task we tackle is arguably challenging, and that we need semantically-rich representations of the analyzed sentences, we decided to rely upon a large Transformer encoder, which makes the evaluation computationally intensive. Unfortunately, the comparison between XLM-RoBERTa Large and its Base counterpart shows that a sizeable improvement is due to the increased size of the model.

Abstract

In this paper, we present the joint contribution of Unbabel and IST to the WMT 2022 Metrics Shared Task. Our primary submission – dubbed COMET-22 – is an ensemble between a COMET estimator model trained with Direct Assessments and a newly proposed multitask model trained to predict sentence-level scores along with OK/BAD word-level tags derived from Multidimensional Quality Metrics error annotations. These models are ensembled together using a hyper-parameter search that weights different features extracted from both evaluation models and combines them into a single score. For the reference-free evaluation we present COMETKIWI. Similarly to our primary submission, COMETKIWI is an ensemble between two models. A traditional predictor-estimator model inspired by OPENKIWI and our new multitask model trained on Multidimensional Quality Metrics which can also be used without references. Both our submissions show improved correlations compared to state-of-the-art metrics from last year as well as increased robustness to critical errors.

1 Introduction

Automatic metrics for Machine Translation (MT) are a fundamental component of MT research and development. While human evaluation is still of great importance, automatic metrics allow the rapid evaluation and comparison of MT systems on large collections of text and facilitate expansion to low resource languages and domains. Neural fine-tuned metrics in particular, have shown the ability to leverage large multilingual data during training to better compare and assess the quality of state-of-the-art MT models, outperforming traditional lexical-based metrics. Hence, our research is targeted to and guided by the advancements in these metrics.

This paper presents the joint contribution of Unbabel and Instituto Superior Técnico (IST) to the WMT 2022 Metrics Shared Task (Freitag et al., 2022). We participated in the segment-level and system-level tracks, as well as the "QE-as-a-Metric". Similar to our participation last year (Rei et al., 2021), our models are based on the COMET framework[1] (Rei et al., 2020a).

Our efforts this year built on findings and observations from our participation in the WMT 2021 Metrics Shared Task (Rei et al., 2021; Freitag et al., 2021b) to further improve COMET for the Metrics task and to increase its robustness to translation errors such as deviation from named entities, reverse polarity and negation, deviation in numbers, etc. These types of fine-grained critical errors have been shown to be challenging for state-of-the-art metrics and QE systems (Amrhein and Sennrich, 2022; Kanojia et al., 2021). For that reason we aim to take advantage of finer-grained information, incorporating word-level supervision from Multidimensional Quality Metrics (MQM) annotations when available. This approach is motivated by the observed improvements in performance in WMT 2021 Metrics when fine-tuning on MQM data. Additionally, the importance of word-level supervision as an auxiliary task was established via our participation in the WMT 2022 Quality Estimation task (Zerva et al., 2022), where we found that we get a boost of performance across language pairs when we combine word- and sentence-level targets (Rei et al., 2022).

Overall, our main contributions are:

- We propose a new model architecture that is trained with a multitask objective to predict a sentence-level score along with word-level tags. This architecture is well suited for MQM data which comes in the form of sentence-level scores

alongside the annotation spans. Also, similarly to UNITE (Wan et al., 2022) we can use this architecture with and without access to a reference translation.

- We show that ensembling scores from different models, trained with different annotations (e.g DA and MQM) can lead to improved correlations and more robust metrics.
- We corroborate our findings from last year (Rei et al., 2021) showing that reference-free evaluation is becoming competitive with reference-based evaluation.

Our submitted metrics, compared to two of the best submissions from last year, improve by a considerable margin in terms of correlations with MQM (≈ 4% in Kendall-Tau at segment level and ≈ 6% on system-level accuracy) and in the ability of detecting critical errors (≈ 30% in accuracy on `SMAUG` challenge set (Alves et al., 2022), a newly proposed challenge set built to test the robustness of MT metrics to errors in named entities, numbers, meaning, inserted content and missing content.).

2 Corpora

Every year, since 2017, the organisers of WMT News translation tasks collect annotations in the form of Direct Assessments (DA) (Graham et al., 2013). Recently, Freitag et al. (2021a) showed that DA annotations, collected by non-professional crowd-source workers, are noisy and unfit to measure the quality of high performing MT systems. For high quality MT evaluation the authors suggest the use of MQM annotations performed by professionals; they released annotations for English→German and Chinese→English on the WMT 2020 translation outputs. Since then, along with the DA annotations coming from the News translation task, the metrics task organizers collect additional MQM data for English→German (`en-de`), Chinese→English (`zh-en`), and English→Russian (`en-ru`) to evaluate metrics against a more reliable ground-truth.

With that said, to test the performance of our new systems we will use the MQM annotations from 2021 News domain. For training we will use all DA ranging from 2017 to 2020 and the remaining MQM annotations.

One of the findings from last years shared task is that metrics struggle to accurately penalize translations with errors in reversing negation (Freitag et al., 2021b). Also, Amrhein and Sennrich (2022) showed that using COMET as a utility function for Minimum Bayes Risk decoding is more likely to lead to errors in named entities and numbers when compared to lexical metrics such as CHRF. In order to measure progress on capturing those errors we will test our new metrics on `SMAUG` (Alves et al., 2022).

3 Implemented Systems

Our goal this year is to build more robust **C**ross-lingual **O**ptimized **M**etrics for **E**valuation of **T**ranslations by ensembling systems that model different aspects of MT evaluation. For that purpose we used three different systems: a COMET Estimator (Rei et al., 2020a) trained on DA, a newly proposed Sequence Tagger, trained with MQM data, that works with and without references, and a COMETKIWI (Rei et al., 2022) model trained on DA.

3.1 COMET Estimator

For a more comprehensive description of the Estimator architecture we direct the reader to the original paper (Rei et al., 2020a). Compared to our COMET-DA model from last year (Rei et al., 2021) we only changed hyper-parameters in order to maximize Kendall-Tau correlations with the MQM annotations from 2021 News domain.

3.2 QE Predictor-Estimator Model

For a more comprehensive description of the implemented Predictor-Estimator architecture we direct the reader to our QE system description paper (Rei et al., 2022). In summary, for this year QE shared task we combine the strengths of COMET and OPENKIWI, leading to models that adopt COMET training features, useful for multilingual generalization, along with the predictor-estimator architecture of OPENKIWI.

3.3 Extending COMET for Sequence Tagging:

Following our experiments for the Quality Estimation shared task we implemented a multitask COMET model that is trained to perform sequence tagging along with sentence-level regression.

Inspired by UNITE (Wan et al., 2022), our model receives three inputs:

1. Source-only (src): machine translated sentence concatenated with its source sentence.

Table 1: Segment-level Spearman R (ρ) and Kendall-Tau (τ) correlations for zh-en, en-de and en-ru 2021 MQM annotations for the News Domain.

2. Reference-only (ref): machine translated sentence concatenated with its reference.

3. Unified input (uni): machine translated sentence concatenated with both source and reference.

These inputs can be seen as a sequence with two parts: 1) the machine translated sentence $\boldsymbol{t} = \langle t_1, ..., t_n \rangle$ and 2) additional support information such as source and/or reference $\hat{\boldsymbol{r}} = \langle r_1, ..., r_m \rangle$.

Given that, for each input, our model works exactly like COMETKIWI. We run three forward passes and we store the corresponding sentence-level scores $\hat{y}_{\text{src}}$, $\hat{y}_{\text{ref}}$ and $\hat{y}_{\text{uni}}$. Additionally, we average the obtained word-level logits to derive a single sequence S of $\{\text{OK}, \text{BAD}\}$ tags from which we compute an additional sentence score by using a similar formula to MQM:

$$\hat{y}_{\text{tags}} = 1 - \frac{w \times \sum_{i}^{N_S} \mathbb{1}[S_i = \text{BAD}]}{N_S} \qquad (1)$$

where w is a severity penalty for BAD tags which we set to 1.

In sum, after running our new model we obtain 4 different scores: $\hat{y}_{\text{tags}}$, $\hat{y}_{\text{src}}$, $\hat{y}_{\text{ref}}$, $\hat{y}_{\text{uni}}$ which we can combine into a single quality score. Also, since this model is trained with a reference-less input it can be used, during inference, as a QE system. In those cases we run a single forward pass with the reference-less input and instead of 4 quality score we only get 2 ($\hat{y}_{\text{tags}}$ and $\hat{y}_{\text{src}}$).

Training Data. Since the MQM training data is not abundant and only covers 3 language pairs we start by training the above model without word-level information for 2 full epochs on DA ranging the shared task data from 2017 to 2020. Then, we fine-tune the model using the multitask setting described above with the available MQM training data for zh-en, en-de and en-ru.

3.4 Primary Submission

Our primary submission is an ensemble between a COMET Estimator model trained on top of XLM-R using DA from 2017 to 2020 and a sequence tagging model, such as the one described above, trained on top of InfoXLM (Chi et al., 2021). The final score is computed by a weighted average of the model outputs (5 scores), where the weights for each language pair were tuned with Optuna (Akiba et al., 2019)[2].

3.5 QE-as-a-metric Submission

Our primary submission is an ensemble between a COMETKIWI model trained on top of RemBERT (Chung et al., 2021) and the same sequence tagger from the primary submission but using a reference-less input during inference. The final score is computed by a weighted average in the

[2] We tuned weights specifically for the 3 MQM language pairs. For all other language pairs the weights were tuned by concatenating the MQM annotations for all three language pairs

same way as for our primary submission but using only the obtained 3 reference-less scores.

4 Experimental Results

As we have seen in Section 2, for our experiments we use WMT 2021 News MQM annotations from last year shared task (Freitag et al., 2021b) for testing our metrics. As for baselines we used lexical metrics such as CHRF (Popović, 2015) and BLEU (Papineni et al., 2002) and three state-of-the-art metrics: BLEURT (Sellam et al., 2020; Pu et al., 2021), COMET-20 (Rei et al., 2020b) and COMET-21 (Rei et al., 2021)[3].

4.1 Segment-level

Segment-level correlations for 2021 MQM annotations on the News domain are shown in Table 1. We used both Spearman R (ρ) and Kendall-Tau (τ) correlation metrics to evaluate our models.

From this table we can observe that some individual scores from the MQM Sequence Tagger already outperform state-of-the-art metrics such as BLEURT and (COMET-20/21). Also, our newly trained DA Estimator is able to outperform BLEURT achieving results close to COMET-21 without ever seeing MQM data. Finally, when ensembled together, we are able to improve correlations by $\approx 1\%$ for both reference-based and reference-free metrics.

4.2 System-level

System-level results for 2021 MQM annotations for the News domain are shown in Table 2. To evaluate how our metrics perform we used the pairwise accuracy proposed in (Kocmi et al., 2021), which simulates a real world scenario where we are interested in comparing two systems and deciding which one is better.

Similarly to segment-level results, from Table 2, we can observe that the accuracy of individual scores from the MQM Sequence Tagger outperform, on average, strong baselines such as BLEURT and COMET-20/21. Nonetheless, when ensembled together, these scores do not improve the overall accuracy which seems to be obtained by using the MQM Sequence Tagger with references only. Another interesting finding is that our QE submission (COMET-KIWI) achieves higher accuracy than our primary submission COMET-22. Also, depending on the language pair the best accuracy is either achieved by $\hat{y}_{\text{src}}$ or $\hat{y}_{\text{ref}}$ but not by $\hat{y}_{\text{uni}}$. This seems to indicate that the unified score is not learning to take the best out of the source and reference and that there might be a best way to combine these two signals.

4.3 Robustness to Critical Errors

The `SMAUG` challenge set was built to specifically test the robustness of metrics in capturing 5 different phenomena: deviation in Named Entities (NE), deviation in Numbers (NUM), deviation in meaning (MEAN), insertion of content (INS) and removal of content (DEL). The goal of this challenge set is to check if metrics correctly penalize an incorrect translation that was created by perturbing a reference. To do so, the perturbed translation (t) is scored using source (s) and reference (r) against an alternative reference ($\hat{r}$). The goal of a metric f is to score $\hat{r}$ above t ($f(s, \hat{r}, r) > f(s, t, r)$). To measure f's performance we will look at the accuracy over the entire challenge set for each phenomena:

$$Acc^P = \frac{\sum_i^{N_P} \mathbb{1}[f(s, \hat{r}, r) > f(s, t, r)]}{N_P} \qquad (2)$$

where P denotes a phenomena and N_P the number of examples for that specific phenomena.

[3] For all neural fine-tuned metrics we used the checkpoints that were used as primary submissions for the WMT20 and WMT21 Metric tasks, more precisely, `BLEURT20`, `wmt20-comet-da` and `wmt21-comet-mqm`

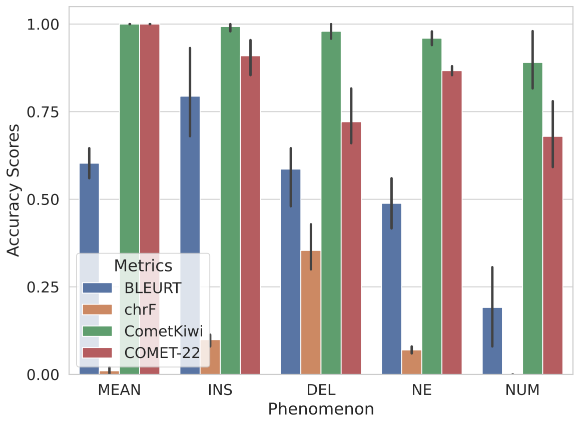

Figure 1: Accuracy Scores on the SMAUG Challenge Set for the baseline and submitted metrics.

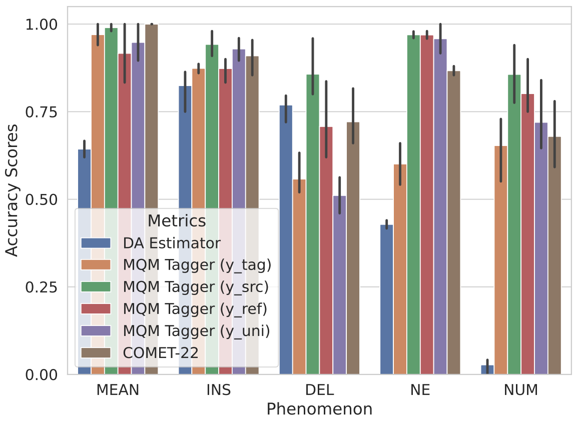

Figure 2: Accuracy Scores on the SMAUG Challenge Set for Primary Submission and respective individual scores.

Figure 1 presents the accuracy of our submissions against a lexical baseline (CHRF) and a learnt baseline (BLEURT) [4]. From these figure we can observe that our reference-free submission seems to be more robust than our primary submission which indicates that, when the reference is present, models look at lexical overlap and can be oblivious to critical errors that were derived from small perturbations. Also, we can observe that our submissions achieve a perfect accuracy on detecting deviations in meaning (which tests phenomena such as negation), above 0.65 accuracy in detecting wrong numbers and above 0.86 accuracy in detecting incorrect named entities. All of which were not correctly detected by previous state-of-the-art metrics such as BLEURT and COMET-20/21.

We also compare the performance of each ensemble with the individual models that compose it. In Figure 2, we observe that the DA Estimator has the worst overall performance. Also, the MQM Sequence Tagger $\hat{y}_{\text{src}}$ achieves the highest scores over all individual models, further suggesting that reference-free evaluation is more robust to these errors. Our final submission, while not reaching the highest accuracy for all phenomena, obtains good results in all cases. Regarding our QE-as-a-metric submission, Figure 3 shows that both the ensemble and individual systems achieve very high scores. Our submission outperforms the MQM Taggers and obtains a performance similar to the DA Predictor-Estimator.

5 Related work

For years, **classic n-gram matching** MT evaluation metrics such as BLEU (Papineni et al., 2002) have been adopted by the MT community as a primary form of MT evaluation yet, recently, these classic metrics have been outperformed by metrics based on large pretrained models such as BERT (Bojar et al., 2017; Ma et al., 2018, 2019; Mathur et al., 2020).

Metrics based on large pretrained models can be divided into two categories: 1) **Embedding-distance metrics** and, 2) **Fine-tuned metrics**. **Embedding-distance metrics** replaced the typical word/n-gram matching by fuzzy matches based on dense representations. Examples of such metrics are BERTSCORE (Zhang et al., 2020) and YISI-1 (Lo, 2019), which has been a top performing metric since WMT 2019 Metrics task (Ma et al., 2019). Note that these metrics used the embedding models without any further fine-tuning relying only on their ability to capture semantic similarity. On the other hand, **fine-tuned metrics** such as RUSE (Shimanaka et al., 2018), BLEURT (Sellam et al., 2020) and COMET (Rei et al., 2020a) modify the underlying embedding models in order to learn how to produce quality scores such as DA and/or MQM, and thus to achieve higher correlations with human judgements of MT quality.

Recently, the evaluation of metrics has been extended to consider not only correlations with human judgements but also sensitivity to specific errors in translations. Namely, several works focused on translations with critical errors, which Specia et al. (2021) defines as translations that deviate in

[4] Performance of COMET-20 and 21 is similar to the performance shown by BLEURT while BLEU accuracy is close to 0.

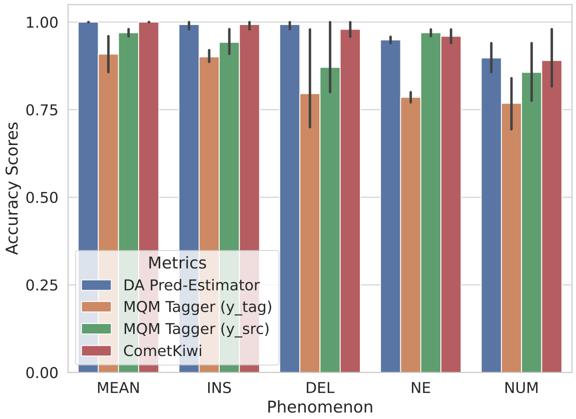

Figure 3: Accuracy Scores on the SMAUG Challenge Set for QE-as-a-metric Submission and respective individual scores.

meaning from their source in such way that they are misleading and can carry health, safety, legal, reputation, religious or financial implications. Amrhein and Sennrich (2022) show that COMET is less sensitive to errors in named entities and numbers than CHRF; Freitag et al. (2021b) found that several metrics struggle with negation and sentiment polarity errors; and Kanojia et al. (2021) showed that several reference-free metrics fail to detect errors related to omitting negation markers.

6 Conclusions

We present the joint contribution of Unbabel and IST to the WMT 2022 Metrics shared task. We propose a new architecture trained in a multitask setting which takes advantage of sentence-level scores along with supervision from MQM annotation spans. Inspired by UNITE, our new model can be used with and without references showing promising results when references are not available.

Our primary submission ensembles our new model along with the COMET Estimator architecture showing both higher correlations and improved robustness to phenomena that was deemed challenging in previous shared task editions.

Finally, our "QE-as-a-metric" submission yet again has shown that reference-free is competitive to reference-based evaluation not only at segment-level but also at system-level and in terms of detecting critical errors.

Abstract

In this report, we present our submission to the WMT 2022 Metrics Shared Task. We build our system based on the core idea of **UNITE** (**Uni**fied **T**ranslation **E**valuation), which unifies source-only, reference-only, and source-reference-combined evaluation scenarios into one single model. Specifically, during the model pre-training phase, we first apply the pseudo-labeled data examples to continuously pre-train UNITE. Notably, to reduce the gap between pre-training and fine-tuning, we use data cropping and a ranking-based score normalization strategy. During the fine-tuning phase, we use both Direct Assessment (DA) and Multidimensional Quality Metrics (MQM) data from past years' WMT competitions. Specially, we collect the results from models with different pre-trained language model backbones, and use different ensembling strategies for involved translation directions.

1 Introduction

Translation metric aims at delivering accurate and convincing predictions to identify the translation quality of outputs with access to one or many gold-standard reference translations (Ma et al., 2018, 2019; Mathur et al., 2020; Freitag et al., 2021b). As the development of neural machine translation research (Vaswani et al., 2017; Wei et al., 2022), the metric methods should be capable of evaluating the high-quality translations at the level of semantics rather than surfance-level features (Sellam et al., 2020; Ranasinghe et al., 2020; Rei et al., 2020; Wan et al., 2022a). In this paper, we describe Alibaba Translate China's submissions to the WMT 2022 Metrics Shared Task to deliver a more adequate evaluation solution at the level of semantics.

Pre-trained language models (PLMs) like BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) have shown promising results in identifying the quality of translation outputs. Compared to conventional statistical- (*e.g.*, BLEU, Papineni et al., 2002 and representation-based methods (*e.g.*, BERTSCORE, Zhang et al., 2020), the model-based approaches (*e.g.*, BLEURT, Sellam et al., 2020; COMET, Rei et al., 2020; UNITE, Wan et al., 2022a) show their strong ability on delivering more accurate quality predictions, especially those approaches which apply source sentences as additional input for the metric model (Rei et al., 2020; Takahashi et al., 2020; Wan et al., 2021, 2022a). Specifically, those metric models are designed as a combination of PLM and feedforward network, where the former is in charge of deriving representations on input sequence, and the latter predicts the translation quality based on the representation. The metric model, which is trained on synthetic or human annotations following a regressive objective, learns to mimic human predictions to identify the translation quality of the hypothesis sentence.

Although those model-based metrics have shown promising results in modern applications and translation quality estimation, they still show their own shortcomings as follows. First, they often handle one specific evaluation scenario, *e.g.*, COMET serves source-reference-only evaluation, where the source and reference sentence should be concurrently fed to the model for prediction. For the other evaluation scenarios, they hardly give accurate predictions, showing the straits of metric models due to the disagreement between training and inference. Besides, recent studies have investigated the feasibility of unifying those evaluation scenarios into one single model, which can further improve the evaluation correlation with human ratings in any scenario among source-only, reference-only, and source-reference-combined evaluation (Wan et al., 2021, 2022a). This indicates that, training with multiple input formats than a specific one can deliver more appropriate predictions for translation

[*] Equal contribution. Work was done when Yu Wan and Keqin Bao were interning at DAMO Academy, Alibaba Group.

quality identification. More importantly, unifying all translation evaluation functionalities into one single model can serve as a more convenient toolkit in real-world applications.

Following the idea of Wan et al. (2022a) and the experience in previous competition (Wan et al., 2021), we directly use the pipeline of UniTE (Wan et al., 2022a) to build models for this year's metric task. Each of our models can integrate the functionalities of source-only, reference-only, and source-reference-combined translation evaluation into itself. When collecting the system outputs for the WMT 2022 Metrics Shared Task, we employ our UniTE models to predict the translation quality scores following the source-reference-combined setting. Compared to the previous version of UniTE (Wan et al., 2022a), we reform the synthetic training set for the continuous pre-training phase, raising the ratio of training examples consisting of high-quality hypothesis sentences. Also, during fine-tuning our metric model, we apply available Direct Assessment (DA, Bojar et al., 2017; Ma et al., 2018, 2019; Mathur et al., 2020) and Multidimensional Quality Metrics datasets (MQM, Freitag et al., 2021a,b) from previous WMT competitions to further improve the performance of our model. Specifically, for each translation direction among English to German (En-De), English to Russian (En-Ru), and Chinese to English (Zh-En) directions, we applied different ensembling strategies to achieve a better correlation with human ratings on MQM 2021 dataset. Results on WMT 2021 MQM dataset further demonstrate the effectiveness of our method.

2 Method

As outlined in §1, we apply the UniTE framework (Wan et al., 2022a) to obtain metric models. We use three types of input formats (*i.e.*, source-only, reference-only, and source-reference-combined) during training. While during inference, we only use the source-reference-combined paradigm to collect evaluation scores. In this section, we introduce the applied model architecture (§2.1), synthetic data construction method (§2.2), and model training strategy (§2.3) for this year's metric competition.

2.1 Model architecture

Input Format Following Wan et al. (2022a), we construct the input sequence for source-only, reference-only, and source-reference-combined input formats as follows:

$$\mathbf{x}_{\text{SRC}} = \texttt{[BOS]}\mathbf{h}\texttt{[DEL]}\mathbf{s}\texttt{[EOS]}, \quad (1)$$

$$\mathbf{x}_{\text{REF}} = \texttt{[BOS]}\mathbf{h}\texttt{[DEL]}\mathbf{r}\texttt{[EOS]}, \quad (2)$$

$$\mathbf{x}_{\text{SRC+REF}} = \texttt{[BOS]}\mathbf{h}\texttt{[DEL]}\mathbf{s}\texttt{[DEL]}\mathbf{r}\texttt{[EOS]}, \quad (3)$$

where [BOS], [DEL] and [EOS] represent the beginning, the delimeter, and the ending of sequence,[1] and $\mathbf{h}$, $\mathbf{s}$, and $\mathbf{r}$ are hypothesis, source, and reference sentence, respectively. During the pre-training phase, we applied all input formats to enhance the performance of UniTE models.

Model Backbone Selection Aside from the reference sentence which is written in the same language as the hypothesis sentence, the source is in another different language. We believe that, cross-lingual semantic alignments can ease the model training on source-only and source-reference-combined scenarios. Referring to the setting of existing methods (Ranasinghe et al., 2020; Rei et al., 2020; Sellam et al., 2020; Wan et al., 2022a), they apply XLM-R (Conneau et al., 2020) as the backbone of evaluation models for better multilingual support. In this competition, we additionally use INFOXLM (Chi et al., 2021), which enhances the XLM-R model with cross-lingual alignments, as the backbone of our UniTE models.

Model Training Following Wan et al. (2022a), we first equally split all examples into three parts, each of which only serves one input format training. As to each training example, after concatenating the required input sentences into one sequence and feeding it to PLM, we collect the corresponding representations – $\mathbf{H}_{\text{REF}}, \mathbf{H}_{\text{SRC}}, \mathbf{H}_{\text{SRC+REF}}$ for each input format, respectively. After that, we use the output embedding assigned with CLS token $\mathbf{h}$ as the sequence representation. Finally, a feedforward network takes $\mathbf{h}$ as input and gives a scalar p as a prediction. Taking $\mathbf{x}_{\text{SRC}}$ as an example:

$$\mathbf{H}_{\text{SRC}} = \texttt{PLM}(\mathbf{x}_{\text{SRC}}) \in \mathbb{R}^{(l_h+l_s)\times d}, \quad (4)$$

$$\mathbf{h}_{\text{SRC}} = \texttt{CLS}(\mathbf{H}_{\text{SRC}}) \in \mathbb{R}^{d}, \quad (5)$$

$$p_{\text{SRC}} = \texttt{FeedForward}(\mathbf{h}_{\text{SRC}}) \in \mathbb{R}^{1}, \quad (6)$$

where l_h and l_s are the lengths of $\mathbf{h}$ and $\mathbf{s}$, respectively.

[1] Those symbols may vary if we use different PLMs, *e.g.*, "[BOS]", "[SEP]", and "[SEP]" for English BERT (Devlin et al., 2019), and "<s>", "</s> </s>", and "</s>" for XLM-R (Conneau et al., 2020).

For learning objectives, we apply the mean squared error (MSE) as the loss function:

$$\mathcal{L}_{\text{SRC}} = (p_{\text{SRC}} - q)^2, \tag{7}$$

where q is the given ground-truth score. Note that, the batch size is the same across all input formats to avoid the training imbalance. During each update, the final learning objective is the sum of losses for all formats:

$$\mathcal{L} = \mathcal{L}_{\text{REF}} + \mathcal{L}_{\text{SRC}} + \mathcal{L}_{\text{SRC+REF}}. \tag{8}$$

2.2 Synthetic Data Construction

To better enhance the translation evaluation ability, we first construct a synthetic dataset for continuous pre-training. The overall stage for obtaining the dataset consists of the following steps: 1) collecting synthetic data from parallel data provided by the WMT Translation task; 2) downgrading the translation quality and keeping the consistency of synthetic and MQM datasets; 3) relabeling them with a ranking-based scoring strategy.

Collecting Synthetic Data Specifically, we first conduct parallel data from this year's WMT Translation competition as the source-reference sentence pairs Then, we obtain hypothesis sentences via translating the source using online translation engines, *e.g.*, `Google Translate`[2] and `Alibaba Translate`[3].

Quality Downgrading We follow existing works (Sellam et al., 2020; Wan et al., 2022a) to apply the word/span dropping strategy to downgrade the quality of hypothesis sentences, thus increasing the ratio of training examples consisting of bad translation outputs. Specially, we notice that the translation quality of hypothesis sentences in the MQM dataset is rather higher than that in the DA dataset. In practice, to reduce the translation quality distribution gap between the synthetic and MQM datasets, we randomly select 15% examples of the entire dataset, which is lower than the applied ratio (*i.e.*, 30%) in BLEURT (Sellam et al., 2020) and UNITE (Wan et al., 2022a).

Data Labeling After downgrading the translation quality of synthetic hypothesis sentences, we then collect predicted scores for each triple as the learning supervision. To increase the confidence of pseudo-labeled scores, we use multiple UNITE checkpoints trained with different random seeds to label the synthetic data. Besides, to reduce the gap of predicted scores among different translation directions, we applied the ranking-based scoring strategy as in Wan et al. (2022a).

2.3 Training Pipeline

Pre-train with Synthetic Data First, we use the synthetic dataset to continuously pre-train our UNITE models to enhance the evaluation ability on three input formats.

Fine-tune with DA Dataset After training UNITE models on the synthetic dataset, we apply the DA dataset for the first stage of model fine-tuning. Considering the support of multilingual translation evaluation, we collect all DA datasets from the previous years, and we leave the year 2021 out of training due to the reported bug from the official committee. We think that, although the DA and MQM datasets have different scoring rules, training UNITE models on DA as an additional phase can enhance both the model robustness and the support of multilingualism. Besides, the number of examples in the DA dataset is extremely larger than that in MQM. The training examples from the DA dataset can provide more learning signals for UNITE model training.

Fine-tune with MQM Dataset After fine-tuning UNITE models on the DA dataset, we then apply the MQM dataset for the second stage of model fine-tuning. For this year's competition, we first use MQM 2020 dataset during this stage, and testify the performance of our models on MQM 2021 to tune the hyper-parameters. Then, after identifying the hyper-parameters, we use all MQM datasets to fine-tune, choose two models whose backbones are XLM-R and INFOXLM, and collect the ensembled scores as submissions.

2.4 Model Ensembling

For each training pipeline, we use the three random seeds to train UNITE models. However, when identifying the performance of all models on the MQM 2021 dataset, we find it hard to select the same strategy across all domains and translation directions. In practice, we select the models trained with different random seeds for each translation direction.

3 Experiments

3.1 Experiment Settings

Implementations All of our models are implemented with the released UNITE repository.[4] We choose the large version of XLM-R (Conneau et al., 2020) and INFOXLM (Chi et al., 2021) as the PLM backbones of all UNITE models, and directly use the released checkpoints from Huggingface Transformers (Wolf et al., 2020).[5]

Continuous pre-training Following Wan et al. (2022a), we collect the translation hypotheses from 10 directions, *i.e.*, English-Czech/German/Japanese/Russian/Chinese, as those translation directions are engaged with massive parallel datasets and the performance of corresponding online translation engines is relatively high. For each translation direction, we collect 0.5M hypotheses, and label the translation quality scores as described in §2.2.

Hyper-parameters Following the setting in Wan et al. (2022a), the feedforward network of our UNITE model contains three linear transition layers, whose output dimensionalities are 3,072, 1,024, and 1, respectively. Between any two adjacent layers, the hyperbolic tangent is arranged as the activations. During the continuous pre-training phase, we set the batch size for each input format as 1,024, and tune the hyper-parameters for our models. For the models whose backbone is XLM-R, the learning rates for PLM and feedforward network are $1.0 \cdot 10^{-4}$ for PLM, and $3.0 \cdot 10^{-4}$, respectively. For the models whose backbone is INFOXLM, the learning rates are $5.0 \cdot 10^{-5}$ for PLM, and $1.5 \cdot 10^{-4}$, respectively. For all the fine-tuning steps, we use the batch size as 32 across all settings, and the learning rates for PLM and feedforward network are $5.0 \cdot 10^{-6}$ for PLM, and $1.5 \cdot 10^{-5}$, respectively.

Performance Evaluation Following the previous setting (Ma et al., 2018, 2019; Mathur et al., 2020; Freitag et al., 2021b), we use the variant Kendall's Tau to evaluate the performance of our models on the MQM 2021 dataset. For comparison, we directly use the officially released COMET checkpoints (Rei et al., 2020)[6], and select the checkpoints which are trained with DA or MQM datasets.

Results Conduction When collecting the results for submitting predictions, we ensembled the models by directly averaging the predictions on the same example. We do not apply the idea of uncertainty-aware sampling (Zhou et al., 2020; Wan et al., 2020; Glushkova et al., 2021) during inference, because it takes far more additional time to collect the results.

4 Results and Analysis

Baselines The experimental results are conducted in Table 1. As seen, among all involved baselines, the source-only evaluation models (models marked with "QE") perform worse than their corresponding source-reference-combined ones, dropping 7.2 and 7.4 Kendall's Tau correlation on DA and MQM settings. This verifies that, the reference sentence in model translation quality evaluation offers more information for metric models to help deliver accurate predictions (Rei et al., 2020; Takahashi et al., 2020; Wan et al., 2022a). Besides, the model fine-tuned on the DA dataset performs slightly better than that on MQM. We think that the DA dataset may show its advantage in the robustness of multilingual support and the scale of the training dataset.

UNITE models As to our UNITE models, replacing the XLM-R backbone with INFOXLM PLM for metric models does not deliver consistent improvement on average. Specifically, for both News and TED domains, the UNITE model with INFOXLM as the backbone shows a better correlation on En-De direction, whereas worse on En-Ru and Zh-En than XLM-R. In addition, the COMET-DA-2021 performs best in En-Ru direction, where we think the reason lies in the scarcity of En-Ru training examples in MQM. In practice, during collecting the ensembled outputs, we mainly use the $\text{UNITE}_{\text{INFOXLM}}$ models for En-De, and $\text{UNITE}_{\text{XLM-R}}$ for En-Ru and Zh-En.

5 Conclusion

In this paper, we describe our submission UNITE for the sentence-level Metrics Shared Task at WMT 2022. We apply UNITE (Wan et al., 2022a) as the pipeline of our models. During training, we utilize three input formats to train our models on our synthetic, DA, and MQM data sequentially. Besides,

UNITE$_{\text{XLM-R}}$	27.7	39.0	**16.3**	19.7	**31.2**	**17.3**	**25.3**
UNITE$_{\text{INFOXLM}}$	**40.0**	36.2	13.0	**25.3**	28.7	9.2	24.9

Table 1: Kendall's Tau correlation (%) on MQM 2021 dataset. The best results for each translation direction are bold. Taking XLM-R as backbone shows better result on En-Ru and Zh-En, and INFOXLM on En-De.

we ensemble the two models which consist of two different backbones – XLM-R and INFOXLM. Experiments demonstrate the reliability of our model for identifying the quality of translation outputs, whereas the two models whose backbones XLM-R and INFOXLM show different performance for different translation directions.

For the future work, we think that exploring the feasibility of model-based evaluation metrics for other natural language processing tasks is interesting. We believe that, building reliable evaluation metrics for translation diversity (Lin et al., 2022, 2021), domain-specific translation quality (Yao et al., 2020; Wan et al., 2022b), and natural language generation (Liu et al., 2022; Yang et al., 2021, 2022) is also of vital importance for the natural language processing community.

Besides, we also submit the source-only predictions of our models to this year's WMT Quality Estimation Shared Task, achieving 1st place on multilingual and En-Ru, and 2nd place on En-De and Zh-En sub-tracks. This further demonstrates the effectiveness of our UNITE approach, that unifying all evaluation scenarios into one single model can enhance the model performances on all evaluation tasks. We believe that, the idea of unifying three kinds of translation evaluation functionalities (*i.e.*, source-only, reference-only, and source-reference-combined) into one single model can deliver strong evaluation models on all scenarios. This research topic is worth further exploration in the future.

Acknowledgements

The participants would like to send great thanks to the committee and the organizers of the WMT Metrics Shared Task competition. Besides, the authors would like to thank the reviewers and meta-review for their insightful suggestions.

Abstract

This paper describes submission to the WMT 2022 Quality Estimation shared task (Task 1: sentence-level quality prediction, Zerva et al. (2022)). We follow a simple and intuitive approach: estimating MT quality by automatically back-translating hypotheses into the source language using a multilingual MT system. Using standard MT evaluation metrics, we then compare the resulting backtranslation with the original source. We find that even the best-performing backtranslation-based scores perform substantially worse than supervised QE systems, including the organizers' baseline. However, combining backtranslation-based metrics with off-the-shelf QE scorers improves correlation with human judgments, suggesting that they can indeed complement a supervised QE system.

1 Introduction

Sophisticated approaches to MT quality estimation (QE) based on large pre-trained models and careful training regimen have enabled great progress in recent years. However, when using online MT systems, such QE technology is not yet available to users and backtranslation provides an appealingly simple strategy to estimate translation quality whether by humans or by automated sytems. Lay users often rely on backtranslation to assess MT quality in languages that they do not understand (Somers, 2005; Mehandru et al., 2022). As a result, from a user experience standpoint, using backtranslation for QE is easy to explain. Furthermore, with the increasing popularity of multilingual neural MT systems that can easily translate between multiple language pairs in any direction, backtranslations are very cheap to obtain, since they do not even require training an auxiliary MT system in the reverse translation direction.

However, the effectiveness of backtranslation for estimating the quality of MT remains unclear. In early rule-based and statistical MT systems, Somers (2005) shows that, when using automatic evaluation methods (e.g., BLEU), backtranslation cannot discriminate good MT systems from bad ones, nor between texts that are easy or hard to translate. This led him to conclude that "round trip translation [is] good for nothing". Recently, Moon et al. (2020) revisited the use of backtranslation for QE with neural systems for MT and with embedding-based similarity metrics to enable a more sophisticated comparison of the backtranslation with the source. They obtained strong results on the WMT 2019 QE task, outperforming the YISI-2 metric (Lo, 2019) on system-level evaluations, but exhibited rather low correlations on the segment-level task which is more directly aligned with how humans use BT to gauge MT quality.

The goal of our submission is to pitch a backtranslation-based QE score that can complement state-of-the-art quality estimation systems in the controlled settings of the WMT shared task (Zerva et al., 2022) and understand its reliability as a sentence-level quality estimation technique.

2 Approach

Following Moon et al. (2020), given a source sentence x and a MT hypothesis, we translate y back into the source language using an off-the-shelf multilingual model M, yielding backtranslation $\tilde{x}$. We then compare x and $\tilde{x}$ using standard machine translation evaluation metrics, and hypothesize that the distance between x and $\tilde{x}$, referred to as **BT-score(x, $\tilde{x}$),** can be an indicative of the translation quality of y.

However, MT systems are prone to making errors and are shown to hallucinate content. When the BT system makes an error, it can misguide the users in believing that the translation is a) erroneous when it is not and b) correct when the BT system magically recovers the source content. In order to improve the reliability of the BT-based QE

[*] equal contribution.

metrics, **BT-score**(x, $\tilde{x}$), and to understand whether they can complement off-the-shelf QE scorers that directly estimate the quality of a source sentence and a MT hypothesis, **FT-score**(x, y), we also propose to combine the two evaluation methods using a simple multiplication ("AND") operation.

Back-translation Model The backward translations were generated from Facebook's mBART-50 Many-to-One and One-to-Many multilingual machine translation (MMT) models. The MMT model can translate between 49 languages into and out of English, and uses 12 layers with 1,024 sized embeddings, 4,096 feedforward neural network (FNN) embedding dimensions, and 16 heads for both encoder and decoders.[3]

MT Evaluation Metrics We experiment with model-free and model-based evaluation metrics. We apply the following sentence-level scores to compare detokenized backtranslations $\tilde{x}$ with the source x:

- BLEU: we use the Sacrebleu implementation of sentence-level BLEU, with an exponential decay smoothing.[4] (Papineni et al., 2002)
- chrF: we use the Sacrebleu implementation of the chrF score, which takes a maximum character n-gram order count of six and calculates the number of ngram overlap between hypothesis and reference n-grams. (Popović, 2015)
- BERTScore: we compute the F-score based on wordpiece-level embedding similarities of, weighted by inverse document frequency (idf), using BERT as the embedding model (Zhang et al., 2019).[5].

We use the publicly available QE metric, Comet-Src ("wmt21-comet-qe-mqm") to compute FT-score(x, y).

3 Official Results using BT-based Metrics

We evaluate our approach on the English-Czech sentence-level quality prediction subtask. As our approach is unsupervised, we do not use the training data provided by the organizers. We report results obtained on the development and test sets, using the Pearson and Spearman correlations with human judgments of quality.

Table 4: Three randomly sampled sentences from the bottom 5% according to DA scores.

As can be seen in Table 4, BERTScore provides a better correlation with human judgments than BLEU and chrF consistently on the development and test sets. This is expected since the underlying BERT model provides a more semantically informed comparison than n-gram metrics. However, the backtranslation metrics yield low correlation scores overall, underperforming the organizer's baseline on the test set.

Our results are complementary to Moon et al. (2020) in that they suggest that BT-based metrics might be better suited to ranking diverse outputs from systems of varying overall quality, than those from a single MT system, i.e. at predicting quality assessments at the segment level.

4 Can BT-based scorers complement existing QE metrics?

While standalone evaluation using BT-based scoring significantly lags behind supervised SOTA QE baselines, we evaluate whether BT-based metrics can provide reliable complementary judgments to a supervised off-the-shelf QE scorer in Table 2. We combine the best BT-based scorer, BT-BERTscore and a standard QE scorer, Comet-Src using a simple multiplication operation. On three sentence level quality estimation tasks: En-Cs (DA), En-Ru (MQM) and Zh-En (MQM), combining both BT and QE scores result in improved correlation across the board over individual metrics, outperforming baselines on both En-Ru and Zh-En.

In order to better understand the source of this improvement, we divide the En-Cs development dataset into different buckets based on the direct assessment scores and report correlation on the resulsubsets in Table 3. On very bad quality translations, i.e. $DA <= -1$, BT-BERTScore exhibits a higher correlation than Comet-Src, suggesting that it is able to more reliably distinguish between bad translations than Comet-Src, hence complementing the QE metric.

5 Qualitative Analysis on En-Cs

In Table 2, we randomly sampled three sentences from the lowest 5% of the human direct assessment scores from the development set data and report the corresponding BT-BLEU, BT-chrF, and BT-BERTScores. The outputs depict how the forward translation output can be of poor quality, as indicated by the human direct assessment scores. However, the semantic similarity between the source and the back-translated source can still suggest that the forward translation is correct. When we apply machine translation to other domains, this can be problematic and misleading since users may mistakenly impart higher trust levels when using backtranslation techniques. From the same table, we can also observe that the automatic metrics cannot capture salient errors as suggested by the high scores generated by the automatic metric for the second example ("who was canceled" vs "that was abolished"). This finding is in line with prior work that has shown a positive correlation between *human evaluations* conducted on input sentences and translated outputs with *human evaluations* on input sentences and round-trip sentences (Aiken and Park, 2010). These results together call for a more systematic assessment of the role of backtranslation in lay users perceptions of MT quality.

6 Conclusion

We evaluated backtranslation-based unsupervised quality estimation systems on the sentence-level quality estimation task. Our results show that backtranslation bases scorers fall substantially behind supervised models such as the organizers' baseline. However, they can complement off-the-shelf QE metrics in distinguishing bad translations. Qualitative analysis on En-Cs indicates that while backtranslation can be a poor indicator of translation quality, the automatic metrics derived using the source and the backtranslated source might also add to the unreliability of the scorer. This suggests that more investigation is needed to determine whether backtranslation can be used effectively for QE in practical systems, whether for automatic quality estimation or to provide quality feedback to human users.

Abstract

In this paper, we present our submission to sentence-level MQM benchmark at Quality Estimation Shared Task, named **UNITE** (**Uni**fied **T**ranslation **E**valuation). Specifically, our systems employ the framework of UNITE, which combined three types of input format during training with a pre-trained language model. First, we apply the pseudo-labeled data examples for the continuously pre-training phase. Notably, to reduce the gap between pre-training and fine-tuning, we use data pruning and a ranking-based score normalization strategy. For the fine-tuning phase, we use both Direct Assessment (DA) and Multidimensional Quality Metrics (MQM) data from past years' WMT competitions. Finally, we collect the source-only evaluation results, and ensemble the predictions generated by two UNITE models, whose backbones are XLM-R and INFOXLM, respectively. Results show that our models reach 1st overall ranking in the Multilingual and English-Russian settings, and 2nd overall ranking in English-German and Chinese-English settings, showing relatively strong performances in this year's quality estimation competition.

1 Introduction

Quality Estimation (QE) aims at evaluating machine translation without access to a gold-standard reference translation (Blatz et al., 2004; Specia et al., 2018). Different from other evaluation tasks (*e.g.*, metric), QE arranges its process of evaluation via only accessing source input. As the performance of modern machine translation approaches increase (Vaswani et al., 2017; Lin et al., 2022; Wei et al., 2022; Zhang et al., 2022), the QE systems should better quantify the agreement of cross-lingual semantics on source sentence and translation hypothesis. The evaluation paradigm of QE shows its own potential for real-world applications (Wang et al., 2021; Park et al., 2021; Specia et al., 2021). This paper describes Alibaba Translate China's submission to the sentence-level MQM benchmark at WMT 2022 Quality Estimation Shared Task (Zerva et al., 2022).

In recent years, pre-trained language models (PLMs) have shown their strong ability on extracting cross-lingual information (Conneau et al., 2020; Chi et al., 2021). To achieve a higher correlation with human ratings on the quality of translation outputs, plenty of trainable model-based QE approaches appear, *e.g.*, COMET-QE (Rei et al., 2020) and QEMIND (Wang et al., 2021). They both first derive the embeddings assigned with source and hypothesis sentence with given PLM, then predict the overall score based on their embeddings with a followed feedforward network. Those model-based approaches have greatly facilitated the development of the QE community. However, those models can only handle source-only input format, which neglects the other two evaluation scenarios, *i.e.*, reference-only and source-reference-combined evaluation. More importantly, training with multiple input formats can achieve a higher correlation with human assessments than individually training on specific evaluation scenarios (Wan et al., 2021, 2022a). Those findings indicate that, the QE and Metric tasks share plenty of knowledge when identifying the quality of translated outputs, and unifying the functionalities of three evaluation scenarios into one model can also enhance the performance of the evaluation model on each scenario.

As a consequence, when building a single model for a sentence-level QE task, we use the pipeline of UNITE (Wan et al., 2022a), which integrates source-only, reference-only, and source-reference-combined translation evaluation ability into one single model. When collecting the system outputs for WMT 2022 Quality Estimation Shared Task, we employ our UNITE models to predict

December 7-8, 2022 ©2022 Association for Computational Linguistics

the translation quality scores following a source-only setting. As for the training data, we collect synthetic data examples as supervision for continuous pre-training and apply a dataset pruning strategy to increase the translation quality of the training set. Also, during fine-tuning our QE model, we use all available Direct Assessment (DA, Bojar et al., 2017; Ma et al., 2018, 2019; Mathur et al., 2020) and Multidimensional Quality Metrics datasets (MQM, Freitag et al., 2021a,b) from previous WMT competitions to further improve the performance of our model. Besides, regarding the applied PLM for UniTE models, we find that for English-Russian (En-Ru) and Chinese-English (Zh-En) directions, PLM enhanced with cross-lingual alignments (InfoXLM, Chi et al., 2021) can deliver better results than conventional ones (XLM-R, Conneau et al., 2020). Moreover, for each subtask including English to German (En-De), En-Ru, Zh-En, and multilingual direction evaluations, we build an ensembled QE system to derive more accurate and convincing results as final predictions.

Our models show impressive performances in all translation directions. When only considering the primary metric – Spearman's correlation, we get 2nd, 3rd, and 3rd place in En-Ru, Zh-En, and multilingual direction, respectively. More notably, when taking all metrics into account, despite the slight decrease in Spearman's correlations, our systems show outstanding overall performance than other systems, achieving 1st place in En-Ru and multilingual, and 2nd in En-De and Zh-En direction.

2 Method

As outlined in §1, we apply the UniTE framework (Wan et al., 2022a) to obtain QE models. We unify three types of input formats (*i.e.*, source-only, reference-only, and source-reference-combined) into one single model during training. While during inference, we only use the source-only paradigm to collect evaluation scores. In this section, we introduce the applied model architecture (§2.1), synthetic data construction method (§2.2), and model training strategy (§2.3).

2.1 Model architecture

Input Format Following Wan et al. (2022a), we design our QE model which is capable of processing **source-only**, **reference-only**, and **source-reference-combined** evaluation scenarios. Consequently, for the consistency of training across all input formats, we construct the input sequence for source-only, reference-only, and source-reference-combined input formats as follows:

$$\mathbf{x}_{\text{SRC}} = \langle \mathrm{s} \rangle \mathbf{h} \langle / \mathrm{s} \rangle \langle / \mathrm{s} \rangle \mathbf{s} \langle / \mathrm{s} \rangle, \tag{1}$$

$$\mathbf{x}_{\text{REF}} = \langle \mathrm{s} \rangle \mathbf{h} \langle / \mathrm{s} \rangle \langle / \mathrm{s} \rangle \mathbf{r} \langle / \mathrm{s} \rangle, \tag{2}$$

$$\mathbf{x}_{\text{SRC+REF}} = \langle \mathrm{s} \rangle \mathbf{h} \langle / \mathrm{s} \rangle \langle / \mathrm{s} \rangle \mathbf{s} \langle / \mathrm{s} \rangle \langle / \mathrm{s} \rangle \mathbf{r} \langle / \mathrm{s} \rangle, \tag{3}$$

where $\mathbf{h}$, $\mathbf{s}$, and $\mathbf{r}$ represent hypothesis, source, and reference sentence, respectively. During the pre-training phase, we apply all input formats to enhance the performance of QE models. Notably, we only use the source-only format setting when fine-tuning on this year's dev set and inferring the test set.

Model Backbone Selection The core of quality estimation aims at evaluating the translation quality of output given source sentence. As the source and hypothesis sentence are from different languages, evaluating the translation quality requires the ability of multilingual processing. Furthermore, we believe that those PLMs which possess cross-lingual semantic alignments can ease the learning of translation quality evaluation.

Referring to the setting of existing methods (Ranasinghe et al., 2020; Rei et al., 2020; Sellam et al., 2020; Wan et al., 2022a), they often apply XLM-R (Conneau et al., 2020) as the backbone of evaluation models for better multilingual support. To testify whether cross-lingual alignments can help the evaluation model training, we further apply InfoXLM (Chi et al., 2021), which enhances the XLM-R model with cross-lingual alignments, as the backbone of evaluation models.

Model Training For the training dataset including source, reference, and hypothesis sentences, we first equally split all examples into three parts, each of which only serves one input format training. As to each training example, after concatenating the required input sentences into one sequence and feeding it to PLM, we collect the corresponding representations – $\mathbf{H}_{\text{REF}}, \mathbf{H}_{\text{SRC}}, \mathbf{H}_{\text{SRC+REF}}$ for each input format, respectively. After that, we use the output embedding assigned with CLS token $\mathbf{h}$ as the sequence representation. Finally, a feedforward network takes $\mathbf{h}$ as input and gives a scalar p as a prediction. Taking $\mathbf{x}_{\text{SRC}}$ as an example:

$$\mathbf{H}_{\text{SRC}} = \texttt{PLM}(\mathbf{x}_{\text{SRC}}) \in \mathbb{R}^{(l_h+l_s)\times d}, \quad (4)$$

$$\mathbf{h}_{\text{SRC}} = \texttt{CLS}(\mathbf{H}_{\text{SRC}}) \in \mathbb{R}^{d}, \quad (5)$$

$$p_{\text{SRC}} = \texttt{FeedForward}(\mathbf{h}_{\text{SRC}}) \in \mathbb{R}^{1}, \quad (6)$$

where l_h and l_s are the lengths of $\mathbf{h}$ and $\mathbf{s}$, respectively.

For the learning objective, we apply the mean squared error (MSE) as the loss function:

$$\mathcal{L}_{\text{SRC}} = (p_{\text{SRC}} - q)^2, \quad (7)$$

where q is the given ground-truth score. Note that, when training on three input formats, one single step includes three substeps, each of which is arranged on one specific input format. Besides, the batch size is the same across all input formats to avoid the training imbalance. During each update, the final learning objective can be written as the sum of losses for each format:

$$\mathcal{L} = \mathcal{L}_{\text{REF}} + \mathcal{L}_{\text{SRC}} + \mathcal{L}_{\text{SRC+REF}}. \quad (8)$$

2.2 Constructing Synthetic Data

To better enhance the translation evaluation ability of pre-trained models, we first construct synthetic dataset for continuous pre-training (Wan et al., 2022a). The pipeline for obtaining such dataset consists of the following steps: 1) collecting synthetic data from parallel data provided by the WMT Translation task; 2) labeling samples with a ranking-based scoring strategy; 3) pruning data samples to increase the quality of dataset; 4) relabeling them with a ranking-based scoring strategy.

Collecting Synthetic Data Pseudo datasets for model pre-training has been proven effective for obtaining well-performed evaluation models (Sellam et al., 2020; Wan et al., 2021, 2022a). Moreover, as in Wan et al. (2022a), training on three input formats requires massive pseudo examples. Specifically, we first obtain parallel data from this year's WMT Translation task as the source-reference sentence pairs, and translate the source using online translation engines, *e.g.*, `Google Translate`[1] and `Alibaba Translate`[2], to generate the hypothesis sentence. As discussed in Sellam et al. (2020), the conventional pseudo hypotheses are usually of high translation quality. Consequently, the dataset hardly possesses a higher level of translation quality diversity, making it difficult to train evaluation models. We follow existing works (Wan et al., 2022a; Sellam et al., 2020) to apply the word and span dropping strategy to attenuate hypotheses quality, increasing the ratio of training examples consisting of bad translation outputs.

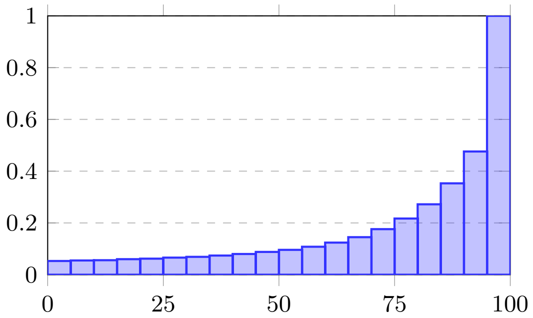

Figure 1: The cumulative distribution of scores in WMT 2020 and 2021 MQM datasets. The x-axis represents the annotated score while the y-axis represents the ratio.

Data Labeling and Pruning After downgrading the translation quality of synthetic hypothesis sentences, we then collect predicted scores for each triple as the learning supervision using checkpoint from UNITE (Wan et al., 2022a).[3] As discussed in Wan et al. (2022a) and Sellam et al. (2020), scores labeled by low-quality metrics have poor consistency, confusing the model learning during the training period. To increase the confidence of pseudo-labeled scores, we use multiple UNITE checkpoints trained with different random seeds to label the synthetic data (Wan et al., 2022a). Besides, to reduce the gap of predicted scores among different translation directions, as well as alleviate the bias among multiple evaluation approaches, we follow the scoring methods in UNITE (Wan et al., 2022a), using the idea of Borda count (Ho et al., 1994; Emerson, 2013). After sorting the collected prediction scores, we use their ranking indexes instead, and apply the conventional Z-score strategy to normalize them.

During our preliminary experiments, we find that the quality of hypotheses in the MQM 2020 and 2021 dataset is generally high. As shown in Figure 1, more than 64% of the human-annotated scores are higher than 90. To further mitigate the disagreement of translation quality distributions between pre-training and test datasets, we arrange

[1] `https://translate.google.com`

[2] `https://translate.alibaba.com`

[3] https://github.com/wanyu2018umac/UniTE

data pruning for synthetic data. Specifically, for each language pair, we ascendingly sort the synthetic examples by their scores, and split the examples into 5 bins. For the examples in each bin, we randomly drop 90%, 80%, 60%, 20%, and 0% data examples, yielding. We obtain 0.5M synthetic data for each language pair, and renormalize our prediction scores by the ranking-based manners as described before. In total, we collect pseudo examples on 10 translation directions, *i.e.*, English ↔ Czech/German/Japanese/Russian/Chinese, each of which contains 0.5M data tuples formatted as $\langle \mathbf{h}, \mathbf{s}, \mathbf{r}, q \rangle$.

2.3 Training Pipeline

To train UNITE models, the available datasets consist of synthetic examples (as in §2.2), human annotations (*i.e.*, DA and MQM), as well as provided development set for this year. In practice, we arrange the training pipeline into three steps as follows.

Pre-train with Synthetic Data As illustrated in §2.2, after collecting synthetic dataset, we use them to continuously pre-train our UNITE models to enhance the evaluation ability on three input formats.

Fine-tune with DA Dataset After collecting pre-trained checkpoints, we first fine-tune them with human-annotated DA datasets. Although the DA and MQM datasets have different scoring rules, training UNITE models on DA as an additional phase can enhance both the model robustness and the support of multilinguality. In practice, we collect all DA datasets from the year 2017 to 2020, yielding 853k training examples. Notably, we leave the year 2021 out of training due to the reported bug from the organizational committee.

Fine-tune with MQM Dataset For the evaluation test set which is assessed with MQM scoring rules, we arrange the MQM dataset from the year 2020 and 2021 for fine-tuning models at the end of the training phase, consisting of 75k examples. Specifically, during this step, we first use the provided development set to tune hyper-parameters for continuous pre-training and fine-tuning, and directly use all data examples to fine-tune our UNITE models following the previous setting.

2.4 Results Conduction

To select appropriate checkpoints, we evaluate our models on this year's development set and select top-3 models for each translation direction. Furthermore, to fully utilize the development set, we conduct a 5-fold cross-validation on the development set to select the best hyper-parameters for each top-3 model training on them. Finally, we use the best hyper-parameters to fine-tune one single model on the entire development set.

As to the results conduction, we first applied multiple random seeds for each setting, and select the checkpoint with the best performance for model training. Besides, to further increase the accuracy of ensembled scores, we choose two checkpoints whose backbones are XLM-R and INFOXLM, respectively.

Notably, uncertainty estimation has been verified in Machine Translation and Translation Evaluation communities (Wan et al., 2020; Zhou et al., 2020; Glushkova et al., 2021). However, applying this method is time consunming and we do not try it in this year's QE task.

3 Experiments

Experiment Settings We choose the large version of XLM-R (Conneau et al., 2020) and INFOXLM (Chi et al., 2021) as the PLM backbones of all UNITE models. The feedforward network contains three linear transition layers, whose output dimensionalities are 3,072, 1,024, and 1, respectively. Between any two adjacent layers, a hyperbolic tangent is arranged as the activations.

During the pre-training phase, we use the WMT 2021 MQM dataset as the development set to tune the hyper-parameters for continuous pre-training and DA fine-tuning phases. For the XLM-R setting, we apply the learning rate as $1.0 \cdot 10^{-5}$ for PLM, and $3.0 \cdot 10^{-5}$ for the feedforward network. Especially, for INFOXLM setting, we halve the corresponding learning rates to maintain the training stability. Besides, we find that raising the batch size can make the training more stable. In practice, we set the batch size for each input format as 1,024. For the following fine-tuning steps, we use the batch size as 32 across all settings.

Evaluation Setup As requested by organizers, we primarily evaluate our systems in terms of Spearman's correlation metric between the predicted scores and the human annotations for each translation direction. Apart from that, we also take other metrics, *e.g.*, Pearson's correlation, into account. Note that, during the evaluation of the multilingual phase, we directly calculate the correlation

Model	Multilingual	En-De	En-Ru	Zh-En
COMET-QE-21 (Zerva et al., 2021)	39.8	49.4	46.5	23.5
UniTE-pretrain	14.0	36.0	15.2	23.8
UniTE-pretrain-prune	28.5	41.5	22.2	20.4
UniTE-pretrain-prune + DA	**44.5**	49.3	50.3	25.2
UniTE-pretrain-prune + MQM	29.2	39.8	49.0	23.9
UniTE-pretrain-prune + DA + MQM	40.2	**52.3**	58.5	25.7

Table 1: Spearman's correlaion (%) on this year's development dataset. The best result for each translation direction are bolded. Applying both DA and MQM datasets for fine-tuning can achieve better results. Taking XLM-R as backbone shows better result on En-De, and InfoXLM on Zh-En and En-Ru.

Model	Multilingual	En-De	En-Ru	Zh-En
Single model	41.1	46.1	47.4	31.3
5-fold ensembling	42.7	53.1	48.4	**34.7**
XLM-R + InfoXLM ensembling	**45.6**	**55.0**	**50.5**	33.6

Table 2: Spearman's correlaion (%) on this year's test set. The best results for each translation direction are viewed in bold. Using 5-fold ensembling strategy delivers better correlation on Zh-En translation direction, and ensembling models trained on different PLM backbones conducts better results on multilingual, En-De, and En-Ru setting.

score for all predictions instead of conducting that for each language direction individually.

Baseline We introduce COMET-QE-21 (Zerva et al., 2021), one of the best-performed QE models as our strong baseline. COMET-QE-21 have shown their strong performance in WMT 2021 QE (Specia et al., 2021) and Metrics Shared Task (Freitag et al., 2021b) competitions. We directly apply the official released COMET-21-QE baseline[4], and use the well-trained checkpoints to infer on this year's development set for comparison.

Main Results We first testify the effectiveness of our systems on this year's development set. As shown in Table 1, our models outperform COMET-QE-21 in all translation directions. As to the results of final submissions, we list the results in Table 2.

4 Analysis

In this section, we discuss the effectiveness of all strategies, *i.e.*, data pruning (§4.1), training data arrangement (§4.2), backbone selection (§4.3), and model ensembling methods(§4.4).

4.1 Data pruning

We first investigate the impact of the data pruning strategy in Table 1. When using the pruneped data to train UniTE models, the performance gains significant improvements, with 14.5, 5.5, and 7.0 Spearman's correlation on Multilingual, En-De, and En-Ru translation direction, respectively. As discussed in §2.2, most training examples in MQM dataset have a higher translation quality. The data pruning method can reduce the ratio of training examples that contains poorly translated hypotheses. In contrast to the unpruneped synthetic dataset, the ratio of those examples consisting of well-translated outputs is raised. Consequently, we can reduce the translation quality distribution gap between synthetic and MQM datasets, and continuous pre-training and fine-tuning phases can share a great deal of learned knowledge. The experimental results validate our thinking, that the data pruning strategy offers a higher transferability of quality evaluation from synthetic to MQM data examples, making the model learning easier on the latter.

4.2 Training Data

To identify which dataset among DA and MQM is more important during fine-tuning, we conduct an experiment for comparing the corresponding effectiveness. As shown in Table 1, using DA or MQM dataset can both give performance improvement compared to only using synthetic data. Notably, the combination of DA and MQM datasets can further

[4] https://github.com/Unbabel/COMET/

boost the performance in En-Ru/En-De/Zh-En directions. However, when comparing UNITE-DA-MQM to UNITE-DA, an unexpected performance drop in the Multilingual setting is observed.

We think the reasons behind this phenomenon are two-fold. On one hand, DA data has 34 translation directions, while MQM data only has three specific directions (*i.e.*, En-De, En-Ru, and Zh-En). The annotation rules applied for those two datasets are inconsistent with each other. Training the model on MQM data can boost the performance in a specific direction. While a model trained on DA data is possessed with a more general evaluation ability for more translation directions, thus delivering more stable results on multilingual evaluation scenarios. On the other hand, for MQM data items, even though the scores may be similar across translation directions and competition years, the corresponding translation quality may vary vastly. For example, a score of 0.3 may be relatively a high score in MQM 2021 Zh-En subset, while it is rather low in this year's En-De direction. This phenomenon is quite critical when handling examples from multiple translation directions. As scores from the involved two translation directions are not compatible, training on those examples concurrently may downgrade the multilingual performance of our models.

4.3 Backbone Selection

As in Table 1, UniTE-pretrain-prune + DA + MQM is trained with XLM-R backbone, while UNITE-INFOXLM-pretrain-prune + DA + MQM is trained with INFOXLM using the same hyper-parameters and strategy. As seen, after updating the backbone of UNITE model from XLM-R to INFOXLM, the latter model outperforms the former in En-Ru and Zh-En directions, with the improvement of Spearman's correlation at 0.5 and 1.4, respectively. We can see that the quality estimation model can benefit from the cross-lingual alignment knowledge during model training. However, as to the En-De direction, the performance shows a significant drop at 4.6. We attribute this to the reason, that English and German are from the same language family, where the two languages can obtain a great deal of cross-lingual knowledge via similar tokens with the same meaning. For Multilingual direction, we claim that the impact of training data makes it unconfident which has been discussed in §4.2.

4.4 Ensemble Methods

As in Table 2, the ensembled models show great improvement on all translation directions. The difference between XLM-R and INFOXLM lies in the training objective and applied training dataset. For the quality estimation task whose core lies in the semantic alignment across languages, the knowledge engaged inside those two PLM models can be complementary to each other. Except for Zh-En direction, XLM + INFOXLM ensembling outperforms the 5-fold ensembling method in three tracks, with the performance increase being 2.9, 1.9, and 2.1 for Multilingual, En-De, and En-Ru settings, respectively. This demonstrates that, ensembling models constructed with different backbones can give better results compared to the k-fold ensembling strategy.

5 Conclusion

In this paper, we describe our UNITE submission for the sentence-level MQM task at WMT 2022. We apply data pruning and a ranking-based scoring strategy to collect massive synthetic data. During training, we utilize three input formats to train our models on our synthetic, DA, and MQM data sequentially. Besides, we ensemble the two models which consist of two different backbones – XLM-R and INFOXLM. Experiments show that, our unified training framework can deliver reliable evaluation results on QE tasks, showing the powerful transferability of UNITE model.

For future work, we believe that exploring the domain adaption problem for QE is an essential task. The existing machine translation system has made great progress in the field of domain transferablity (Lin et al., 2021; Yao et al., 2020; Wan et al., 2022b). Nevertheless, the confident evaluation metrics for those translation systems are few to be explored. Apart from that, developing a unified framework with high transferability for evaluating translation and other natural language generation tasks (Yang et al., 2021, 2022; Liu et al., 2022) is quite an interesting direction.

Notably, we also participated in this year's WMT Metrics Shared Task with the same models. We believe that, the idea of unifying three kinds of translation evaluation functionalities (*i.e.*, source-only, reference-only, and source-reference-combined) into one single model can deliver dominant results on all scenarios. Better solutions for achieving this goal are worth to be explored in the future.

Acknowledgements

The participants would like to send great thanks to the committee and the organizers of the WMT Quality Estimation Shared Task competition. Besides, the authors would like to thank the reviewers and meta-review for their insightful suggestions.

Abstract

This paper presents KU X Upstage's submission to the quality estimation (QE): critical error detection (CED) shared task in WMT22. We leverage the XLM-RoBERTa large model without utilizing any additional parallel data. To the best of our knowledge, we apply prompt-based fine-tuning to the QE task for the first time. To maximize the model's language understanding capability, we reformulate the CED task to be similar to the masked language model objective, which is a pre-training strategy of the language model. We design intuitive templates and label words, and include auxiliary descriptions such as demonstration or Google Translate results in the input sequence. We further improve the performance through the template ensemble, and as a result of the shared task, our approach achieve the best performance for both English-German and Portuguese-English language pairs in an unconstrained setting.

1 Introduction

This paper presents our submission to the critical error detection (CED) shared task among the quality estimation (QE) tasks of WMT22 (Zerva et al., 2022). CED is a task of detecting cases where translation errors in source sentences or translation results distort meaning in terms of race, gender, safety, law, finance, etc. (Specia et al., 2021; Rubino et al., 2021; Jiang et al., 2021). Critical translation errors in the shared task appear in the form of mistranslation, hallucination, and deletion in source sentences or translation results, and errors can be classified into five categories: additions, deletions, named entities, meaning, and numbers. Even if machine translation (MT) systems produce fluent translations, the fact that they cannot be free from fatal semantic errors emphasizes the importance of preventing social repercussions from the errors. Forbidding socially bad influences and losses from these meaning deviations is the purpose of the CED task (Specia et al., 2021).

Participating systems distinguish only critical errors, not correct translations or simple translation errors. In contrast to last year, submissions should be provided with continuous scores rather than binary labels. The official script calculates scores with automatically assigned classes based on the threshold value of the index corresponding to the number of errors. Similar to last year, we participated in unconstrained English-German (En-De) and Portuguese-English (Pt-En) utilizing released training datasets[1].

To perform the CED task, we exploit the XLM-RoBERTa large model (Conneau et al., 2019) as utilized in the baseline without additional parallel data. In addition, we adopt prompt-based fine-tuning to mitigate catastrophic forgetting during fine-tuning by maximizing the linguistic capability obtained through pre-training. In prompt-based fine-tuning, the downstream task is reformulated into a cloze-style, which is consistent with the masked language modeling objective. The word for the masked part is predicted by the model based on the task-specific template (Liu et al., 2021a). Recent studies have demonstrated the remarkable effects of prompt-based learning in the natural language processing field (Brown et al., 2020; Gao et al., 2020; Schick and Schütze, 2020; Liu et al., 2021b; Zhao and Schütze, 2021), and we apply this new paradigm to the QE task. We manually generate templates each containing a source sentence, its translation result, and a description with a mask token for the CED task. Furthermore, we generate label words (Liu et al., 2021b) to map the words to be filled in the masked part and labels.

Exploring appropriate templates in prompt-based fine-tuning is important because the performance ranges widely depending on the template

used. Therefore, we design multiple hard prompts through prompt engineering, and these are configured into three types of templates according to additional information: plain template, template with demonstration, and template with Google Translate. Through answer engineering, we map contrastive words for each OK and BAD tag in diverse combinations. To obtain the final score, we extract probability for words mapped to BAD. We further improve performance by ensembling values from templates.

Our approach outperforms the baseline models in En-De and Pt-En by a substantial margin and achieves first place. Experimental results demonstrate that simply setting up the training method without modifying the model or augmenting the data with additional parallel corpora significantly affects the performance.

Template
<s> **src** </s> **mt**. <mask> translation.</s>
<s> **src** </s> **mt**. It was <mask> translation.</s>
<s> A <mask> translation of **src** is **mt**.</s>

OK: "great", BAD: "terrible"
OK: "good", BAD: "bad"
OK: "!", BAD: "?"
OK: "nice", BAD: "poor"
OK: "yes", BAD: "no"

Table 1: Prompt templates and label words utilized in our experiments. We denote a source sentence as **src** and its translation result as **mt**.

2 Proposed Method

2.1 Prompt-based Fine-tuning

We adopt prompt-based fine-tuning to diminish the discrepancy between the training objectives of the fine-tuning and pre-training (Shin et al., 2020). By applying this, we induce our CED model to preserve the linguistic capability obtained via the pre-training phase.

In our task, we denote $(src, mt, y) \in D$ for a CED training dataset D, where src and mt denote a source sentence and its translated sentence, respectively, and y denotes its corresponding label (*e.g.* OK, BAD). Furthermore, we define two mapping functions T, L that transform all the data in D to implement prompt-based fine-tuning in the CED task.

The template function T transforms each src and mt into a single input sequence that contains description with masked token. In generating the input sequence, T also defines the placement of a special <mask> token to fill in. During training, we induce the model to infer the appropriate word suitable for the corresponding <mask> token position that is coherent with the overall context. Subsequently, the label word function, referred to as verbalizer, L transforms the given label y into an appropriate label word to be placed in the masked position of the input sequence transformed through T.

For example, given src as "indigenous peoples constitute just 0.7% of the global population", mt as "Indigene Völker machen nur 5% der Weltbevölkerung aus", and their corresponding label y as BAD with label words "OK:great, BAD:terrible", T convert these sentences into "<s> indigenous peoples constitute just 0.7% of the global population </s> Indigene Völker machen nur 5% der Weltbevölkerung aus </s>. It was <mask> translation." and L convert its label into "terrible". Then the original fine-tuning objective of CED that determines whether the label is "OK" or "BAD" is converted to predict the correct word for the <mask> token position. Specifically, the model is trained to predict the following probability:

$$P(y|src, mt) = P(\langle mask \rangle = L(y)|T(src, mt)) \quad (1)$$

Considering the scoring method of the WMT22 CED task, we do not binarize the model inference results into a OK or a BAD tag. Instead, we use the softmax function to normalize the overall score as in Equation (2) and extract the probability that the decoded token in the <mask> position will be mapped to BAD. We regard this probability as the estimated quality score of the mt.

$$\text{score}(src, mt) = \frac{\exp(P(\texttt{BAD}|src, mt))}{\sum_{y' \in \{\texttt{OK},\texttt{BAD}\}} \exp(P(y'|src, mt))} \quad (2)$$

2.2 Prompt and Answer Engineering

Because the effective prompt for the CED task has not been revealed, we design various prompt candidates (Gao et al., 2020). We attempt to organize the model input into a natural context, such as "src

Table 2: Dataset statistics on WMT22 CED task

mt. It was <mask> translation, A <mask> translation of src is mt". For the label words, we select two distinct words, such as "great/terrible", and "good/bad". We intend to obviate ambiguity during model training by establishing clear contrasting label words, although naive errors are not considered a good translation result. All types of templates and label words are listed in Table 1, and the entire prompt used in our experiments is described in Appendix A.

2.3 Auxiliary Description

We append auxiliary descriptions that provide supplementary information to the model input (Gao et al., 2020; Chen et al., 2021; Brown et al., 2020). We select two types of auxiliary descriptions: demonstration and Google Translate results.

The demonstration extracts a single example for each class from the training data and concatenates them into the input sequence, similar to the in-context learning approach proposed in GPT3 (Brown et al., 2020) and LM-BFF (Gao et al., 2020). In contrast to LM-BFF, we randomly select training examples without any constraints on sampling to avoid unintended bias that may occur when extracting demonstrations based on semantic similarity.

The Google Translate results append translation results from the commercialized MT system. As demonstrated in previous studies (Chen et al., 2021; Wang et al., 2020; Moon et al., 2021), adding Google Translate results contributes to a significant performance improvement. Regarding this, we use Google Translate to generate mt' by translating each src in the entire data. By adding this to the input sequence, we distill the knowledge of the external MT system into the model.

Auxiliary descriptions are combined with each example in D to compose a new input sequence. Through this, we induce the model to determine the critical errors by grounding more information.

2.4 Prompt Ensemble

As mentioned previously, prompt-based fine-tuning shows various deviations in model performance depending on the designed prompts (Shin et al., 2020). We aim to boost performance by aggregating the results from multiple prompts to minimize bias and distribute contributions per template. For the ensemble, we add the top K values with high Matthew's correlation coefficient (MCC) results.

3 Experimental Setting

3.1 Dataset Details

We leverage the dataset provided by WMT22[2]. The dataset statistics for each language pair are reported in Table 2. In summary, a sentence contains an average of 22 to 26 tokens, with a bad tag ratio of 5-6%. When using auxiliary descriptions, we randomly extract data corresponding to `OK` and `BAD` tags from the training dataset to configure the demonstration. When leveraging the commercialized MT result, we translate source sentences using the most widely adopted Google Translate[3].

We tokenize sentences with the XLM-RoBERTa tokenizer. Considering the average token and maximum sequence length of statistics, after concatenating src and mt, we filter cases where the tokenized sentence length is over 250. We score our predictions with the official script[4] provided by WMT22 and MCC.

3.2 Model Details

We exploit the same multilingual language model, XLM-RoBERTa large (Conneau et al., 2019), for both En-De and Pt-En language pairs and leverage the model and tokenizer[5] distributed by Huggingface (Wolf et al., 2019). For conducting prompt-based fine-tuning, we experiment after modifying LM-BFF[6] framework. In the case of hyperparameters, the max sequence length is set to 256 and batch size is set to 32 if auxiliary description is not used in model training, otherwise we set the max sequence length to 350 and batch size to 16. As shown in Table 2, considering the total data size for each language pair, we train Pt-En to 10K training

Google MT (Max)	**0.9218**	0.9165	**0.9211**	**0.9649**	**0.9565**	**0.9588**

Table 3: Unconstrained En-De, Pt-En development (dev) set result on WMT22 CED task. We measure MCC from the WMT22 official script. As the official script refines the inference results to have the same distribution of OK and BAD with reference, precision and recall always indicate the same value. Therefore, we denote precision and recall as P&R. We further present the MCC (Binary) result measured through the binary label. This result tends to be higher than the official script.

	En-De		Pt-En	
	MCC	P&R	MCC	P&R
All	0.9265	0.9305	0.9565	0.9588
Top 5	0.9309	0.9347	0.9695	0.9712
Top 10	0.9309	0.9347	**0.9739**	**0.9753**
Top 15	**0.9321**	**0.9358**	0.9652	0.9671
Truncate	0.9287	0.9326	0.9521	0.9547

Table 4: MCC results on top K template ensemble. Truncate indicates an ensemble result only when the dev MCC is over the baseline result.

steps and En-De to 35K. As a GPU setting, one RTX 8000 is used for learning.

4 Experimental Results

4.1 Prompt-based Fine-tuning Results

We present the prompt-based fine-tuning results for En-De and Pt-En language pairs in Table 3. We mainly divide results into three categories: plain template, template with demo, and template with Google Translate according to the auxiliary description we used. Each consists of 8, 11, and 20 different templates, and we report the average and max values in the table. Performances by leveraging each template is described in Appendix A. The baseline is the official fine-tuning results for the XLM-RoBERTa large model. Our approach significantly outperforms the baseline performance in average and maximum performance for all experiments.

Specifically, templates with no auxiliary description (*i.e.* Plain) show comparatively high results in En-De. When using demonstration (*i.e.* Demo) and Google Translate (*i.e.* Google MT), the performance is slightly decreased. However, templates with a demonstration show effective benefits in the max MCC. In addition, the best performance is achieved in templates with Google Translate in the case of MCC (Binary), which measured MCC by comparing binary predictions and labels. Through the results, we conclude that including additional information in the input sequence leads to performance improvement.

Pt-En Google MT MCC results strongly support our hypothesis. Additional translation results within the input sequence competitively contribute to performance improvement in both average and max, outperforming +0.0392 MCC over the Plain (Max). When comparing demonstration and Google Translate, we infer that presenting information related to the input example has a better effect on learning than providing representative examples of tasks.

In the average results (*i.e.* Avg), the performance gap per template is indicated by ±. Under the setting where the selected auxiliary description is fixed, the performance of different templates varies considerably, from 0.0037 to 0.0217 MCC for En-De and from 0.0089 to 0.444 MCC for Pt-En. Therefore, we perform ensembles to obtain the final score by aggregating the top K predictions.

4.2 Template Ensemble Results

Table 4 is the ensemble results of the top K templates, showing notable performance. Ensembles against the top 15 templates for En-De and the top 10 templates for Pt-En yield the best MCC results. These show +0.0134 MCC higher in En-De and +0.0174 MCC higher in Pt-En than the max results listed in Table 3. This demonstrates that the distributed contribution to multiple prompts per example further improves the final performance.

	En-De		Pt-En	
	MCC	P&R	MCC	P&R
Baseline	0.855	0.873	0.934	0.944
aiXplain	0.219	0.318	0.179	0.296
Ours	**0.964**	**0.968**	**0.984**	**0.986**

Table 5: Official result on En-De, Pt-En CED blind test set

Furthermore, we note All and Truncate in the table. The former ensembles all results and the latter removes templates with lower results than the baseline evaluation MCC before ensembling. Through this, we observe that including most of the templates does not necessarily contribute to performance improvement. High performance is obtained by training models with various types of templates and selecting appropriate predictions together.

4.3 Results on Test dataset

The experimental results for the test set are shown in Table 5. We submit the final score obtained through the ensemble. As a result, we significantly outperform the baseline result, achieving +0.109 MCC in En-De and +0.05 MCC in Pt-En. This is a notable margin because we use the same model as the baseline without utilizing any supplementary parallel data or scaling model parameters.

5 Conclusion

We applied prompt-based learning to the CED task by forming a learning objective for the task similar to that in pre-training. This method outperformed the baseline performance while preserving the model parameters and data settings. We performed manual prompt engineering and answer engineering to explore intuitive hard prompts. In addition, because finding optimal prompts is difficult, we ensembled predictions from diverse templates to address the performance variation and achieve additional performance boost. Our method is simple but powerful, and we hope that this method will be actively introduced to QE tasks in future studies.

Limitations

This study used models trained only on English-German and Portuguese-English language pairs. Therefore, language extension is challenging because data for training the CED task must be prepared for each language pair and direction. Non-trivial costs may be incurred in the data construction process. Furthermore, because we manually generated prompts and answer engineering, finding the optimal prompt is sub-optimal. Soft prompts that leverage the trained embedding values in the prompt configuration can mitigate this limitation. However, because embedding vectors in soft prompt are not described in human words, and we are the first to introduce prompt-based learning in QE tasks, we focused on interpretability.

Ethics Statement

We created task-specific templates during prompt engineering. We have not used problematic statements at this time. In addition, when engineering label words, words without ethical issues were used. However, unethical expressions such as socially problematic words and abusive language are included in the CED data. Owing to the nature of the task, this is intentionally appended by annotators to detect critical errors. The purpose of this task is to classify and exclude ethical issues that occur in the machine translation field.

Abstract

This paper presents submissions of the NJUNLP team in WMT 2022 Quality Estimation shared task 1, where the goal is to predict the sentence-level and word-level quality for target machine translations. Our system explores pseudo data and multi-task learning. We propose several novel methods to generate pseudo data for different annotations using the conditional masked language model and the neural machine translation model. The proposed methods control the decoding process to generate more real pseudo translations. We pre-train the XLMR-large model with pseudo data and then fine-tune this model with real data both in the way of multi-task learning. We jointly learn sentence-level scores (with regression and rank tasks) and word-level tags (with a sequence tagging task). Our system obtains competitive results on different language pairs and ranks first place on both sentence- and word-level sub-tasks of the English-German language pair.

1 Introduction

Quality Estimation (QE) of Machine Translation (MT) is a task to predict the quality of translations at run-time without relying on reference translations (Specia et al., 2018). This paper describes the contribution of the NJUNLP team to the WMT2022 QE Shared Task (Zerva et al., 2022) on sentence- and word-level sub-tasks (task 1)[1]. For the sentence-level task, participating systems are required to predict the quality score for each translation output, and all scores are standardized using the z-score by the rater. The result is evaluated using Spearman's rank correlation coefficient as the primary metric. For the word-level task, participating systems are required to tag each token of the translation output with OK and BAD. The BAD tag denotes this token is wrong, or there is one or more missing token(s) on the left side. The result is evaluated in terms of Matthews correlation coefficient (MCC) as the primary metric.

Inspired by DirectQE(Cui et al., 2021), we further explore pseudo data and multi-task learning for the QE shared task. Our main contributions are as follows:

- We propose several novel methods to generate pseudo data for different annotations using the conditional masked language model (Cui et al., 2021) and the neural machine translation model (Vaswani et al., 2017).
- We use the XLMR-large model (Conneau et al., 2020) as the QE model rather than a transformer base model with random initialization in (Cui et al., 2021).
- We pre-train the QE model with pseudo data and then fine-tune it with real data both in the way of multi-task learning. We explore the rank task in addition to commonly used regression and sequence tagging tasks.
- We also explore post-editing annotation data of the previous years for the multi-dimensional quality metrics (MQM) annotation sub-task.
- We propose a new ensemble technique for combining the scores of models trained with different sentence-level scores.

Our system obtains competitive results on different language pairs. Moreover, we rank first place on both sentence- and word-level of the English-German language pair with the Spearman score of 63.47 (+1.33 than the second best system) and MCC score of 35.19 (+3.33).

2 Sentence- and Word-Level Task

Formally, given a source language sentence $\mathbf{X}$ and a target language translation $\hat{\mathbf{Y}} = \{y_1, y_2, \ldots, y_n\}$ with n tokens. The sentence-level score m denotes the whole quality of the target $\hat{\mathbf{Y}}$. The word-level labels is a sequence of n tags $\mathbf{G} = \{g_1, g_2, \ldots, g_n\}$. g_j is the quality label for the word translation y_j, which is a binary label (OK or BAD).

In WMT2022, sentence scores are derived not only using direct assessments (DA) (Graham et al., 2013; Guzmán et al., 2019; Fomicheva et al., 2020) but also multi-dimensional quality metrics (MQM) (Burchardt and Lommel, 2014; Freitag et al., 2021). Similarly, organizers derive word tags in two different ways: Post-Editing (PE) (Snover et al., 2006; Fomicheva et al., 2020) and MQM. Moreover, MQM is introduced for the first time in the sentence- and word-Level QE shared task. MQM provides fine-grained error annotations produced by human translators. Annotators are instructed to span all errors in translation $\hat{\mathbf{Y}}$ given source sentence $\mathbf{X}$. Besides, they annotate categories and severity levels (minor, major, and critical) for these errors. According to the number of errors at different severity levels, the MQM score can be calculated as follows:

$$\mathrm{MQM} = 1 - \frac{n_{\text{minor}} + 5n_{\text{major}} + 10n_{\text{critical}}}{n}. \quad (1)$$

We show an example in Table 1.

3 Methods

To handle the few-shot and zero-shot settings, we follow DirectQE (Cui et al., 2021) framework. Specifically, we first generate pseudo data using parallel data, then pre-train the QE model with generated data, and fine-tune the pre-trained model with real QE data if provided. We will describe these steps as follows.

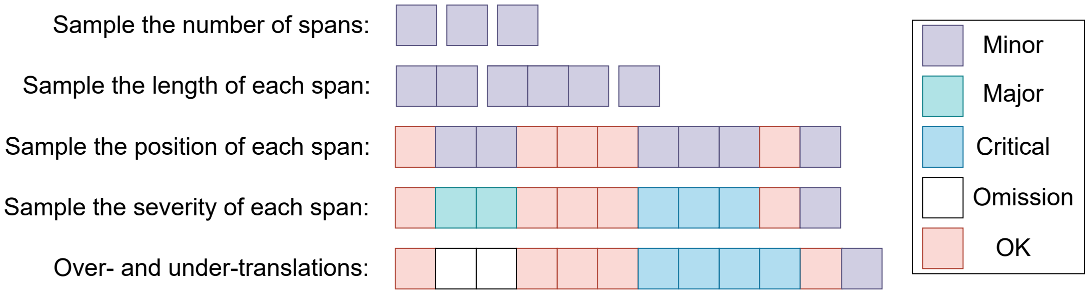
3.1 Pseudo Data

3.1.1 MQM Annotations

DirectQE randomly replaces some target tokens in parallel pairs with tokens sampled from the conditional masked language model. The replaced tokens are annotated as BAD, and they denote the ratio of BAD tokens as the pseudo sentence scores. There are several gaps between DirectQE pseudo data and MQM data:

- **Error distribution:** DirectQE generates errors at the token-level while MQM annotates translations with spans.
- **Error severity levels:** DirectQE uses the same sampling strategy and assigns the same weight for every pseudo error. As mentioned above, MQM assigns different weights for errors with varying levels of severity.
- **Error categories:** DirectQE does not involve error types of over- and under-translations, which are essential in real applications.
- **Generator:** DirectQE only uses a conditional masked language model as the generator for pseudo translations. This generator could perform quite differently from the target machine translation system.

To handle these problems, we proposed two novel methods to generate pseudo MQM data with different generators: the conditional masked language model and the neural machine translation model. The conditional masked language model is trained using masked language model task (Devlin et al., 2019) conditioned on the source sentence. Please refer DirectQE (Cui et al., 2021) for more details. The neural machine translation model is a common transformer base model as described in (Vaswani et al., 2017).



Sample the number of spans:
Sample the length of each span:
Sample the position of each span:
Sample the severity of each span:
Over- and under-translations:
Minor
Major
Critical
Omission
OK

Figure 1: Illustration of the proposed method for generating pseudo MQM data. Given a reference sentence with eleven OK tokens, we randomly sample three error spans with a length of two, three, and one and the severity of major, critical, and minor. Besides, we randomly insert one token in the second span and remove all tokens from the first span to simulate over- and under-translations.

To simulate the target error distribution, we first count the number of spans in each translation, the length of each span, and the frequency of different severity levels. Then, we can sample pseudo errors according to the target error distribution as shown in Figure 1. Finally, we use the generator to generate these error tokens except for omissions. The conditional masked language model generates pseudo errors parallel, while the neural machine translation model generates these errors from left to the right in an autoregressive fashion. Similar to DirectQE, we random sample one of the tokens with the top k generation probability as the error token. We use bigger k for graver pseudo errors to simulate errors at different severity levels. Empirically, we set k as 2, 10, and 100 for minor, major, and critical errors, respectively. The pseudo MQM scores can be calculated according Eq. 1.

3.1.2 DA and PE Annotations

For DA and PE annotations, we also explore the above two generators with different generation processes. We use the conditional masked language model as described in DirectQE. The only difference is that we normalize the pseudo sentence scores using the z-score because these scores are on a different scale from real scores.

We utilize the neural machine translation model in quite a different way. Instead of replacing target tokens at random, we let the neural machine translation model decide which tokens need to be replaced. Specifically, we compare the generation probability $P_i = \log P(y_i|X, y_{<i}; \theta_{\mathrm{MT}})$ of i-th reference token with ϵ. If $P_i < \epsilon$, we replace y_i with $y_{\max} = \arg\max_y \log P(y|X, y_{<i}; \theta_{\mathrm{MT}})$ whose generation probability is highest at this position and tag this token as BAD. Empirically, we set ϵ according to the different corpus. In addition, whatever the generation probability is, we have a chance of forcing the generated token to be consistent with the reference one. In this way, we can avoid the phenomenon that the generation probabilities of the reference token are always on a low level because of continuous replacement.

3.2 Pre-training and Fine-tuning

3.2.1 QE Model

Recently, many QE works have focused on transferring knowledge from large pre-trained language models for the QE task. In this study, we adopt XLMR large model (Conneau et al., 2020) as our QE model instead of a transformer base model with random initialization as described in (Cui et al., 2021). The XLMR large model, successfully used in the QE task(Ranasinghe et al., 2020), is a cross lingual pre-trained sentence encoder. Thus, we concatenate both source and target sentences as the input. We directly use the corresponding outputs from the last layer as token representations. We average sub-tokens' representations as the representation of the whole word. We average the representations of all target tokens as the score representation. We use linear layers for predicting sentence scores and word tags with these representations.

3.2.2 Multi-task Learning

Multi-task learning has been widely studied for QE task (Fan et al., 2019; Cui et al., 2021). Usually, the word-level task is formulated as a sequence labeling problem using cross-entropy (CE) loss as follows:

$$L_{\mathrm{CE}} = \sum_{i=1}^{n} \mathrm{CE}(g_i, \hat{g}_i), \tag{2}$$

Annotation	Pair	Spearman (Rank)	MCC (Rank)	F1-BAD	F1-OK
MQM	EN-DE	63.47 (1)	35.19 (1)	35.09	98.03
	EN-RU	47.42 (4)	38.98 (3)	43.96	94.90
	EN-ZH	29.56 (7)	30.84 (3)	30.25	98.77
	Multilingual	46.82 (2)	-	-	-
PE and DA	EN-MR	58.47 (4)	41.16 (2)	47.22	93.86
	KM-EN	-	42.12 (3)	74.42	67.68

Table 2: Results on different test sets of WMT2022.

where $\hat{g}_i$ denotes the tag predicted for i-th word. Traditional methods formulate the sentence-level task as a constraint regression problem with mean square error (MSE) loss:

$$L_{\text{MSE}} = \text{MSE}(m, \hat{m}), \tag{3}$$

where $\hat{m}$ denotes the output score. However, the ordinal relations between different translations are more important in many real applications, such as re-ranking for candidate translations and selecting the best translation models. Therefore, we introduce the additional rank loss to model the ordinal information between translations:

$$L_{\text{Rank}} = \max(0, -r(\hat{m}^i - \hat{m}^j) + \epsilon), \tag{4}$$

where $\hat{m}^i$ and $\hat{m}^j$ denote the output scores of i-th and j-th translations from current batch; r denotes the rank label, $r = 1$ if $m^i > m^j$, $r = -1$ if $m^i < m^j$; ϵ denotes the margin, we set $\epsilon = 0.03$ for all experiments. Since sentence- and word-level sub-tasks use the same source-target sentences, it is convenient to learn these tasks jointly as follows:

$$L_{\text{QE}} = L_{\text{CE}} + \alpha L_{\text{MSE}} + \beta L_{\text{Rank}}. \tag{5}$$

We use the same loss Eq. 5 for both pre-training and fine-tuning. When pre-training, we use the pseudo data as mentioned above. For fine-tuning, we also explore PE annotation data of the previous years for the MQM sub-task (EN-DE language pair). Target side word-level errors of PE annotation consist of two types of labels: word tags and gap tags (labeled BAD if one or more words should be inserted in between two words). Word tags can be directly converted to MQM tags. To convert gap tags, we label the right word as BAD if the gap tag is BAD. For sentence-level, we normalize the PE sentence scores using the z-score. We mix the PE data and MQM data and use them to fine-tune the QE model.

3.3 Ensemble

We ensemble sentence-level results by averaging all output scores and ensemble word-level results by voting. We also train some models to predict MQM scores without normalization for the EN-DE language pair. To ensemble these models trained with different sentence-level scores, we propose calculating their z-scores and then averaging all z-scores as the ensemble result.

4 Experiments

4.1 Data and Pre-processing

For training the generators and generating pseudo data, we use several parallel data sets. We use the parallel data provided by the WMT translation task [2] for EN-DE(9M), EN-RU(3M), and ZH-EN(3M) language pairs. We use 660K parallel data from OPUS[3] for the KM-EN language pair. Besides, 3.6M parallel data from the target translation model[4] are used for the EN-MR language pair. The PE data used for the EN-DE language pair are provided by WMT2017, WMT2019, and WMT2020.

For pseudo data generation, we learn the BPE vocabulary (Sennrich et al., 2016) with 30K steps using parallel data from each language pair. We can directly use the vocabulary of the XLMR model [5] for pre-training and fine-tuning.

4.2 Implementation and Hyper-parameters

We implement our system with the open source toolkit Fairseq(-py) (Ott et al., 2019). All experiments were conducted on NVIDIA V100 GPUs. Using grid search, we search hyper-parameters (learning rate, weights for different losses). We

perform early stopping if the performance does not improve for the last 20 runs.

4.3 Results

We summarize our main results on the test set in Table 2. Our system obtains competitive results over different annotation and language pairs. Especially when we use all techniques proposed in this paper, we finished 1st at both sentence- and word-level on the EN-DE pair.

4.4 Analysis

We conduct preliminary experiments on sentence-level EN-DE sub-task to better reveal the factors that contribute to the performance. Note that we search hyper-parameters with a different scale between different analyses. Thus only results in the same table are comparable.

As shown in Table 3, our pseudo data significantly improve the performance over the baseline. Besides, the rank loss can further improve performance. Table 4 shows that the neural machine translation model is better than the conditional masked language model for generating the pseudo data. Moreover, PE data from WMT2019 is helpful for the MQM task. Surprisingly, PE data from WMT2020 and WMT2017 do not further improve the results. That may be because there are more errors in translations from WMT2020, and the translations from WMT2017 are generated by a statistical machine translation system. We also find that models trained with the MQM scores are better than these using z-scores, shown in Table 5. The MSE score loss seems more stable when using the MQM label, as shown in Figure 2.

Data	Spearman
MLM + Real	49.21
NMT + Real	51.01

5 Conclusion

We present NJUNLP's work to the WMT 2022 Shared Task on Quality Estimation. We propose several novel pseudo data generation methods to bridge the gaps between existing pseudo data and real QE data. To learn the ordinal information, we extend multi-task learning for the QE task with the rank task. We also explore the PE data for the MQM annotation sub-task and propose to ensemble output scores with different scales using the z-score. Experiments show that our pseudo data significantly improve the performance over the baseline. Meanwhile, rank loss and PE data do help. In future research, we will conduct more ablation studies to reveal the contributions of each part.

Abstract

This paper presents the BJTU-Toshiba joint submission for WMT 2022 quality estimation shared task. We only participate in Task 1 (quality prediction) of the shared task, focusing on the sentence-level MQM prediction. The techniques we experimented with include the integration of monolingual language models and the pre-finetuning of pre-trained representations. We tried two styles of pre-finetuning, namely Translation Language Modeling and Replaced Token Detection. We demonstrate the competitiveness of our system compared to the widely adopted XLM-RoBERTa baseline. Our system is also the top-ranking system on the Sentence-level MQM Prediction for the English-German language pair[1].

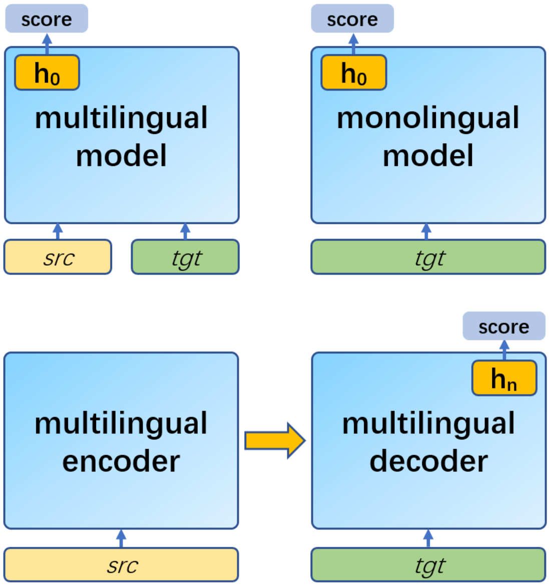

Figure 1: The three QE architectures we adopted.

1 Introduction

Machine translation Quality Estimation (QE) aims to evaluate the quality of machine translation automatically without reference. Compared with commonly used machine translation metrics such as BLEU (Papineni et al., 2002), QE can be applicable to the case where references are unavailable. It has a wide range of applications in post-editing and quality control for machine translation.

This paper introduces in detail the joint submission of Beijing Jiaotong University and Toshiba (China) Corporation to the quality estimation shared task in the 7th Conference on Machine Translation (WMT22), and we mainly focus on the Task 1: quality prediction. This year, the quality prediction task consists of two annotations (DA and MQM) and two levels (sentence-level and word-level), and we only participate in the Sentence-level MQM prediction, of which the goal is to predict the MQM score (Freitag et al., 2021) for each source-target sentence pair. Three language pairs are involved: English-German, Chinese-English and English-Russian, with roughly 10K-20k training pairs provided for each direction.

Our system is mainly based on the ensemble of multiple pre-trained models, both monolingual and multilingual. The monolingual models receive only the target sequence to perform regression (only estimating the target fluency). The multilingual models receive both the source and target sequence to perform regression. We also use in-domain parallel data to pre-finetune the pre-trained models, to adapt their representations to the target language and domain. We try two styles of pre-finetuning, namely Translation Language Model (TLM) and Replaced Token Detection (RTD). The translation language model is to predict the random masked tokens based on the concatenation of source-target pairs. The RTD is to first randomly replace some tokens by another generator, then to detect which token is replaced. Different models are ensembled to get further improvement.

[1] Our codes are openly available at the public repository https://github.com/HuihuiChyan/AwesomeQE.

2 Methods

2.1 Architecture

In this work, we perform massive comparison between the multilingual models and monolingual models on QE. Our backbone network is based on several multilingual understanding models, including Multilingual BERT (Devlin et al., 2018), XLM (Lample and Conneau, 2019), XLM-RoBERTa (Ruder et al., 2019), etc. Meanwhile, we integrate several monolingual models, including BERT, RoBERTa (Liu et al., 2020b), DeBERTa (He et al., 2021b), DeBERTa-v3 (He et al., 2021a), Electra (Clark et al., 2020), etc. We also perform estimation on multilingual encoder-decoder models, including Multilingual BART (Liu et al., 2020a) and OpusMT (Tiedemann and Thottingal, 2020)[2].

For multilingual understanding models, we feed the concatenation of *src* (source sentence) and *tgt* (machine translated sentence) to the model, and take the first output hidden state for regression. For monolingual understanding models, we simply feed the *tgt* to the model, and take the first output hidden state for regression. For encoder-decoder

[2] To be specific, we use the released models from https://huggingface.co/Helsinki-NLP/opus-mt-en-de, https://huggingface.co/Helsinki-NLP/opus-mt-zh-en, and https://huggingface.co/Helsinki-NLP/opus-mt-en-ru for En-De, Zh-En and En-Ru, respectively

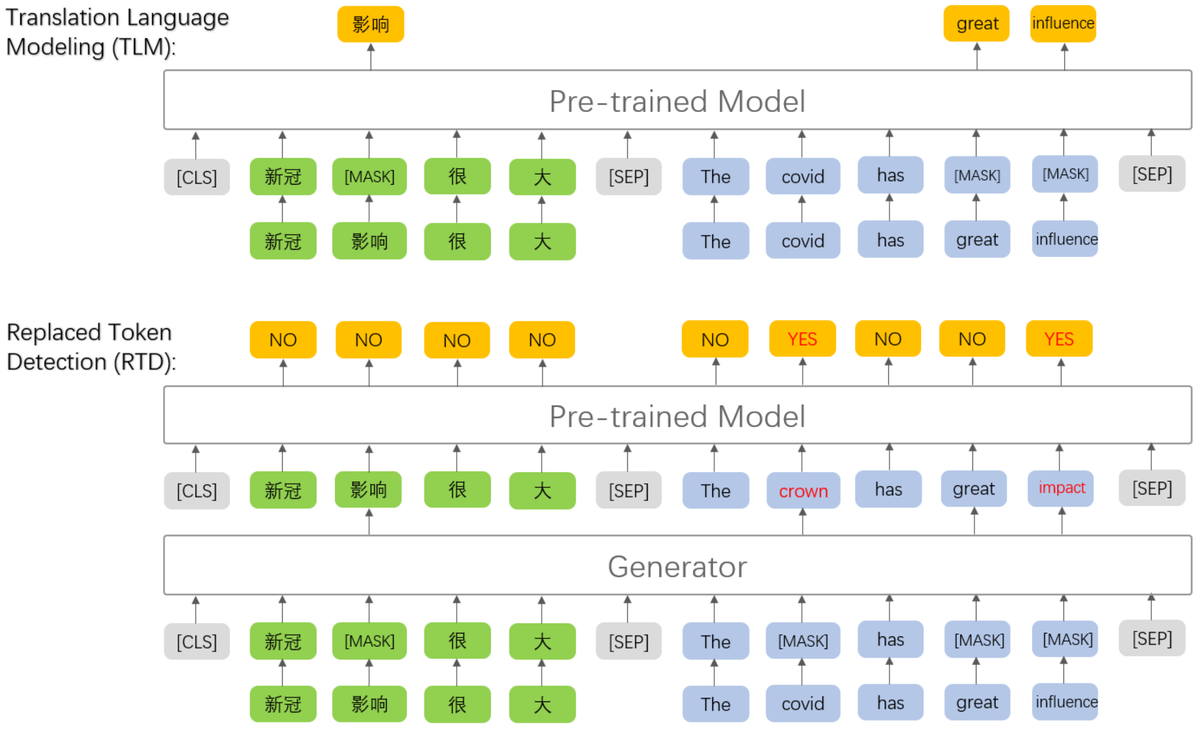

Figure 2: The two different pre-finetuning schemes. Notice for RTD, some masked tokens may be restored correctly by the generator, and we only detect the mismatched tokens.

style models, we feed the *src* to the encoder, the *tgt* to the decoder, and take the last hidden state corresponding to the last token of the *tgt* for regression. All three architectures are depicted in Figure 1.

As shown in Table 1, the monolingual baselines can surpass the multilingual baselines in all directions. Although the alignment information is absent, estimation can still be performed solely on the target text to estimate the fluency. In this year, the MQM prediction data are actually the submissions from the translation evaluation task, therefore most *tgt*s are roughly correct translations aligned with the source sentence, and most translation errors are very subtle. Therefore, it would be easier for the model to estimate the fluency instead of the alignment. With the help of powerful monolingual models, we are able to achieve higher estimation accuracy based solely on the target input.

2.2 Adaptative Pre-finetuning

Fine-tuning pre-trained language models on domain-relevant unlabeled data has become a common strategy to adapt the pretrained parameters to downstream tasks (Gururangan et al., 2020). Previous works also demonstrate the necessity of pre-finetuning when performing QE on pretrained models (Kim et al., 2019; Hu et al., 2020). In this work, we perform two methods to pre-finetune the pre-trained models, namely Translation Language Modeling (TLM) (Lample and Conneau, 2019) and Replaced Token Detection (RTD) (Clark et al., 2020), as shown in Figure 2.

The TLM simply takes the concatenation of parallel sentence pairs as input, and perform masked language modeling. Therefore, when predicting the masked tokens in one side, the model could utilize its context in the parallel side, learning the bilingual alignment.

On the contrary, instead of masking, RTD corrupts the input by replacing some tokens with samples from the output of a smaller masked language model (Specifically, we use the first 1/3 layers of the pre-trained model to initilize the generator). Then the model is trained as a discriminator that predicts for every token whether it is an original or a replacement, learning to distinguish real input tokens from plausible replacements.

Compared with TLM, RTD mainly has three benefits: 1) The corruption procedure solves a mismatch in MLM (or TLM) where the network sees artificial [MASK] tokens during pre-training but not when being fine-tuned on downstream tasks. 2) The loss is calculated on all tokens instead of a subset, therefore improving the pre-finetuning efficiency. 3) The mismatch produced by a language model is more subtle than random masking or replacement, therefore the pre-finetuning naturally fits the final objective, whitch is to detect subtle semantic mismatch.

Direction	Model	Spearman	Pearson

	Roberta-large	*src-tgt*	0.5321↑

Table 3: Experiment results on the DEV set of pre-finetuned models with bilingual or monolingual input.

Both methods are performed on millions of parallel sentence pairs. We firstly train a BERT-based domain classifier to select the in-domain parallel data. Here we use the parallel data from the general translation task of WMT22[3], which contains roughly 20 million pairs for Zh-En and En-De, and 10 million for En-Ru. Specifically, the sentence pairs in the QE training set are deemed as in-domain data, and we randomly sample the same size of data as the general-domain data, and the BERT model is fine-tuned on them as a binary classifier. After that, we select roughly 1 million sentence pairs for each direction.

Notice that for monolingual models we also perform TLM with bilingual input, expecting to introduce further gain with the help of extra information.

As shown in Table 2, both TLM and RTD can improve the estimation accuracy significantly. The multilingual pre-trained model is trained on hundreds of languages simultaneously without any cross-lingual supervision. The monolingual pre-trained model is trained only on the target language. Therefore, adaptation is necessary for both models to solve the language and domain mismatch. Also, the RTD outperforms TLM in most cases, verifying that RTD is more suitable as the pre-finetuning scheme for QE task. Since QE is also targeted at detecting mismatched and disfluent tokens, therefore RTD is more in line with the QE objective.

We also found that after the pre-finetuning step, it would be helpful to feed the bilingual input to the monolingual models, as shown in Table 3. Although monolingual models did not see any text from the source language during pre-training, the knowledge between different languages is transferrable (Artetxe et al., 2020), therefore the fine-tuned model on the target side can also be used to model the semantics of the source side. Besides, subword segmentation also enables the model to represent sequences from unseen language.

The only exception is on Electra, where pre-finetuning brings degradation in all cases. It is possibly because we use the released generator instead

[3] https://www.statmt.org/wmt22/translation-task.html

of using the first few layers to initialize a generator, but it is still confusing why their released generator (which is also used to perform replacement during pre-training stage) would lead to degradation.

2.3 Model Ensemble

Till now, we have obtained different QE models trained with different data and strategies, which can capture different information from the same text. While previous work resort to statistical learning methods to perform model ensemble (Kepler et al., 2019), we think their methods might be overfitting. Therefore, we simple take the average of different predictions (normalized between 0 and 1) as the ensemble result. More specifically, we try different combinations of all available predictions (which are all listed in the Table 2), and make submissions based on the best ensemble result on the DEV set. The performance gain compared to single model is significant as can be seen in Table 2.

3 Conclusion

In this paper, we present our WMT22 QE shared task submission to the sentence-level MQM prediction. We perform massive comparison and demonstrate the effectiveness of monolingual language model. We verify that the pre-trained models can be further improved on target language and target domain via pre-finetuning, and we propose different strategies to pre-finetune the model.

As the machine translation has been developing rapidly, the translation errors current MT system makes have also become more than shallow disalignment. While MT systems are mostly trained with massive parallel data, using the same amount of parallel data to train another QE model seems inefficient, and the monolingual knowledge contained in monolingual models can be more helpful than we expected. While previous work mainly rely on the semantic alignment to perform QE, we think it might be a better option to rely more on monolingual fluency in real applications.

Abstract

This paper describes anonymous submission to the WMT 2022 Quality Estimation shared task. We participate in `Task 1: Quality Prediction` for both sentence and word-level quality prediction tasks. Our system is a multilingual and multi-task model, whereby a single system can infer both sentence and word-level quality on multiple language pairs. Our system's architecture consists of Pretrained Language Model (PLM) and task layers, and is jointly optimized for both sentence and word-level quality prediction tasks using multilingual dataset. We propose novel auxiliary tasks for training and explore diverse sources of additional data to demonstrate further improvements on performance. Through ablation study, we examine the effectiveness of proposed components and find optimal configurations to train our submission systems under each language pair and task settings. Finally, submission systems are trained and inferenced using K-folds ensemble. Our systems greatly outperform task organizer's baseline and achieve comparable performance against other participants' submissions in both sentence and word-level quality prediction tasks.

1 Introduction

Quality Estimation (QE) evaluates the quality of machine translated output without human reference translation (Blatz et al., 2004). Apart from QE models' most obvious usage as being reference-less metrics for MT, it has variety of other applications in Machine Translation (MT) pipeline including but not limited to: parallel corpus filtering (Schwenk et al., 2021), curriculum learning (Ramnath et al., 2021) and decoding (Fernandes et al., 2022).

High performance in both sentence and word-level quality prediction tasks is achieved by incorporating PLM as part of QE model architecture as demonstrated in previous WMT QE findings (Specia et al., 2020, 2021). Previous years' top performers generally incorporate various data augmentation techniques in order to account for limited amount of annotated gold data (Lim et al., 2021; Chen et al., 2021). Multi-task training, ensembling, or incorporating features extracted from external models are few other popular approaches that proved to work well (Lim et al., 2021; Chen et al., 2021; Zerva et al., 2021; Wang et al., 2021a).

Our system is a multilingual and multi-task model, whereby a single system can infer both sentence and word-level quality on multiple language pairs. Our system's architecture (§3.1) consists of PLM and task layers, and is jointly optimized for both sentence and word-level quality prediction tasks (§3.2.1) using multilingual dataset. We propose novel auxiliary tasks (§3.2.2) for training and explore diverse sources of additional data (§3.3) to demonstrate further improvements on performance. Through ablation study (§5), we evaluate each components of our proposed model and use optimal configurations to train our submission systems under each language pair and task settings. Finally, submission systems are trained and inferenced using K-folds ensemble (§3.4.2). Our systems greatly outperform task organizer's baseline and perform very competitively against other participants' submissions in both sentence and word-level quality prediction tasks.

2 Quality Prediction Task and Dataset

In this section we briefly overview two subtasks and their datasets in `Task 1`. Apart from provided `Gold` data as described below, participants are allowed to leverage additional sources of data.

2.1 Sentence Level Quality Prediction

The goal of sentence-level quality prediction is to predict the quality score for each *(source, hypothesis)* sentence pair. Participants are provided with two types of sentence-level quality prediction

[*] These authors contributed equally to this work

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 627 - 633
December 7-8, 2022 ©2022 Association for Computational Linguistics

data depending on how annotations are created: Multi-dimensional Quality Metrics (MQM)[1] and Direct Assessments (DA)[2]. All three language pairs in MQM, and En-Mr in DA are supervised, while remaining four language pairs in DA are unsupervised. Submission systems are evaluated on aforementioned eight language pairs and one surprise language pair[3]. Note that MQM scores are inverted in order to align MQM scores with DA scores.

2.2 Word Level Quality Prediction

The goal of word-level quality prediction is to predict translations errors, assigning OK/BAD tags to each word in hypothesis, given *(source, hypothesis)* sentence pairs. Word-level tags are provided for language pairs same as in sentence-level task, and tags are derived from either MQM annotations (MQM) or post-edited sentences (DA).

3 Approach

Below we describe relevant components of our proposed QE model.

3.1 Model Architecture

Our system employs the Predictor-Estimator architecture (Kim et al., 2017). For our **predictor** we use a PLM, and our choice of PLM is XLM-RoBERTa-large (Conneau et al., 2020) due to its impressive performance on crosslingual downstream tasks. Given source sentence src^X in language X and target sentence tgt^Y in language Y, the concatenation of src^X and tgt^Y are fed as input to the PLM and feature vectors relevant to each task are then passed as inputs to the **estimator**. We utilize four independent 2-layer feed-forward networks as estimators, which are 1024 and 200 dimensions, and are stacked in parallel above PLM. The Predictor-Estimator architecture can be described as:

$$\begin{aligned}
&f(src^x, tgt^y)\\
&= H_{sent}, H_{word}, H_{sentaux}, H_{wordaux}\\
&V_{sent} = \phi_{sent}(H_{sent})\\
&V_{word} = \phi_{word}(H_{word})\\
&V_{sentaux} = \phi_{sentaux}(H_{sentaux})\\
&V_{wordaux} = \phi_{wordaux}(H_{wordaux}),
\end{aligned} \tag{1}$$

where f, H, ϕ, and V are predictor, feature extracted from predictor, estimator, and our final prediction, respectively. We describe H, ϕ, and their corresponding training objectives in §3.2.

3.2 Training Objective

The full training objective of our QE model is shown below in equation (2),

$$\begin{aligned}
\mathcal{L} = &(w_{sent} \cdot \mathcal{L}_{sent}\\
&+ (1 - w_{sent}) \cdot \mathcal{L}_{sentaux}) +\\
&(w_{word} \cdot \mathcal{L}_{word}\\
&+ (1 - w_{word}) \cdot \mathcal{L}_{wordaux}).
\end{aligned} \tag{2}$$

$\mathcal{L}$ and w denote loss functions and loss weight values. w_{sent} and w_{word} are 0.6 and 0.7 respectively. We describe each loss function components in the following subsections.

3.2.1 Multi-task Training

To build a system that is capable of predicting both sentence and word-level quality, our proposed training objective optimizes for $\mathcal{L}_{sent}$ and $\mathcal{L}_{word}$ jointly as shown in equation (2). We use mean squared error (MSE) and weighted cross entropy loss[4] as loss functions for $\mathcal{L}_{sent}$ and $\mathcal{L}_{word}$ respectively. Therefore, ϕ_{sent} is a classification layer with input H_{sent}, which is PLM's last layer [CLS] representation; ϕ_{word} is a classification layer with input H_{word}, which is created by mean pooling PLM's last layer token hidden states[5]. Since sentence and word-level quality prediction tasks are two closely related tasks, we assume some level of transferability of task knowledge between the two when jointly trained.

3.2.2 Auxiliary-task Training

Auxiliary-tasks are additional objectives that are jointly optimized with losses described in §3.2.1.

[1] English-Russian (En-Ru), English-German En-De), and Chinese-English (Zh-En)

[2] English-Marathi (En-Mr), English-Czech (En-Cs), English-Japanese (En-Ja), Khmer-English (Km-En), and Pashto-English (Ps-En)

[3] English-Yoruba (En-Yo), where no train and development data is provided at all

[4] In order to reduce the problem of label imbalance between OK and BAD, we use weighted cross entropy with ratio of OK:BAD = 1:3

[5] If $word_n$ spans $token_{i:j}$, then $H_{word_n} = mean(H_{token_i}, ..., H_{token_j})$

Table 1: Ablation on Train Data, Train Method, and Train Objective. Multi column contains development portion of Gold for all 14 language pairs.

Our intuition is that quality prediction is inherently a complex task even for humans such that human-labels may contain noise. Hence, we appropriately craft original gold labels into secondary labels and use those labels during training as additional learning signals. We expect that training with auxiliary labels can make training more robust and produce a model that is more generalizable.

Sentence-level auxiliary task is a classification task and labels are made as follows: given the n_{th} train set sample's z-standardized score $score_n$, we scale $score_n$ by applying min-max normalization and assign bin (class) labels to each sample. For our experiments, the number of bins is set to 10. Note that min-max scaling is applied to each language pair dataset in order to account for different scales of $score_n$ per dataset. $\phi_{sentaux}$ is a regression layer with input $H_{sentaux}$, which is PLM's last layer [CLS] representation. Likewise, **word-level auxiliary task** is also a classification task and labels are made as follows: given a sample's word-level tags, a sample is assigned to BAD if there exists at least one BAD tags in word-level tags, else OK. $\phi_{wordaux}$ is a classification layer with input $H_{wordaux}$, which is created by mean pooling PLM's last layer token hidden states, excluding special tokens.

3.3 Data Augmentation

We augment training data with additional data, which can be categorized as follows: task-related or pseudo-generated. **Task-related** data are open source data of other downstream tasks, but are similar or can be useful to quality prediction task. We collect data from previous years' WMT Metrics Shared Task[6] and WMT APE Task[7]. Since WMT Metrics Shared Task data contain human DA scores for *(source, hypothesis)* pairs, and WMT APE Task data contain *(source, hypothesis, post-edited)* triplets such that word-level quality annotations can be built using provided word label tagging conventions[8], sentence or word quality labels for this dataset type can be considered high quality.

Pseudo-generated data first assumes bitext[9], *(source, reference)* pairs. We then use NMT models provided by organizers to create *(source, reference, hypothesis)* triplets. Sentence quality labels are generated using COMET[10], which is an open source reference-less QE model. Word quality labels are generated adhering to word label tagging conventions. Labels for pseudo-generated data are considered less accurate compared to task-related data since either labels are pseudo-generated via external model instead being human generated (sentence-level) or do not use actual *(hypothesis, post-edited)* pairs to compute labels (word-level). Refer to Appendix A for detailed list of augmented data.

3.4 Final Model Training

3.4.1 Optimized Configuration

Although we can submit a single model for all language pairs because all our models are multilingual, we submit optimized models for each language pair and task submissions. This is done by choosing and training with optimal configuration for each language pair and task as found in our ablation study (§5, Table 1) or summarized in Appendix B. Our final submissions are optimized for three configurations: train data, train objective, and train method. We further explain each configurations in detail below.

[6] WMT17-21 Metrics Shared Task

[7] WMT16-21 APE Shared Task

[10] wmt21-comet-qe-da, https://github.com/Unbabel/COMET

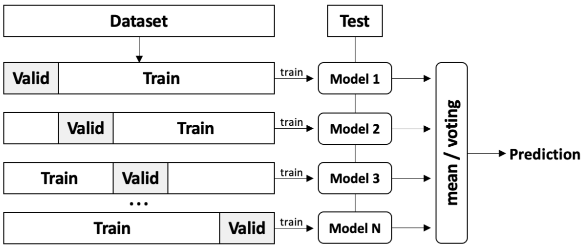

Figure 1: K-folds Ensemble

We have two sources of **train data**: Gold which is data provided by task organizers, and Additional as described in §3.3. This leads us to experiment on two different compositions of train data: Gold and Augmented, where the latter is the aggregation of Gold and Additional.

There are three variants of **train objective**: Single, Multi, and Multi+Aux. Single refers to models that are trained with a single-task objective, either being $\mathcal{L}_{sent}$ or $\mathcal{L}_{word}$. Multi are multi-task models that are trained jointly on both sentence and word-level quality prediction objectives $\mathcal{L}_{sent} + L_{word}$, as described in §3.2.1. Multi+Aux refers to models that are trained with multi-task and auxiliary objectives, as described in equation (2).

For models trained with Vanilla **train method**, we can train with variants of train data but always select best checkpoint using the development set portion of Gold. We explore advanced training methods such as K-folds ensemble (§3.4.2) to further improve model performance.

3.4.2 K-folds Ensemble

As demonstrated in Figure 1, K-folds ensemble (Domingo et al., 2022) distributes the dataset in different training and validation folds such that each individual model uses discrete dataset for training and validation. Compared to vanilla ensembles, where all models are trained using same train data, we expect this method to generate more robust final predictions and become less over-fitted to validation data.

Given a complete set of data[11], we randomly select 1,000 samples for each supervised language pair Gold dataset to create validation set, while the rest are used for training. We repeat this process N=5 times with the constraint that N=5 mutually exclusive validation sets are created. We then train and select best checkpoints for each partition using discrete datasets. An ensemble of N=5 best models, one from each partition, are taken to make final predictions. Prediction mean and majority voting is used for sentence-level and word-level quality prediction respectively.

4 Settings

For all training phases and experiments, we train our model in data parallel on multiple NVIDIA Tesla V100 GPUs for maximum 10 epochs with batch size of 16 and is optimized with Adam (Kingma and Ba, 2015) with a learning rate of $7e^{-6}$. Our implementation is based on PyTorch[12] framework.

All models trained within the scope of this paper are multilingual QE models. We concatenate dataset of all individual language pairs to create a multilingual train dataset for both sentence and word-level quality prediction tasks. We apply the same for development set and always perform model selection using a multilingual dataset[13].

5 Ablation

In this section, we present ablation study of individual components to our model described in §3. All evaluations for ablation in Table 2 are conducted on development portion of Gold.

5.1 Does multilingual training help?

Task	Language	En-De	En-Ru	En-Mr	Ne-En	Si-En
Sent	Single	0.491	0.399	**0.560**	0.798	0.538
	Multi	**0.499**	**0.516**	0.555	**0.805**	**0.550**
Word	Single	0.225	0.306	**0.360**	0.438	0.408
	Multi	**0.229**	**0.386**	0.358	**0.469**	**0.452**

Table 2: Ablation on multilingual training

Training multiple language pairs in a single model through parameter sharing can significantly reduce the cost of model training and maintenance compared with training multiple separate models (Wang et al., 2021b) in Neural Machine Translation. Moreover, we argue that multilingual QE models can collectively learn knowledge from multiple language pairs, which can be particularly be useful in this shared task scenario considering limited training data available per language pair. Table 2 compares the performance of single language pair

[11] We concatenate train and development portion in the case of Gold

[12] https://pytorch.org/

[13] Checkpoints for our final submissions (Table 3, 4) are selected base on performance on multilingual dataset

QE models to multilingual QE models. We see that the performance of multi models are higher than or similar to the performance of single models. Since the performance of multilingual models are at least on par with separate models, this motivates us to use multilingual training when considering additional training and parameter costs of maintaining multiple separate models.

5.2 Does multi-task or auxiliary-task training help?

Row 1 to 3 and 7 to 9 in Table 1 demonstrates ablation on different training objectives. For sentence-level quality prediction tasks, we see that the performance of Multi or Multi+Aux is higher than that of single in all cases except for Zh-En. We observe that adding auxiliary tasks to multi-tasking can give further improvements in most cases. In general, we argue that multi-tasking or adding auxiliary tasks help improve performance of sentence-level QE models. The results for word-level quality prediction tasks are a bit mixed; single achieves highest performance compared to adding any additional training tasks at all for En-De, Zh-En, Ps-En, En-Ja, and En-Cs. We conjecture that multi-tasking or adding auxiliary tasks do not help in word-level as much as they do in sentence-level quality predictions tasks.

5.3 How does train data and train method impact performance?

Row 4 to 6 and 10 to 12 in Table 1 demonstrates ablation on train data and train method. Using additional data (i.e Augmented) improves over Gold in most cases, confirming the importance of using augmented data for quality prediction tasks which mostly are low-resource condition. K-folds ensemble[14] further improves over Vanilla in all cases, again confirming the widely accepted fact that ensembling techniques are useful to give additional boost in performance.

6 Results

Table 3 and 4 demonstrate our final submission systems for sentence-level and word-level quality prediction task respectively. Refer to Appendix B for detailed configurations used for each final submission models.

7 Conclusions

In this work, we describe our system submission to the WMT 2022 Quality Estimation shared task. Our system is a multilingual and multi-task model for both sentence and word level quality prediction tasks. We demonstrate through ablation study that additional training objectives and data can further improve quality prediction performance. Our final model is trained and inferenced using K-folds ensemble which show remarkable performance in all language pairs and tasks. However, we find that multi-task or auxiliary-task training do not help in word-level as much as they do in sentence-level quality prediction. Further analysis to understand the dynamics of training with multiple objectives and improvements on word-level quality prediction are challenges that we need to overcome in future work.

[14] We leave out development portion of Gold for final evaluation within the scope of ablation

Abstract

We present the joint contribution of IST and Unbabel to the WMT 2022 Shared Task on Quality Estimation (QE). Our team participated on all three subtasks: (i) Sentence and Word-level Quality Prediction; (ii) Explainable QE; and (iii) Critical Error Detection. For all tasks we build on top of the COMET framework, connecting it with the predictor-estimator architecture of OPENKIWI, and equipping it with a word-level sequence tagger and an explanation extractor. Our results suggest that incorporating references during pretraining improves performance across several language pairs on downstream tasks, and that jointly training with sentence and word-level objectives yields a further boost. Furthermore, combining attention and gradient information proved to be the top strategy for extracting good explanations of sentence-level QE models. Overall, our submissions achieved the best results for all three tasks for almost all language pairs by a considerable margin.[1]

1 Introduction

Quality Estimation (QE) is the task of automatically assigning a quality score to a machine translation output without depending on reference translations (Specia et al., 2018). In this paper, we describe the joint contribution of Instituto Superior Técnico (IST) and Unbabel to the WMT22 Quality Estimation shared task (Zerva et al., 2022), where systems were submitted to three tasks: (i) Sentence and Word-level Quality Prediction; (ii) Explainable QE; and (iii) Critical Error Detection.

This year, we leverage the similarity between the tasks of MT evaluation and QE and bring together the strengths of two frameworks, COMET (Rei et al., 2020), which has been originally developed for reference-based MT evaluation, and OPENKIWI (Kepler et al., 2019), which has been developed for word-level and sentence-level QE. Namely, we implement some of the features of the latter, as well as other new features, into the COMET framework. The result is COMETKIWI, which links the predictor-estimator architecture with COMET training-style, and incorporates word-level sequence tagging.

Given that some language pairs (LPs) in the test set were not present in the training data, we aimed at developing QE systems that achieve good multilingual generalization and that are flexible enough to account for unseen languages through few-shot training. To do so, we start by pretraining our QE models on Direct Assessments (DAs) annotations from the previous year's Metrics shared task as it was shown to be beneficial in our previous submission (Zerva et al., 2021). Then we fine-tune our models with the data made available by the shared task.[2] We experimented with different pretrained multilingual transformers as the backbones of our models, and we developed new explainability methods to interpret them. We describe our systems and their training strategies in Section 3. Overall, our main contributions are:

- We combine the strengths of COMET and OPENKIWI, leading to COMETKIWI, a model that adopts COMET training features useful for multilingual generalization along with the predictor-estimator architecture of OPENKIWI.

- Following our previous work (Zerva et al., 2021), we show the importance of pretraining QE models on annotations from the Metrics shared task.

- We show that we can improve results for new LPs with only 500 examples without harming correlations for other LPs.

- We propose a new interpretability method that uses attention and gradient information along

[*] Equal contribution. ✉ ricardo.rei@unbabel.com

[1] https://github.com/Unbabel/COMET

[2] For zero-shot LPs we use 500 training examples which means we turn it into a few-shot setting. The only exception is English→Yoruba which was kept zero-shot.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 634 - 645
December 7-8, 2022 ©2022 Association for Computational Linguistics

with a head-level scalar mix module that further refines the relevance of attention heads.

Our submitted systems achieve the best multilingual results on all tracks by a considerable margin: for sentence-level DA our system achieved a 0.572 Spearman correlation (+7% than the second best system); for word-level our system achieved a 0.341 MCC score (+2.4% than the second best system); and for Explainable QE our system achieved 0.486 R@K score (+10% than the second best system). The official results for all LPs are presented in Table 6 in the appendix.

2 Background

Quality Estimation. QE systems are usually designed according to the granularity in which predictions are made, such as sentence and word-level. In sentence-level QE, the goal is to predict a single quality score $\hat{y} \in \mathbb{R}$ given the whole source and its translation as input. Word-level QE works in a lower granularity level, with the goal of predicting binary quality labels $\hat{y}_i \in \{\text{OK}, \text{BAD}\}$ for all $1 \leq i \leq n$ *machine-translated words*, indicating whether that word is a translation error or not.

Transformers. The multi-head attention mechanism is the key component in transformers, being responsible for contextualizing the information within and across input sentences (Vaswani et al., 2017). Concretely, given as input a matrix $\boldsymbol{Q} \in \mathbb{R}^{n \times d}$ containing d-dimensional representations for n queries, and matrices $\boldsymbol{K}, \boldsymbol{V} \in \mathbb{R}^{m \times d}$ for m keys and values, the *scaled dot-product attention* at a single head is computed as:

$$\mathsf{att}(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \pi \underbrace{\left(\frac{\boldsymbol{Q}\boldsymbol{K}^\top}{\sqrt{d}} \right)}_{\boldsymbol{Z} \in \mathbb{R}^{n \times m}} \boldsymbol{V} \in \mathbb{R}^{n \times d}. \quad (1)$$

The π transformation maps rows to distributions, with softmax being the most common choice, $\pi(\boldsymbol{Z})_{ij} = \mathsf{softmax}(\boldsymbol{z}_i)_j$. Multi-head attention is computed by evoking Eq. 1 in parallel for each head h:

$$\mathsf{head}_h(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \mathsf{att}(\boldsymbol{Q}\boldsymbol{W}_h^Q, \boldsymbol{K}\boldsymbol{W}_h^K, \boldsymbol{V}\boldsymbol{W}_h^V),$$

where $\boldsymbol{W}_h^Q$, $\boldsymbol{W}_h^K$, $\boldsymbol{W}_h^V$ are learnable linear transformations. Finally, the output of the multi-head attention module at the ℓ-th layer is a set of hidden states $\boldsymbol{H}_\ell \in \mathbb{R}^{n \times d}$ formed via the concatenation of all $\boldsymbol{h}_{\ell,1}, ..., \boldsymbol{h}_{\ell,H}$ heads in that layer followed by a learnable linear transformation $\boldsymbol{W}^O$:

$$\boldsymbol{H}_\ell = \mathsf{concat}(\boldsymbol{h}_{\ell,1}, ..., \boldsymbol{h}_{\ell,H})\boldsymbol{W}^O.$$

The hidden states are further refined through position-wise feed-forward blocks and residual connections to obtain a final representation: $\boldsymbol{H}_\ell = \mathsf{FFN}(\boldsymbol{H}_\ell) + \boldsymbol{H}_\ell$. Transformers with only encoder-blocks, such as BERT (Devlin et al., 2019) and XLM (Conneau et al., 2020), have only the encoder self-attention, and thus $m = n$.

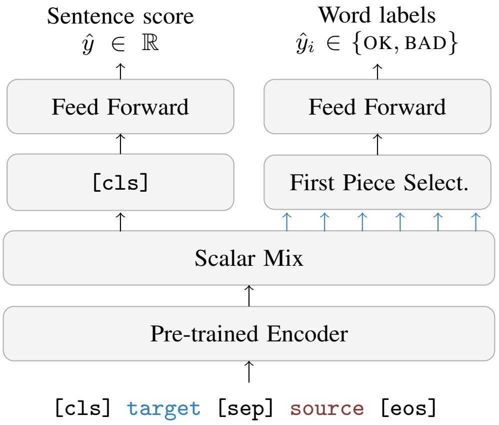

Figure 1: General architecture of COMETKIWI for sentence-level (left part) and word-level QE (right part).

3 Implemented Systems

The overall architecture of our models is shown in Figure 1. The machine translated sentence $\boldsymbol{t} = \langle t_1, ..., t_n \rangle$ and its source sentence counterpart $\boldsymbol{s} = \langle s_1, ..., s_m \rangle$ are concatenated and passed as input to the encoder, which produces d-dimensional hidden state vectors $\boldsymbol{H}_0, ..., \boldsymbol{H}_L$ for each layer $0 \leq \ell \leq L$, where $\boldsymbol{H}_i \in \mathbb{R}^{(n+m) \times d}$, where $\ell = 0$ corresponds to the embedding layer. Next, all hidden states are fed to a scalar mix module (Peters et al., 2018) that learns a weighted sum of the hidden states of each layer of the encoder, producing a new sequence of aggregated hidden states $\boldsymbol{H}_{\text{mix}}$ as follows:

$$\boldsymbol{H}_{\text{mix}} = \lambda \sum_{\ell=0}^{L} \beta_\ell \boldsymbol{H}_\ell, \quad (2)$$

where λ is a scalar trainable parameter, $\boldsymbol{\beta} \in \triangle^L$, is given by $\boldsymbol{\beta} = \mathsf{sparsemax}(\boldsymbol{\phi})$ using a sparse transformation (Martins and Astudillo, 2016), with $\boldsymbol{\phi} \in \mathbb{R}^L$ as learnable parameters and $\triangle^L := \{\boldsymbol{\beta} \in \mathbb{R}^L : \boldsymbol{1}^\top \boldsymbol{\beta} = 1, \boldsymbol{\beta} \geq 0\}$[3].

[3] As it has been shown in (Rei et al., 2022) not all layers are relevant and thus, using sparsemax we learn to ignore layers

For sentence-level models, the hidden state of the first token (`<cls>`) is used as sentence representation $\boldsymbol{H}_{\text{mix},0} \in \mathbb{R}^d$, which, in turn, is passed to a 2-layered feed-forward module in order to get a sentence score prediction $\hat{y} \in \mathbb{R}$. For word-level models, we first retrieve the hidden state vectors associated with the first word piece of each machine translated token, and then pass them to a linear projection to get word-level predictions $\hat{y}_i \in \{\text{OK}, \text{BAD}\}, \forall_{1 \leq i \leq n}$. Moreover, attention matrices $\boldsymbol{A}_{1,1}, ..., \boldsymbol{A}_{L,H}$ for all layers and heads are also recovered as a by-product of the forward propagation.

Pretraining on Metrics Data. Every year, the WMT News Translation shared task organizers collect human judgments in the form of DAs. The collective corpora of 2017, 2018, and 2019 contain 24 LPs and a total of 657k samples with source, target, reference, and DA score. We follow our experiments from last year (Zerva et al., 2021) and start by pretraining our QE models on this data using the learning objective proposed by UniTE (Wan et al., 2022), which incorporates reference translations into training and thus acts as data augmentation.

Setting pretrained transformers as encoders. We follow the recent trend (Kepler et al., 2019; Ranasinghe et al., 2020) and experiment with three different pretrained multilingual transformers as the encoder layer of our models: XLM-R Large (Conneau et al., 2020),[4] InfoXLM Large (Chi et al., 2021),[5] and RemBERT (Chung et al., 2021).[6] XLM-R and InfoXLM consist of 24 encoder blocks with 16 attention heads each, whereas RemBERT has 32 encoder blocks with 18 attention heads each.

3.1 Task 1: Quality prediction

After the pretraining phase, we adapt our models to the released QE data using source and translation (i.e., in this phase we do not include references) to the different type of quality assessments provided, namely, DA and HTER[7] from the MLQE-PE corpus (Fomicheva et al., 2022) and Multidimensional Quality Metrics (MQM) annotations from WMT 2020 and 2021 (Freitag et al., 2021a,b).

3.1.1 Sentence-level quality prediction

For the sentence-level QE task we consider a multi-task setting (using sentence scores alongside supervision from OK/BAD tags) and the sentence-level only setting, with supervision only from the sentence-level quality assessment y. We found that adding the word-level supervision was beneficial for models built on top of InfoXLM. For the sentence-level supervision we used both DA and MQM scores. In this multi-task setting we use a combined loss as described in Eq. 5:

$$\mathcal{L}_{\text{sent}}(\theta) = \frac{1}{2}(y - \hat{y}(\theta))^2 \tag{3}$$

$$\mathcal{L}_{\text{word}}(\theta) = -\frac{1}{n}\sum_{i=1}^{n} w_{y_i} \log p_\theta(y_i) \tag{4}$$

$$\mathcal{L}(\theta) = \lambda_s \mathcal{L}_{\text{sent}}(\theta) + \lambda_w \mathcal{L}_{\text{word}}(\theta), \tag{5}$$

where $w \in \mathbb{R}^2$ represents the class weights given for OK and BAD tags, and λ_s, λ_w are used to weigh the combination of the sentence and word-level losses, respectively. Note that $\lambda_s = 1$ and $\lambda_w = 0$ yields a fully sentence-level model.

Few-shot language adaptation. Since in this shared task submissions are tested on 5 LPs for which there is no official training data (*km-en*, *ps-en*, *en-ja*, *en-cs*, *en-yo*), we experimented with few-shot adaptation using half of the data released in the official development set. The official development set has 1K examples for each language pair (except *en-yo* for which there is no available data). To perform few-shot language adaptation we split the data into two halves: one for fine-tuning and another for validation.

Ensembling models. For our final submission for Direct Assessments we combine six multilingual systems using different hyperparameters by computing an weighted average of their outputs, where the weights for each language pair were tuned with Optuna (Akiba et al., 2019). The major difference between the ensembled models comes from the underlying encoder and whether or not they used word-level supervision. Three models of our final ensemble use word-level supervision while the other three use only sentence-level supervision. Regarding the encoder, three models use InfoXLM, two models use RemBERT and a single model uses XLM-R.

Our final submission for MQM predictions was an ensemble of eleven multilingual systems, which

that do not help in the task at hands

[4] https://huggingface.co/xlm-roberta-large

[5] https://huggingface.co/microsoft/infoxlm-large

[6] https://huggingface.co/google/rembert

[7] HTERs are available only for word-level subtasks.

combined the six systems used in the DA ensemble as well as five additional systems. For these additional systems, we made two major adjustments to the fine-tuning process. First, we filtered the DA data to the languages that were included in the MQM LPs, namely *ru-en*, *en-zh*, and *en-de*. Second, we incorporated the MQM data into the fine-tuning process, either as an additional fine-tuning step after fine-tuning on the language-filtered DA data, or by concatenating the DA and MQM data together. All additional systems used word-level supervision in addition to sentence-level and used InfoXLM as encoder.

3.1.2 Word-level quality prediction

Similarly, for the word-level QE tasks we experimented with both the multi-task setting and word-labels only ($\lambda_s = 0$ and $\lambda_w = 1$). Overall, we found that adding the sentence-level supervision was beneficial, especially for the languages pairs included in the test-set. Nonetheless, for some LPs, ignoring sentence-level supervision showed superior performance. Due to the mix of high-, mid- and low-resource languages in the data, the distribution of OK and BAD tags differs substantially between LPs leading to inconsistent performance in terms of MCC (see Table 5 in the appendix). To mitigate this, for the word-level subtask, we prepend a language prefix token to the beginning of the source and target segments during training and testing.

Pretraining on post-edit corpora. Extending the pretraining on Metrics data, we pretrain the word-level models on two corpora that include both word-level labels and sentence (HTER) scores, namely QT21 (Specia et al., 2017) and APEQuest (Ive et al., 2020). We compute the sentence-level score, using translation edit rate (TER) (Snover et al., 2006) between the target and the corresponding post-edited sentence.

Ensembling models. For word-level we followed a similar ensembling technique used for sentence-level, namely we combine multiple systems trained with different hyperparameters, encoders and pre-training setups. In the case of word-level predictions however, we need to resolve how to aggregate multiple predictions into OK/BAD tags. We use Optuna (Akiba et al., 2019) to choose how to weight and combine the models based on performance for each language pair on our internal test-set and we compare three different approaches:

1. A naive "best-only" approach: we identify the best model for each LP and use its predictions.

2. We ensemble the logits of each model: for each input segment we compute an ensembles of logits as $\sum_{i \in \mathcal{M}} w_i v_i$, where $\mathcal{M}$ is the set of models, w_i is the weight of each model and v_i the model logit vector. We use Optuna to find the optimal weight w_i for each model in each LP.

3. We ensemble the predicted tags of each model: for each input segment we compute an ensembles of tags as $\alpha \sum_{i \in \mathcal{M}} w_i c_i$, where c_i is the predicted class and α is the weight given for the BAD class. We use Optuna to find the optimal weights w_i for each model and the optimal BAD weight α for each LP.

In the final submission we combine five models for the post-edit originated LPs: a RemBERT based model, an InfoXLM based model pretrained on APEQuest and QT21, and three checkpoints that are based on InfoXLM but use different parameters for the BAD/OK weights and learning rate that were found via Optuna. For MQM we also combine five models, but this time instead of choosing three checkpoints based on optimising weights and learning rate, we use three different checkpoints with different training data mix on the relevant DA LPs, as this seemed to impact the performance on MQM word-level more than the weight ratios. Refer to §4 and Table 3 for more details.

3.2 Task 2: Explainable QE

The goal of the Explainable QE task is to identify machine translation errors without relying on word-level label information. In other words, it can be cast as an unsupervised word-level quality estimation problem, where explanations can be seen as highlights, representing the relevance of input words w.r.t. the model's prediction via continuous scores, aiming at identifying tokens that were not properly translated.

Several explainability methods can be used to extract highlights from a sentence-level model, such as post-hoc (Ribeiro et al., 2016; Arras et al., 2016) or inherently interpretable methods (Lei et al., 2016; Guerreiro and Martins, 2021). In our submission, we opted to use attention-based methods as they achieved the best results in the previous constrained track of the Explainable QE shared task (Fomicheva et al., 2021). Concretely, we take inspiration in the method developed by Treviso et al.

Table 1: Results for sentence-level QE in terms of Spearman correlation for DA.

(2021), which consists of scaling attention weights by the ℓ_2-norm of value vectors (Kobayashi et al., 2020) and finding the attention heads with the best performance on the dev set, and propose two new modifications:

- **Attention × GradNorm:** Following the findings of Chrysostomou and Aletras (2022), we decided to extract explanations that consider both attention and gradient information. More precisely, we scale the attention weights by the ℓ_2-norm of the gradient of value vectors:

$$\boldsymbol{A}_{\ell,h} \left\| \nabla \boldsymbol{V}_{\ell,h} \right\|_2 . \tag{6}$$

- **Head Mix:** We reformulate the scalar mix module (Eq. 2) to consider different weights for representations coming from different attention heads as follows:

$$\boldsymbol{H}_{\text{mix}} = \lambda \sum_{\ell=0}^{L} \beta_\ell \sum_{h=1}^{H} \gamma_{\ell,h} \boldsymbol{h}_{\ell,h}, \tag{7}$$

where the *layer* mix coefficients $\boldsymbol{\beta} \in \triangle^L$ are given by $\boldsymbol{\beta} = \pi(\boldsymbol{\phi})$, and the *head* mix coefficients $\boldsymbol{\gamma}_\ell \in \triangle^H$ are given by $\boldsymbol{\gamma}_\ell = \pi(\boldsymbol{\theta}_\ell)$. $\lambda \in \mathbb{R}$, $\boldsymbol{\phi} \in \mathbb{R}^L$ and $\boldsymbol{\theta} \in \mathbb{R}^{L \times H}$ are learnable parameters. We experimented both with dense (π as softmax) and sparse (π as sparsemax, Martins and Astudillo 2016) transformations. After training, the Head Mix coefficients can help to find attention heads with high validation performance, which is helpful for explaining zero-shot LPs.

Furthermore, since all of our sentence-level models use subword tokenization, to get explanations for an entire word we follow Treviso et al. (2021) and sum the scores of its word pieces.

Ensembling explanations. In our final submissions we average the explanation scores of different attention heads and layers to create a final explainer. We decided which heads and layers to aggregate together by looking at their performance on the dev set, selecting the top-5 with the highest explainability score.

3.3 Task 3: Critical Error Detection

Critical translations are defined as translations with strongly semantic deviations from the original source sentence, with the potential to lead to negative impacts in critical applications. The goal of this task is to predict sentence-level scores indicating whether a translation contains a critical error. Since the evaluation metrics automatically account for different binarization thresholds to separate good translations from bad ones, for this task we employed a single sentence-level InfoXLM model from Task 1 that was trained on DA data. Moreover, we participated only in the *constrained setting*, meaning that we did not trained our systems specifically for this task. Therefore, our goal for this task was to validate whether our QE system from Task 1 was able to detect and differentiate translations with critical errors.

4 Experimental Results

As we have seen in Section 3, for our experiments we split the provided development sets into two equal size halves creating a new internal devset and an internal testset. The resulting sets contain ≈ 500 segments per language pair for both DA and MQM, word and sentence-level. As for baselines we used our submitted systems from previous shared tasks: for Task 1 we used the M1M-ADAPT (Zerva et al., 2021), and for Task 2 we used the Attn × Norm explainer (Treviso et al., 2021). The official results for Task 1 and Task 2 are shown in Table 6.

4.1 Quality Estimation

Sentence-level submissions were evaluated using the Spearman's rank correlation. Pearson's correlation, MAE, and RMSE were also used as secondary metrics, but here we report only Spearman correlation since it was the primary metric used to rank systems. Word-level submission were evaluated using MCC, F_1-OK, and F_1-BAD, but we report only MCC as it was considered the main metric. The submitted systems were independently evaluated on in-domain and zero-shot LPs for direct assessments and MQM.

Direct Assessments. Results for sentence-level DAs can be seen in Table 1. The results show that the training strategies employed in COMETKIWI, namely (i) pretraining models using Metrics data and (ii) incorporating references into training, lead to a correlation close to our best system from last year while disregarding the data from the MLQE-PE corpus. When fine-tuning on MLQE-PE data, we get overall improvements of $\sim$ 4%, and further fine-tuning on new LPs gives $\sim$ 1% overall improvement. Still, for the unseen LPs (*km-en, ps-en, en-ja, en-cs*), we got improvements between 2-3% with just 500 samples. Among the three backbone transformers, we noticed that InfoXLM is the one that leads to a higher Spearman correlation (+1.7% than XLM-R and RemBERT). Furthermore, including word-level supervision always maintains or improves the results, especially for InfoXLM. In contrast, RemBERT does not seem to benefit from this signal. We suspect that, for this task, the benefit of word-level supervision is not higher because the word-level information is coming from post-editions, which are conceptually different from DA annotations.

Table 2: Results for sentence-level QE in terms of Spearman correlation for MQM.

MQM. Results for sentence-level MQM systems are shown in Table 2. The results show that the two main techniques used for adapting to MQM data, filtering DA data to the three MQM LPs and using MQM data for fine-tuning, improved Spearman correlations for all LPs over the pure DA baseline, for both sentence-level and multi-task systems. However, these techniques improved certain LPs more than others, so combining them together improved multilingual scores even further. Overall, we noticed that our results for MQM data have a high variance. To mitigate this, we concatenated the DA and MQM datasets together for a single fine-tuning, resulting in our best individual system on our internal test set. Due to these peculiarities in the MQM LPs, we decided to ensemble systems tuned on both DA and MQM data. Our final ensemble did not have as strong results as the individual systems on our internal test set, yet, it showed superior performance upon submission to codalab leader-board.

Word-level. For the word-level task we tuned models separately for the LPs that consisted of post-edit-derived word tags and the ones consisting of MQM-derived word tags; we report the Matthew's correlation coefficient (MCC) in Table 3. We experimented with multi-tasking by adding sentence-level supervision to the word-level task and found

that it boosts performance especially for the out-of-English translations. For the non-MQM LPs we used the HTER scores as sentence level targets as we found they lead to significantly higher correlations. We can also see that using the sentence-mix and the language prefix boosted the performance for all LPs, both in the MQM and post-edit originated LPs. Overall, the results show further improvements when we use the HTER scores of APEQuest and QT21 as additional pretraining data, but only for specific LPs. These findings merit further investigation, since the directionality of the LPs seems to have impacted our experiments. Finally, ensembling led to better results across all languages. Ensembling the logits led to better results for the post-edit originated LPs, while word-level ensembling helped more the MQM-originated LPs. Yet, in the submitted versions we found that the difference in performance between the three ensembling methods yielded similar results, with only 1-2% difference, while in the averaged multilingual versions these differences were even smaller, varying less than 0.1%.

4.2 Explainable QE

Since the explanations are given as continuous scores, they are evaluated against the ground-truth word-level labels in terms of the Area Under the Curve (AUC), Average Precision (AP), and Recall at Top-K (R@K) metrics only on the subset of translations that contain errors. Although R@K was considered the main metric for this task, we optimized internally for the average of all three metrics. The results are shown in Table 4.

Discussion. The results highlight several contrasts between explanations for DA and MQM data: (i) while RemBERT is useful as an encoder for DA data (outperforms InfoXLM in 3 out of 5 LPs), it is outperformed by InfoXLM for all MQM LPs; (ii) the Head Mix component improves performance for DA, but it does not impact significantly the scores for MQM; and (iii) the Sparse Head Mix generally outperforms the Soft Head Mix for DA, but the trend flips for MQM. On what comes to the explainability methods, the baseline method (Attn × Norm – scaling the attention weights by the ℓ_2-norm of value vectors), which obtained the best results in last year's Explainable QE shared task, is outperformed by our new method (Attn × GradNorm) for both DA and MQM data. Moreover, ensembling explanations from different heads brings further consistent improvements across the board for all LPs. For the zero-shot setting (*en-yo*), we build an ensemble of explanations by using the heads that were more common among the ensembles for all other LPs. This approach might be worth researching further, since it is possible to study the Head Mix coefficients to select good-performing attention heads.

5 Official Results

We present the official results of our submissions alongside the results from other competitors in Section B for all three tasks. For sentence-level, our submissions achieved the best results for 6/9 LPs. For word-level, we obtained the best results for 5/9 LPs. For the explainable QE track, we obtained the

best results for all but two LPs (*km-en* and ps-en). Although the critical error detection task had no other competitor for the *constrained setting*, our submission vastly surpassed the organizers' baseline. We also obtained the best results for the multilingual settings (including and excluding *en-yo*) for all tasks. Finally, when averaging the results for all LPs, our submissions place on top for all tasks.

6 Conclusions and Future Work

We presented the joint contribution of IST and Unbabel to the WMT 2022 QE shared task. We found that incorporating references during pretraining improves performance across several LPs on downstream tasks, and that jointly training with sentence and word-level objectives yields a further boost. For Task 1, our final submissions were ensembles of models finetuned with different pretrained language models as encoders, boosting the results when compared to the previous year submission. For Task 2, we take inspiration on the literature of explainability and propose to use gradient information in tandem with attention weights, and to further refine the impact of attention heads towards the prediction via the Head Mix component. Besides leading to better explainability performance for some LPs, this strategy is potentially useful to identify good attention heads at inference time for zero-shot LPs, and deserves more investigation. Overall, our submissions achieved the best results for all tasks (including Task 3) for almost all LPs by a considerable margin.

One of the challenges of leveraging big ensembles is the burdensome weight of parameters and inference time. For future work we will extend our recent work, COMETINHO (Rei et al., 2022) and explore how to effectively distill large ensembles into small and more practical QE systems.

A Data Information

The data used for finetuning our QE systems is shown in Table 5. For DA data, we split the original development set to generate a new dev/test split, therefore the reported numbers in the table correspond to this "internal" dev split.

Abstract

Quality estimation (QE) is a crucial method to investigate automatic methods for estimating the quality of machine translation results without reference translations. This paper presents Huawei Translation Services Center's (HW-TSC's) work called CrossQE in WMT 2022 QE shared tasks 1 and 2, namely sentence- and word- level quality prediction and explainable QE. CrossQE employes the framework of predictor-estimator for task 1, concretely with a pre-trained cross-lingual XLM-RoBERTa large as predictor and task-specific classifier or regressor as estimator. An extensive set of experimental results show that after adding bottleneck adapter layer, mean teacher loss, masked language modeling task loss and MC dropout methods in CrossQE, the performance has improved to a certain extent. For task 2, CrossQE calculated the cosine similarity between each word feature in the target and each word feature in the source by task 1 sentence-level QE system's predictor, and used the inverse value of maximum similarity between each word in the target and the source as the word translation error risk value. Moreover, CrossQE has outstanding performance on QE test sets of WMT 2022.

1 Introduction

Quality estimation (QE) is the task of evaluating a translation system's quality without access to reference translations (Specia et al., 2018). In WMT 2022 QE shared task [1], there are three tasks — Quality Prediction, Explainable QE and Critical Error Detection. Each task involves several language pairs. Our team — Huawei Translation Services Center (HW-TSC) — participated in quality prediction and explainable QE tasks over all language pairs.

This paper describes the HW-TSC's systems called CrossQE submitted for these tasks. Some key steps are summarized as follow:

- We used pre-trained Cross-lingual XLM-Roberta large (Lample and Conneau, 2019; Conneau et al., 2019) as predictor instead of RNN-based model in the two-stage Predictor-Estimator architecture (Kim et al., 2017). The task-specific classifier or regressor is used as quality estimator, and multitasks are trained at the same time.

- The cross-lingual XLM-RoBERTa large model is pre-trained on large-scale parallel corpora where source and target tokens are concatenated by MLM task. Shuffling those tokens and predicting those tokens' index by the pre-trained model as an additional pre-training task can improve the QE model's effect.

- We build on the COMET architecture [2] by exploring adapter layers (Houlsby et al., 2019) for quality estimation to eliminate the overfitting problem instead of fine-tuning the whole base pre-trained model for different NLP tasks (He et al., 2021).

- In the training step, the Mean Teacher loss (Baek et al., 2021) was added to improve model's over-fitting problem.

- We explored data augmentation a method based on Monte Carlo (MC) dropout (Gal and Ghahramani, 2016) which to enhance the performance in sentence-level Direct Assessment (DA) and Multidimentional Quality Metrics (MQM) score task. During prediction, the dropout function is still enabled, and the prediction is performed for N times. The average value of the prediction is the final prediction value.

- We used QE model's predictor of the sentence-level quality prediction sub-task as a words' features. extractor cosine similarity's opposite value of target words' vectors extracted from the predictor trained from sentence-level quality prediction sub-task between source and target as the explainable QE task's token-level scores.

Our methods achieve impressive performance on both sentence- and word- level tasks. Specifically, we peak the top-1 on quality prediction sentence-level sub-task over Chinese-English language pair and word-level sub-task over English-Japanese language pair. We also win the first place in explainable QE task in Khmer-English and Pashto-English language pairs. We will describe the datasets and our methods for those tasks in section 2 and section 3. Section 4 presents details of our experimental setup and results. In section 5, a brief discussion and conclusion are presented.

2 Task & Data Set

2.1 Task Description

Task 1

The quality prediction task follows the trend of the previous years in comprising a sentence-level sub-task where the goal is to predict the quality score for each source-target sentence pair and a word-level sub-task where the goal is to predict the translation errors, assigning OK/BAD tags to each word of the target. Both sub-tasks include annotations derived in two different ways, depending on the language pair: direct assessment (DA), following the trend of the previous years, and multidimensional quality metrics (MQM), introduced for the first time in the QE shared task. The sentence- and word-level sub-tasks use the same source-target sentences for each language pair.

Task 2

The explainable QE task proposes to address translation error identification as rationale extraction. Instead of training a dedicated word-level model, to infer translation errors as an explanation for sentence-level quality scores, a list of continuous token-level scores where the tokens with the highest scores are expected to correspond to translation errors should be calculated.

2.2 Data Set & Data Processing

Some information about the data set is as follow:

There are three language pairs annotated with MQM annotations for training/development/test set: English-Russian (En-Ru), English-German (En-De), Chinese-English (Zh-En) and the one language pair annotated with DA annotations for training/development/test set: English-Marathi (En-Mr).

The data set of these four language pairs contains 15k training data for En-Ru, 26k training data for En-De, 31k training data for Zh-En, 26k training data for En-Mr and 1k development data for each language pair.

There are seven language pairs annotated with DA annotations for training/development ser: English-German (En-De), English-Chinese (En-Zh), Esthonian-English (Et-En), Nepali-English (Ne-En), Romanian-English (Ro-En), Russian-English (Ru-En), Sinhala-English (Si-En), and four zero-shot language pairs annotated with DA annotations for test set: English-Czech (En-Cs), English-Japanese (En-Ja), Khmer-English (Km-En) and Pashto-English (Ps-En). The data set of these seven language pairs contains 9k training data and 1k development data.

The word-level sub-task data set consists of predicting word-level tags for the target side (to detect mistranslated or missing words). Each token is tagged as either OK or BAD. The OK/BAD tags are provided for each of the language pairs of the sentence-level task, and are derived from either MQM annotations (En-De, Zh-En and En-Ru) or post-edited sentences.

So for MQM language pairs, it is a few-shot task, and for DA language pairs, it is a zeor-shot task. For training data of each language pair, sentence scores are linearly normalized from 0 to 1, and can be restored to the original value, so a multilingual sentence-level QE model can be trained for all language pairs.

3 Methodology

3.1 System

Task 1

Our quality estimator system follows the two-stage Predictor-Estimator architecture, which uses a languange model encoder as predictor and using task-specific classifier or regressor as estimator (Chen et al., 2021). In our system, the predictor is a pre-trained cross-lingual XLM-RoBERTa model (f). For the sentence-level quality score prediction task, the estimator is a regressor (σ_{score}), and for the word-level quality label prediction task, the estimator is a classifier (σ_{class}), as depicted in figure 1.

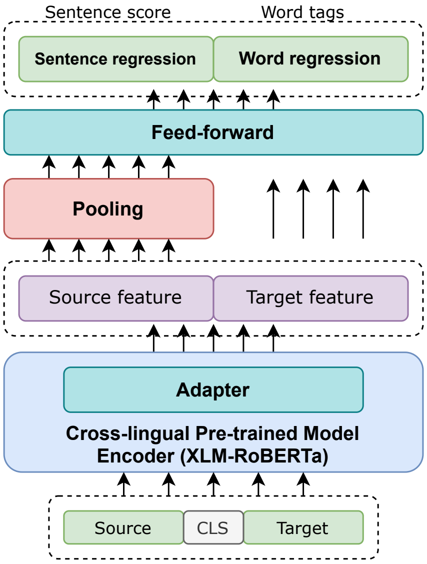

Figure 1: The architecture of CrossQE quality estimator system

Sentence-level

After the predictor obtaining tokens embedding features (H_s, H_t; where H_s for source embedding features and H_s for target embedding features), we use masked pooling p to calculate the entire source or target sentence feature vector. In the experiment, we put combination of [source, target] ($[S, T]$) and [target, source] ($[T, S]$) as the input data into the predictor, and get four types of sentence feature vectors ($F_{s_A}, F_{t_A}, F_{t_B}, F_{s_B}$). All the sentence feature vectors are combined to the estimator perform score prediction, and the performance is improved obviously.

Word-level

In the task, OK is set to 1 and BAD is set to 0, thus the word-level estimator becomes a binary classification model. To avoid overfitting, the OK label is set to 0.9, the BAD label is set to 0.1, and the index 0's value of outputs softmax logits is used as the word quality score ($V_{w-score}$). The mean squared error (MSE) loss is calculated on the outputs and labels and the word-level QE model is updated. In the prediction phase, if the output word score is greater than 0.5, it is considered as an OK label. Otherwise, it is considered as a BAD label.

The equation of task 1 is shown as equation 1:

$$\begin{aligned}
H_{s_A}, H_{t_A} &= f([S, T]), \\
F_{s_A}, F_{t_A} &= p(H_{s_A}, H_{t_A}), \\
H_{t_B}, H_{s_B} &= f([T, S]), \\
F_{t_B}, F_{s_B} &= p(H_{t_B}, H_{s_B}), \\
V_{score} &= \sigma_{score}([F_{s_A}, F_{t_A}, F_{s_B}, F_{t_B}]), \\
V_{class} &= \sigma_{class}([H_{s_B}, H_{t_B}]), \\
V_{w-score} &= softmax(V_{class})[0]
\end{aligned} \tag{1}$$

Where V_{score} is output of the sentence-level estimator and V_{class} is logits of the word-level estimator.

Task 2

We use the sentence-level QE model's predictor from task 1 as a sentence word embedding feature extractor. Similarity is used as the possibility of word translation (Yang et al., 2022). If a word in target is highly similar to a word in source, the word translation is correct. Otherwise, the word translation is incorrect. The higher the similarity, the higher the probability of correct translation, and vice versa.

We extracted the source and target sentence embedding features by word and calculated the cosine similarity between each word feature in the target and each word feature in the source. The maximum similarity between each word in the target and the source is used as the score of the word translation quality. We used the inverse of the quality score of each word in the target as the translation error risk value, so each target sentence can obtain a word error risk value list, in which a higher score indicates a higher probability of incorrect translation.

3.2 Model Pre-training

Cross-lingual Language Model

As XLM-RoBERTa, a multilingual model that can override the QE tasks' language pairs, does a good job with language tasks, it was chosen as the predictor. Cross-lingual language model pre-training is outstanding in low-resource training data. We add [CLS] between the tokens of the source text and the tokens of the target text and input the combined tokens to the XLM-RoBERTa model for masked language modeling (MLM) task pre-training (Devlin et al., 2018) to enhance the model's ability to understand words and sentences between languages. We sampled randomly 15% of the sub-word tokens from the text streams, replaced them by a [MASK] token in 80% probability, by a random token in 10% chance, and we keeped them unchanged in 10% chance.

Token Shuffling Pre-training

We randomized the sequence of input tokens and let the cross-lingual language model predict the sequence number of' each token. This pre-training task has an obvious positive effect on word-level QE sub-task. Because the model has never done a position prediction task, the training task is divided into two stages for the sake of training stability. In stage one, 50% of the tokens are selected and shuffled, and in stage two, all the tokens are shuffled.

3.3 Bottleneck Adapter Layer

The provided training set is relatively small, making the model to be easily over-fitted if all weights are updated. Therefore, we decided to integrate the Bottleneck Adapter Layers (BAL) (Wang et al., 2020) while keeping parameters of the original Transformer fixed (Yang et al., 2020). The bottle with a "thick" neck could further improve the performance without seriously sacrificing training efficiency. By increasing the parameter size of BALs, the performance also increased linearly, finally reaching the peak of 104% of the baseline performance with the neck having twice the hidden size.

3.4 Model Training

Mean Teacher Loss

Mean teacher is a method that uses consistency regularization. As shown in figure 2, the process is as follows:

1) Copy the predictor as a teacher model and the original model as a student model.

2) At the training step, apply two random augmentations η and η' on the same mini-batch tokens' embedding features.

3) Input the former data $(Input_{embedding} + \eta)$ to the student model and the latter data $(Input_{embedding} + \eta')$ to the teacher model.

4) Calculate the MSE loss on their outputs.

5) Use the MSE loss to update the t th iter's parameters of the student model $P_{stu}[t]$.

6) Use the exponential moving average (EMA) method to update the t th iter's parameters of the teacher model $P_{tea}[t]$ as shown in equation 2.

$$P_{tea}[t] = \alpha \times P_{tea}[t-1] + (1-\alpha) \times P_{stu}[t] \quad (2)$$

Where, α is a hyperparameter (0.95 in this paper).

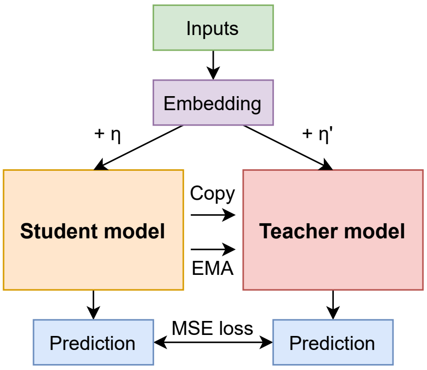

Figure 2: Mean teacher loss

MLM Task Loss

To further improve the language understanding capability of the model, we add MLM task loss into the training. We find adding MLM training task during the training of sentence-level and word-level QE models for multi-task training can improve the model performance.

Total loss for the CrossQE system to update model parameters is shown as equation 3:

$$\begin{aligned} Loss = \alpha_1 \times [Loss_s|Loss_w] + \\ \alpha_2 \times Loss_{MT} + \alpha_3 \times Loss_{MLM} \end{aligned} \quad (3)$$

Where, α_1, α_2 and α_3 are hyperparameters, $[Loss_s|Loss_w]$ is the sentence-level or word-level sub-task training loss, $Loss_{MT}$ is the mean teacher loss and $Loss_{MLM}$ is the MLM task loss.

4 Experiments & Results

4.1 Model Settings

We followed the model settings of COMET (Rei et al., 2022) to fine-tune our QE model based on the XLM-RoBERTa large model [3] with a classification/regression head on a single V100 GPU. The XLM-RoBERTa large model pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages is a multilingual version of RoBERTa which is a transformers model pretrained on a large corpus in a self-supervised fashion. It has approximately 550M parameters and 24 hidden encode layers. The training batch size is set to 4, the gradient accumulation number is set to 4 and it took about 2 hours for the model to converge in the training step. The XLM-RoBERTa large model has been pre-trained on the WMT 2021 news translation shared task's parallel corpora [4] by model pre-training methods described in the section 3.2.

4.2 Experiments of Sentence-level QE Task

In our experiment, we set $\alpha_1 = 1.0$, $\alpha_2 = 0.5$ and $\alpha_3 = 0.5$ (we also set $\alpha_1 = 1.0$, $\alpha_2 = 1.0$, $\alpha_3 = 1.0$ or $\alpha_1 = 0.5$, $\alpha_2 = 1.0$, $\alpha_3 = 0.5$ or $\alpha_1 = 0.5$, $\alpha_2 = 0.5$, $\alpha_3 = 1.0$ or $\alpha_1 = 0.5$, $\alpha_2 = 1.0$, $\alpha_3 = 1.0$, but all of them can not get the best result). Our baseline model is the COMET's open-source framework model with the self pretrained XLM-RoBERTa model as predictor. The primary evaluation metric for the sentence-level sub-task of Task 1 is the spearman r coefficient as show in Table 1.

Obviously, the performance of the baseline model is relatively poor. By leveraging Cross-lingual language model as predictor (M-Cross model), the model achieved much better performance. Adding the BAL adapter (M-Adapter model) into Cross-lingual language model, the effect is further improved. In the experiment, it is found that excessive training leads to reduced effectiveness on development set, while the addition of mean tearcher loss (M-MT model) can significantly suppress the overfitting problem and further improve the model performance. Adding the MLM loss (M-MLM model) to the training process enhances the model performance to some degree. Finally, the MC dropout method is used to predict the QE sentence-level scores (M-Final model), which can improve the performance coefficient by at least 1%.

Finally, we committed our results of M-Final model on the test set. The performance of the system on the test set is shown in Table 3. For the zero-shot data, the system also has good performance. Specifically, we get the best performance on Zh-En language pair.

4.3 Experiments of Word-level QE Task

In our experiment, we set $\alpha_1 = 0.5$, $\alpha_2 = 1.0$ and $\alpha_3 = 1.0$ (we also set $\alpha_1 = 1.0$, $\alpha_2 = 1.0$, $\alpha_3 = 1.0$ or $\alpha_1 = 0.5$, $\alpha_2 = 1.0$, $\alpha_3 = 0.5$ or $\alpha_1 = 0.5$, $\alpha_2 = 0.5$, $\alpha_3 = 1.0$ or $\alpha_1 = 1.0$, $\alpha_2 = 0.5$, $\alpha_3 = 0.5$, but all of them can not get the best result). Our baseline model is the cross-lingual language model that is used as predictor by the COMET's open-source framework. The primary evaluation

Language	MCC

Table 5: Results for the task 2 target recall at top-K's performance on the test set over eight language pairs.

metric for the word-level sub-task of Task 1 is the matthews correlation coefficient (MCC) as shown in Table 1.

Compared with the baseline, the model has better performance after the BAL adapter is added (M-Adapter model). Also, the addition of mean tearcher loss (M-MT model) can further improve the model pereformance. However, we found after adding the MLM loss to the training process (M-Final model), there were no significant improvement in pereformance.

Finally, we committed our results of M-Final model on the test set. The performance of the system on the test set is shown in Table 4. For the zero-shot data, the system also has good performance. Specifically, we get the best performance on En-Ja language pair.

4.4 Experiments of Explainable QE Task

As stated in the mission requirements, the participants are not allowed to supervise their models with any token-level or word-level labels or signals (whether they are from natural or synthetic data) in order to directly predict word-level errors. We just used the sentence-level quality prediction model's predictor as the sentence word embedding feature extractor, and calculated the translation error risk value as stated in section 3.1.

Finally, we committed our results on the test set. The performance of the system on the test set is shown in the Table 5. We get the best performance on the Km-En and Ps-En language pairs.

5 Conclusion

This paper presents HW-TSC's work called CrossQE on WMT 2022 QE shared task. CrossQE got the first place in four single projects. For the tasks 1, CrossQE employed the predictor-estimator framework as baseline. To further boost performance, we investigated the usage of pre-trained cross-lingual XLM-RoBERTa large language model as predictor, and added the bottleneck adapter layer into the predictor to mitigate overfitting issues. For both sentence- and word- level sub-task, we added mean teacher loss and MLM task loss into model training step, and added MC dropout at the inference step in sentence-level sub-task. Those methods delivered a good performance in all language pairs, including zero-shot language pairs. For task 2, we used the sentence-level QE model's predictor from task 1 as a sentence word embedding feature extractor, and used the inverse value of maximum similarity between each word in the target and the source as the word translation error risk value. In future, we will invest time and effort in studying the effect of involving additional translations into QE tasks, for example, how the additional translation quality will affect QE performance.

Abstract

This paper presents our submission to the WMT 2022 quality estimation shared task and more specifically to the quality prediction sentence-level direct assessment (DA) subtask. We build a multilingual system based on the predictor–estimator architecture by using the XLM-RoBERTa transformer for feature extraction and a regression head on top of the final model to estimate the z-standardized DA labels. Furthermore, we use pretrained models to extract useful knowledge that reflect various criteria of quality assessment and demonstrate good correlation with human judgements. We optimize the performance of our model by incorporating this information as additional external features in the input data and by applying Monte Carlo dropout during both training and inference.

1 Introduction

Machine translation quality estimation (MTQE) is the task of automatically estimating the quality of the MT output without using reference translations or any other human input (Blatz et al., 2004; Specia et al., 2009, 2018). MTQE has many use cases and can be applied in various settings (Specia and Shah, 2018). It can be used to estimate the post-editing effort, to rank and compare outputs of different MT systems or to classify the segments that need post-editing. It can also be used to estimate the quality of the final translations as well as to filter out noisy segments from translation memories or training datasets. MTQE techniques usually have multiple granularity levels and can be applied to a word, phrase, sentence or even to an entire document. Such systems are highly efficient when a vast amount of machine translated segments need to be evaluated in less time, with less effort and lower costs compared to traditional evaluation techniques.

The WMT 2022 quality estimation shared task includes the following separate tasks: quality prediction, explainable QE and critical error detection. Our team participated in the quality prediction sentence-level direct assessment (DA) subtask with a multilingual MTQE system.

Specifically, we developed a cross-lingual MTQE system following the predictor–estimator architecture (Kim and Lee, 2016; Kim et al., 2017). We used the large-scale pretrained XLM-RoBERTa (XLM-R)[1] model (Conneau et al., 2020) for feature extraction, similarly to Chen et al. (2021). We combined the model's output with additional external features that demonstrate good correlation with the target variable. We then used the concatenated vector as input to our final MTQE regression model. Our regressor is a feed-forward neural network with a linear output layer used to estimate the z-standardized DA labels.

2 Quality prediction: sentence-level direct assessment

The quality prediction task of the WMT 2022 quality estimation shared task consists of a sentence-level and a word-level subtask. Using the provided annotated training data, the objective of the sentence-level direct assessment subtask is to develop a system that automatically estimates a quality score for each provided sentence pair which is highly correlated with human-generated z-standardized DA values.

2.1 Data

According to the instructions, for each language pair, participants can use all the annotations offered for the quality estimation shared tasks of the preceding year(s) that are accessible through the MLQE-PE GitHub page.[2]

MLQE-PE is a multilingual dataset for quality estimation which includes 11 language combinations covering low, medium and high re-

source languages (Fomicheva et al., 2020a,c). The dataset is mainly created by translating sentences from Wikipedia articles using cutting-edge transformer NMT models, and by having expert linguists annotate the translations based on a modified version of DA ratings. Each sentence is annotated individually using the FLORES setup (Guzmán et al., 2019), in which three qualified translators provide evaluations on a scale of 0–100 based on their perceived translation quality. Raw DA scores are then standardized and transformed into z-scores by using the mean and standard deviation of every single annotator. The z-standardized per-annotator values are then averaged in order to get one final score for every translation.

The organizers also provide additional train, development, and test sets for the English–Marathi language pair that is not included in the MLQE-PE dataset.

language pair	Train	Dev.	Test

Table 1: Size of the provided train, development and test sets per language (in sentences)

The data for the sentence-level quality prediction subtask can be downloaded from the task's GitHub page.[3] The number of the available sentences per language is illustrated in the Table 1.

According to the instructions, it is also feasible to use the DA annotations that were generated for the metrics shared tasks in previous years.

For the training of our models, we use only the training part of the data provided by the organizers. For the English–Japanese language pair, we also use the training data of the 2020 metrics shared task.

2.2 Evaluation

This year, the primary evaluation metric for the sentence-level DA subtask is the *Spearman*'s rank correlation coefficient which is used to reflect the correlation between the predicted scores and the human annotated z-standardized DA labels. Secondary metrics also include MAE, RMSE, and *Pearson*'s correlation coefficient.

3 Method

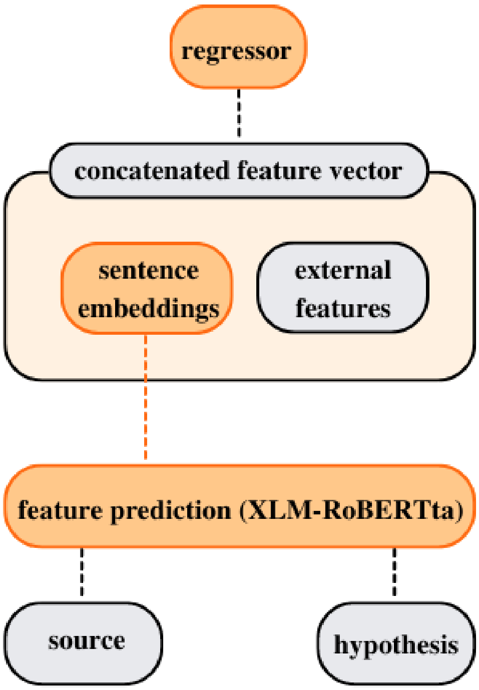

Figure 1: Model architecture

For the sentence-level direct assessment subtask we build and use a system based on the predictor–estimator architecture (Kim and Lee, 2016; Kim et al., 2017). Following similar state-of-the-art approaches (Fomicheva et al., 2020b; Moura et al., 2020; Rei et al., 2020; Zerva et al., 2021; Chen et al., 2021; Wang et al., 2021) we choose the pretrained XLM-RoBERTa[1] model (Conneau et al., 2020) to encode the input sequences and predict our features. We keep the XLM-R encoder frozen during training and we use it to generate cross-lingual representations over the source sentences and their corresponding translations. We then concatenate the output with additional external features and we feed the final feature vector to a feed-forward layer to finally estimate the continuous

[3] https://github.com/WMT-QE-Task/wmt-qe-2022-data/

z-standardized DA scores. We also employ Monte Carlo dropout during both training and inference to optimize the performance of our model. We use the mean-squared-error loss function and the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 10^{-5}. The architecture of our model is illustrated in the Figure 1.

3.1 Cross-lingual Representations

In order to extract cross-lingual representations for each sentence pair, we start by encoding each source sentence and its hypothesis separately. From the output vectors, we extract the <s> classification token (equivalent to the [CLS]) that corresponds to the representation of the whole sequence (Ranasinghe et al., 2020). Then, similarly to the methodology proposed in RUSE (Shimanaka et al., 2018), we use the following sentence embeddings:

- Source embedding representation: $\vec{s}$
- Hypothesis embedding representation: $\vec{h}$
- Element-wise product: $\vec{s} \circ \vec{h}$
- Element-wise absolute difference: $| \vec{s} - \vec{h} |$

Motivated by the implementation of Rei et al. (2020), we concatenate the above representations into a single vector. Furthermore, we enrich the vector with additional external features $\vec{f}$ resulting in a final feature vector $\vec{x} = \left[\vec{f}; \vec{h}; \vec{s}; \vec{s} \circ \vec{h}; |\vec{s} - \vec{h}|\right]$, which is used as input to the output layer of our model.

3.2 Additional external features

Fomicheva et al. (2020c) suggested the use of glass-box features to predict the quality of the NMT outputs. Specifically, they proposed methods to quantify the model's uncertainty in unsupervised QE scenarios. Moura et al. (2020) and Zerva et al. (2021) also used such glass-box features as an effective strategy for the development of their QE systems. In our approach, we use the sentence-level NMT model scores included in the MLQE-PE dataset (Fomicheva et al., 2020a,c) and we further explore additional characteristics that can be effectively used in similar QE settings. We suggest a set of external features that reflect various criteria of translation quality assessment and exhibit good correlation with human judgements, as illustrated in Table 2.

Masked Language Model scores
(features: src_ppl, hyp_ppl, diff_ppl)

According to Lau et al. (2017), language models (LMs) can be effectively used to estimate linguistic acceptability judgements. Salazar et al. (2020) showed that pseudo-log-likelihood scores (PLLs) and their corresponding pseudo-perplexities (PPPLs) derived from masked language models (MLMs) can help to distinguish linguistically acceptable from unacceptable sentences in an unsupervised way with comparable performance to large unidirectional autoregressive LMs. Based on the above observation, our primary objective is to derive scores at the sentence level that reflect the overall likelihood that the model gives to an entire sentence. We choose the multilingual XLM-RoBERTa[1] model and compute PLL scores by iteratively masking all tokens of the sequence. We generate PLL scores for both the source and the hypothesis and then we also calculate their absolute difference.

NMT Model scores
(features: model_scores)

According to Fomicheva et al. (2020c), seq2seq NMT models can provide meaningful insights for measuring the model's uncertainty that can be effectively used to estimate translation quality. At each timestep, the NMT system returns the probability distribution for every token in the sequence by applying a softmax function over the target language vocabulary. The token-level probabilities are then used to compute a sentence-level log-likelihood score. In our implementation we extracted this feature directly from the MLQE-PE dataset (Fomicheva et al., 2020a,c). Even if this information is already included in the provided dataset, we also decided to build another model, similar to the one described in this paper, that predicts these specific values when there is no access to the NMT system used to produce the translations.

Independent NMT Model scores
(features: M2M100_loss)

We use the pretrained M2M100 multilingual seq-to-seq model (Fan et al., 2020) to re-score the provided NMT outputs for each sentence pair. Our objective is not to generate a new hypothesis for each source sentence, but to compare every given hypothesis with the prediction produced by another multilingual translation system. The final score corresponds to the calculated cross-entropy loss when comparing the generated prediction of the M2M100 model to the provided NMT hypothesis.

Semantic Textual Similarity scores
(features: cos_sim)
Sentence similarity corresponds to the task of automatically identifying how similar or dissimilar two texts are. Neural models compare sentences by initially transforming them into semantic vectors, also known as sentence embeddings. We use the LaBSE[4] (Feng et al., 2022) pretrained model through the sentence transformers library (Reimers and Gurevych, 2019, 2020) to obtain a vector representation for every source sentence and its hypothesis. Then we compare their embeddings and get a cosine similarity score at sentence level.

COMET scores
(features: COMET_qe)
COMET (Rei et al., 2020) is a multilingual MT quality evaluation framework that demonstrates high correlation with human judgements. In our implementation, we use the reference-free wmt21-comet-qe-mqm[5] model (Rei et al., 2021), pretrained based on the MQM benchmark, which can be computed automatically without having available any reference translation. In this way, we are able to get one predicted score for every sentence and use this value as an additional feature during the training of our model.

HTER scores
(features: hter_scores)
The translation edit rate (TER) (Snover et al., 2006) calculates the editing operations needed to transform an MT output into a version that exactly matches at least one candidate translation among a list of gold-standard reference texts. The human-targeted translation edit rate (HTER) (Snover et al., 2006) is another version of the TER metric which incorporates the human factor in the process and requires human post-edits of the MT output. Even if this information is already included in the MLQE-PE dataset, we use the available HTER annotations in order to train another model, similar to the one described in this paper, that estimates the post-editing effort by predicting HTER scores for each source sentence and its translation. We finally use this information as an additional external feature for our final model.

The *Spearman* and *Pearson* correlation between all the aforementioned features and the target variable can be found in the Table 2. Based on these values, it seems that the features with the highest correlation are the cosine similarity (cos_sim), the COMET qe (COMET_qe), and the human-targeted translation edit rate (hter_scores). The NMT model scores (model_scores) and the independent NMT model scores (M2M100_loss) also demonstrate a moderate correlation with the z-standardized DA scores, while the masked language model scores (src_ppl, hyp_ppl, diff_ppl) have quite lower correlation comparing to the rest.

features	***Spearman* r**	***Pearson* r**
src_ppl	-0.15	-0.16
hyp_ppl	-0.14	-0.14
diff_ppl	-0.11	-0.13
M2M100_loss	-0.29	-0.25
cos_sim	0.34	0.40
COMET_qe	0.42	0.41
model_scores	0.25	0.30
hter_scores	-0.37	-0.37

Table 2: *Spearman* and *Pearson* correlation between the external selected features and the z-standardized DA scores. Features are described one by one in section 3.2.

3.3 Monte Carlo dropout

Dropout refers to randomly dropping nodes while training a neural network (Srivastava et al., 2014) and it is an effective strategy to prevent a model from overfitting. During training we use Monte Carlo dropout with a rate of 0.1 to mask random neurons of the model. Likewise, during inference we perform numerous iterations for each test instance and in this way we obtain a different score each time for the same instance by applying Monte Carlo dropout. Then, we use all the model's estimates to get an average score for every single sentence.

4 Experimental Results

In this section we present the performance of our model on the provided test dataset for the WMT 2022 shared task on quality evaluation for the prediction of sentence-level direct assessments. In particular, our model outperformed the baseline system in terms of *Spearman* and *Pearson* correlation in all the multilingual and bilingual tasks, in which we participated, as illustrated in the Tables 3 and 4 respectively. In the multilingual (full) sub-

baseline model	0.393	0.511	0.576	0.273	0.525	0.568

Table 4: *Pearson*'s correlations of the 2022 sentence-level DA subtask

task we were ranked 3rd while in the multilingual (w/o en–yo) we got the 4th place.

Based on the official results, it seems that the lowest performing language pair, for both our model and the baseline, is English–Japanese while the highest performing one is Khmer–English. We did not further examine the reasons of this pattern, as we considered this exercise out of the scope of our study. In a future work, it would be useful to investigate whether certain factors contribute to this pattern (such as the source and target language complexity, the writing script, the performance of the pretrained models used to generate the features for each language, or even the content of the test dataset).

It is also worth mentioning that for most language pairs of the test sets, as illustrated in the Table 1, we did not have available training data. If our model had explicitly seen all of these languages during training, we would expect its performance to be improved.

The results of the test set from the official leaderboard[6] for each language pair, in which we participated, can be found in the Official results of the WMT 2022 QE Task 1 – Sentence-level Direct Assessment. In these tables, our proposed model is compared to the baseline system in terms of RMSE, MAE, *Spearman* and *Pearson* correlation coefficient.

5 Conclusions

This paper presents our submission to the WMT 2022 quality estimation Task 1 on sentence-level direct assessment. We introduce a model trained based on the predictor–estimator architecture using the XLM-RoBERTa[1] for feature prediction and a regression head to finally estimate the z-standardized DA values. We suggest the use of additional external features that reflect different criteria of human judgements and multiple levels of translation quality. These features exhibit good correlation with the target variable and consequently with human annotations. Our approach is applicable in multilingual settings even with languages or writing scripts not explicitly seen during the training of the MTQE model. Our system demonstrates competitive results and a strong correlation with human judgements of quality assessment outperforming the baseline system in terms of both *Spearman* and *Pearson* correlation coefficient.

6 Acknowledgements

The work reported in this paper was performed as part of the final master's thesis titled "Quality Estimation for Neural Machine Translation" for the completion of the MSc in Language Technology, a degree co-organized by the National Kapodistrian University of Athens and the Institute for Language and Speech Processing of the Athens Research Center. We would like to thank Welocalize and especially David Clarke for greatly supporting the development of this MSc thesis.

Abstract

We participated in all tracks of the WMT 2022 efficient machine translation task: single-core CPU, multi-core CPU, and GPU hardware with throughput and latency conditions. Our submissions explore a number of efficiency strategies: knowledge distillation, a simpler simple recurrent unit (SSRU) decoder with one or two layers, shortlisting, deep encoder, shallow decoder, pruning and bidirectional decoder. For the CPU track, we used quantized 8-bit models. For the GPU track, we used FP16 quantisation. We explored various pruning strategies and combination of one or more of the above methods.

1 Introduction

This paper describes the University of Edinburgh's submission to Seventh Conference on Machine Translation (WMT2022) Efficiency Task[1], which measures performance on latency and throughput on both CPU and GPU, in addition to translation quality. Our submission focused on the trade-off between these metrics and quality.

Our submission builds upon the work of last year's submission (Behnke et al., 2021). We trained our models in a teacher-student setting (Kim and Rush, 2016), using the data provided by the organisers. For the students, we used a Simpler Simple Recurrent Unit (SSRU) (Kim et al., 2019) decoder, used a target vocabulary shortlist, and experimented with pruning the student models by removing component and block-level parameters to improve speed. We used 8-bit quantisation for the CPU submission and FP16 quantisation for the GPU submission. We further experimented with IBDecoder (Zhang et al., 2020).

For running our experiments, we improved upon the Marian (Junczys-Dowmunt et al., 2018) machine translation framework by incorporating speed ups for 8-bit matrix multiplication operations, optimizations for pruning neural network parameters on Intel CPUs, and profiler aided optimisation of various components.

1.1 Efficiency Shared Task

The WMT22 efficiency shared task consists of two sub-tasks: throughput and latency. Systems should translate English to German under the constrained conditions, where the teacher model and the distilled data are provided. For each task, systems are provided 1 million lines of raw English input with at most 150 space-separated words. The throughput task receives this input directly. The latency task, introduced in WMT21, is fed input one sentence at a time, waiting for the translation output before providing the next sentence.

Throughput is measured on multi-core CPU or GPU system, and latency is measured on single-core CPU or GPU systems. The CPU-based evaluations use an Intel Ice Lake system via Oracle Cloud BM.Optimized3.36, while the GPU-based use a single A100 via Oracle Cloud BM.GPU4.8.

Entries to both tasks are measured on quality, approximated via COMET score (Rei et al., 2020), speed, model size, Docker image size, and memory consumption. We did not optimise specifically for the latency task beyond configuring the relevant batch sizes to one. We used Ubuntu 22.04 based images for our systems, with standard Ubuntu for CPU-only systems and NVIDIA's Ubuntu-based CUDA-11.7 docker for GPU-capable systems. Docker images were created using multi-stage builds, with model disk size reduced by compression with xzip.

2 Knowledge distillation

We used the provided distilled data to build different student systems. The provided data was distilled through two different processes; for the monolingual input, distilled data was generated using a

beam-size of 6. For the parallel data, the teacher ensemble was used to produce the 6 best candidate translations for each input sentence, the candidate most similar to the parallel reference in BLEU score was kept as the distilled sentence. We trained student models using just the provided parallel data and identical systems using parallel+monolingual data. Our early comparisons showed that the full corpora produced higher quality student systems according to automatic metrics; submitted systems therefore use both parallel and monolingual data.

The student models were trained using a validation set consisting of the subset of sentences in the English-German WMT test sets from 2014–2019 that were originally in English. Training concluded after reaching 20 consecutive validations without an improvement in BLEU score. The student models all used the provided shared SentencePiece vocabulary. We used the default training hyperparameters from Marian for the transformer-base model with the learning rate reduced to 0.0002.

We explored a number of different configuration in order to find the optimal system on the Pareto frontier for speed-quality. We experimented with the following configurations:

Deep encoders/Shallow decoders The majority of the computational cost of the machine translation system falls to the decoder. We can therefore increase drastically the number of encoder layers and decrease the decoder layers without noticeable drop in quality (Kong et al., 2021).

Tied decoder layers Since matrix multiplication is a memory bound problem, we can increase the number of decoder layers, as long as we don't add extra parameters. Tied decoder layers allow us to maintain the same memory footprint and keep all the traversed matrices in cache.

SSRU We replace the self-attention in the decoder with an RNN using the less computation and memory intensive cell SSRU.

Reduced model dimensions We reduce the model dimensions, using several presets. See table 1 for details.

Wide embeddings We increased the size of the embedding dimension to match the FFN dimension. While this produces models that are strictly larger than their non-wide equivalent, the initial increased capacity can yield competitive systems using fewer layers.

Fewer heads We reduced the number of attention heads for some of the smaller models. These have the same number of parameters, but intermediate computations have different shape inputs.

3 Pruning

Attention is a crucial part of the transformer architecture, but it is also computationally expensive. Research has shown that many heads can be pruned after training; with further work suggesting that pruning during training can be less damaging to quality. Feedforward layers are also expensive and could be reduced.

We expand upon our work from the previous year on the group lasso regularisation. We build upon the standard group lasso with a novel approach of *aided regularisation*. The idea behind it is to use supplementary information to scale the penalties per layer to steer them towards a specific behaviour. In practice, it means adding a new scalar γ alongside an already existing λ:

$$E(batch) = \frac{1}{|batch|}\left(\sum_{x \in batch} CE(x) + \lambda \sum_{l \in layers} \gamma_l^{batch} R(l)\right)$$

As shown in the equation above, each layer has its individual γ, which gets updated after every backpropagation pass. In order to avoid sudden shits in γ between individual batches, which could make a ratio between perplexities and penalties even more unstable, γ are exponentially smoothed as training progresses:

$$\gamma^j \leftarrow \alpha\gamma^j + (1 - \alpha) * \gamma^{j-1}$$

After every batch i, we calculate a local scalar γ_j for each layer j based on information gathered during this specific update, which then updates a smoothed global scalar. α is a constant used in exponential average that controls the contribution of a new element in a sequence towards the overall average. We use $\alpha = 1\mathrm{e}{-4}$ in my experiments.

We explore *gradient-aided regularisation* which *scales penalties based on layer gradients*. γ scalars should increase as gradients stop flowing through a layer since it indicates that this layer does not contribute to training as much, possibly stopping learning altogether. A layer with small gradients is a good candidate to be regularised more aggressively and vice versa.

With W_i being a regularised layer and ∇W as accumulated gradients in a model, the gradient-aided γ function is defined as:

	Layers		Dimensions			Size		Quality			Speed
Model	Encoder	Decoder	Emb.	FFN	Att. heads	Params	Disk	BLEU	chrF	COMET	Time

Table 2: The evaluation of student models pruned with aided regularisation and quantised to 8-bits. Both quality and speed has been averaged over WMT16–20 testsets. Quantised models were finetuned shortly to help recover quality.

$$\gamma_i = -log\left(\frac{\|\frac{\partial W_i}{\partial E}\|_2}{\|\nabla W\|_2}\right)$$

We follow the training regime outlined by Behnke et al. (2021):

1. Pretraining (50k batches)
2. Regularise (200/300k batches)
3. Slice and converge (200k+ batches)

All on-going training statistics including the learning rate and Adam optimiser were refreshed after each step. The results are presented in Tab. 2. The results include quantised inference with models finetuned for the best quality performance. The 12-1.Base model was regularised for 300k batches with $\lambda = 0.05$. The 12-1.Tiny model was regularised for 200k batches with $\lambda = 0.5$. Both aforementioned models were pruned in the encoder only. The 8-4.Tiny.Tied model was regularised for 200k batches with $\lambda = 0.3$ with both encoder and decoder layers being penalised.

The quality gap becomes larger the harsher pruning is. The base transformer model with 12 pruned encoder layers gets 1.3× faster at the cost of 0.0017 COMET point. Applying quantisation on the top of it makes translation 3.1× faster in exchange of 0.13 COMET points.

We applied regularisation onto both encoder and decoder with the "8-4" tied tiny transformer architecture. This pruned and quantised model speeds up by a factor of 2.3× at a 0.8 BLEU drop.

The most aggressive pruning among the presented results is a tiny transformer with 12 encoder layers with more than 70% parameters removed. This model is 4× faster in comparison to its baseline with 3.3 BLEU and 0.09 COMET points drop.

We note that quantisation struggles with quality on smaller models, both when trained from scratch or pruned. Fine-tuning rectifies the problem to some degree, but quality is sacrificed for faster translation in the end.

4 Fixed Point 8-bit Quantisation

Quantising FP32 models into 8-bit integers is a known strategy to reduce decoding time, specifically on CPU, with a minimal impact on quality (Kim et al., 2019; Bhandare et al., 2019; Rodriguez et al., 2018). This year's submission closely follows the quantisation scheme of last year's work (Behnke and Heafield, 2021).

Quantisation entails computing a scaling factor to collapse the range of values to $[-127, 127]$. For parameters, this scaling factor is computed offline using the maximum absolute value but activation tensors change at runtime. To compute a scaling factor for them, we decoded the WMT16-20 datasets and recorded the scaling factor $\alpha(A_i) = 127/max(|A_i|)$ for each instance A_i of an activation tensor A. Then, for production, we fixed the scaling factor for activation tensor A to the mean scaling factor plus 1.1 standard deviation: $\alpha(A) = \mu(\{\alpha(A_i)\}) + 1.1 * \sigma(\{\alpha(A_i)\})$. These scaling factors were baked into the model file so that statistics were not computed at runtime.

We used predominantly *intgemm*[2] for our 8-bit GEMM operations, including for the shortlisted output layer. All parameter matrices are quantised to 8-bit offline and the activations get quantised dynamically before a GEMM operation. We only perform the GEMM operation and the following activation in 8-bit integer mode. After a GEMM operation, the output is de-quantized back to FP32. More formally we perform $dequantize(\sigma(A{*}B{+}bias))$, where the addition of the $bias$, the activation function σ, and the de-quantisation are applied in a streaming fashion to prevent a round trip to memory.

Furthermore we make use of Intel's *DNNL*[3] for our pruned models, as it performs better than *intgemm* for irregular sized matrices. Unfortunately, *DNNL* doesn't support streaming de-quantisation, bias addition or activation function application.

Quantisation does not extend to the attention layer, which is still computed in FP32. The reason being is that in the attention layer, both the A and B matrices of the GEMM operation would need to be quantised at runtime, which makes the quantisation too expensive. We note that we only perform the GEMM operations in 8-bit integers.

Similar to previous' year's submission, we performed quantisation fine-tuning for some 8-bit models, where we perform a small amount of training with low learning rate and a damaged GEMM implementation that simulates the quantised output. We found that this helps regain some quality, especially in smaller models.

5 Shortlisting

The single most expensive computation in machine translation is the cost of the output layer. We can reduce the computation if we only take into account likely output tokens, reducing the output layer size from 32000 to something much more manageable like 500-2000. We used IBM model based shortlisting (Kim et al., 2019).

This lexical shortlist is straightforward to work with, but it is limiting in the sense that it doesn't capture well idioms and favours more literal translations. The hyper-parameters that control the size of this shortlist are: the number of most frequently targeted words included, and the number of probable translations for each token in the input. This year we increased the number of most-frequent and aligned tokens to `100,100` (from `50,50` in the previous year) in order to improve quality.

The shortlist is built using alignment models trained on a specific corpora. The total number of tokens in a shortlist considered is influenced by the size of the current batch: The shortlist produced is the union of probable translations for each input token and overall most-likely candidates. In latency scenarios, where batches are a single sentence, a small shortlist is more detrimental to the quality than for larger batches, such as in throughput scenarios, that benefit from inclusion of more candidate tokens. Similarly, this approach benefits when inputs are batched.

6 IBDecoder

The sequential nature of autoregressive decoding forms an inference bottleneck, hurting decoding parallelisation and latency. A popular method to break this bottleneck is to allow the parallel prediction of multiple target tokens per step through semi- or non-autoregressive modelling (Gu et al., 2018; Wang et al., 2018) with a quality tradeoff.

We experimented with Interleaved Bidirectional Decoder (Zhang et al., 2020), a variant of semi-autoregressive decoder that predicts target tokens from the left-to-right and the right-to-left directions

Table 3: The evaluation of IBDecoder models and their 8-bit quantisation (without finetuning). Both quality and speed has been averaged over WMT16–20 testsets.

simultaneously. Zhang et al. (2020) showed that words from different directions are more loosely dependent thus their parallel generation hurts quality less. IBDecoder produces one word in each direction at a time, thus halving the total decoding steps and approximately doubling speed.

The efficiency gains from IBDecoder decrease when using deep encoders and shallow decoders (Tab. 3). In general, IBDecoder delivers a speed-up over our baseline system and is competitive at BLEU scores but much worse at COMET scores. IBDecoder shows higher sensitivity to model sizes, where reducing model size dramatically hurts its performance regardless of BLEU or COMET. We also tried to initialise IBDecoder from the baseline system which unfortunately doesn't help. IBDecoder also benefits from pruning and quantisation in speed, but at the cost of losing COMET.

7 Quality issues

Quantisation applied to small models, especially those that were pruned, struggles with maintaining the quality. For example, as can be seen in Tab. 2, quantisation on top of pruned models damages the quality from 0.1 to 0.3 COMET points. This gap is more evident in smaller architectures such as Tiny or Tied Tiny. We hypothesise that the fewer parameters there are in a model, the more difficult it is to optimise through pruning and/or quantisation, or using a bidirectional generation.

IBDecoder suffers from the pruning and quantisation particularly on the COMET scores as shown in Tab. 3.

We compared several sentences that showed little difference in BLEU but significant difference in the COMET scores and tried to see what went wrong (Table 4). We can see that the IBDecoder is prone to pathological repetitions (Example 1) and even more so when quantised (Examples 3 and 4). Those repetitions, especially long ranged one don't hurt the BLEU score, but they get heavily penalised by the COMET score (Example 3).

It seems quantisation doesn't always result in a a worse transaltion. In the second example the quantised IBDecoder produces a more complicated, but overall much better translation than the IBDecoder, which also suffers from a repetition error. This suggests that the model is quite brittle and very susceptible to small changes.

8 Software improvements

We built our work using the Marian machine translation framework, making some improvements on top of the submission from last year:

AVX512 inrinsics We implemented hand crafted intrinsics for various arithmetic operations, resulting in .5% improvement in performance.

Max element We identified via a profiler that the *max element* implementation was taking more time than usual so we implemented a hand optimised version resulting in 5% performance improvement. More details are available in Appendix A.

Thread configuration For the CPU_ALL throughput track, we swept configurations of multiple processes and threads on the platform, settling

on 4 processes with 9 threads each. The input text is simply split into 4 pieces and parallelised (Tange, 2011) over processes. The mini-batch sizes past 16 did not impact performance substantially but 32 was chosen as the best performing one. The Hyperthreads do not increase performance. Each process is bound to 9 cores assigned sequentially and to the memory domain corresponding to the socket with those cores using *numactl*. Output from the data parallel run is then stitched together to produce the final output.

For our GPU submission we reused the work from the last year's submission (Behnke et al., 2021) with the improved models.

9 Conclusion

We participated in all tracks of the WMT 2022 efficiency task and we submitted multiple systems that have different trade-offs between speed and translation quality. For the CPU submission we used 8-bit integer decoding and a combination of pruned and non-pruned system, together with a lexical shortlist in order to reduce the computational cost of the output layer. We also experimented with IBDecoder in both CPU and GPU setting.

A Profiler aided optimisation

We used a profiler to identify hotspots for potential software optimisations.

Max element improvements We identified that the *max element* operation takes surprisingly large amounts of runtime during decoding. *max element* is used to select the next word to be produced from the output layer during decoding with beam size of 1. We explored various different implementations and achieved 10X performance improvement compared to the standard library when using GCC and 2X otherwise. This resulted in about 5% performance improvement in the CPU setting. More details about different implementations can be seen on Table 5

Abstract

We present a non-autoregressive system submission to the WMT 22 Efficient Translation Shared Task. Our system was used by Helcl et al. (2022) in an attempt to provide fair comparison between non-autoregressive and autoregressive models. This submission is an effort to establish solid baselines along with sound evaluation methodology, particularly in terms of measuring the decoding speed. The model itself is a 12-layer Transformer model trained with connectionist temporal classification on knowledge-distilled dataset by a strong autoregressive teacher model.

1 Introduction

In the past few years, non-autoregressive (NAR) models for neural machine translation (NMT) attracted interest from the research community (Gu et al., 2018; Lee et al., 2018). Given the conditional independence between the output states, the decoding process can be parallelized across time steps. In theory, this leads to higher decoding speeds.

Since efficient decoding is claimed to be the main motivation of non-autoregressive models, the Efficient Translation Shared Task seems to be the appropriate venue to provide fair comparison between these models and their autoregressive counterparts. However, all submissions to this task were autoregressive so far (Birch et al., 2018; Hayashi et al., 2019; Heafield et al., 2020, 2021).

Recently, Helcl et al. (2022) pointed out common flaws in the evaluation methodology of NAR models. We found that optimized autoregressive models still achieve superior performance over NAR models. The only scenario where NAR models showed some potential is GPU decoding with batch size of 1 (latency). Nevertheless, optimized autoregressive models were still both faster and better in terms of translation quality. The main purpose of this submission is to provide a reasonable baseline to future non-autoregressive submissions.

2 Model

In our experiments, we use the non-autoregressive model proposed by Libovický and Helcl (2018) based on Connectionist Temporal Classification (CTC; Graves et al., 2006). We submit models that have been trained as a part of Helcl (2022).

Architecture. The architecture is a 6-layer Transformer encoder, followed by a state-splitting layer and another stack of 6 Transformer layers. The state-splitting layer takes the encoder states, project them into k-times wider states using an affine transformation, and then split the states into k-times longer sequence while retaining the original model dimension. In the submitted model, we set $k = 3$. The latter 6 layers cross-attend to the states immediately after state-splitting. We use Transformer model dimension of 1,024, 16 attention heads and a dimension of 4,096 in the feed-forward sublayer.

The defining property of non-autoregressive models is that the decoding process treats output states as conditionally independent. In this architecture, we set the output sequence length to $k \times T_x$ where T_x is the length of the source sentence. To allow for shorter output sequences, the any output state can produce an empty token. The training loss is then computed using a dynamic programming algorithm as a sum of losses of all possible empty token alignments which lead to the same output sentence. The schema of the architecture is shown in Figure 1.

Training. We train our model on the knowledge-distilled data generated by the provided teacher (Chen et al., 2021). We use learning rate of 0.0001 in a inverse square-root decay scheme with 8,000 warm-up and decay steps.

Implementation. We implement and train our model in the Marian toolkit (Junczys-Dowmunt et al., 2018). For the CTC implementation,

we use the warp-ctc library[1]. We release our code at https://github.com/jindrahelcl/marian-dev. The trained model (and a number of different variants including models in opposite translation direction) can be downloaded at https://data.statmt.org/nar.

3 Results

We refer the reader to the original paper for more details about the evaluation and its results. The model we submitted is denoted in the paper as "large". A summary of the results follows.

Translation Quality. To summarize the main findings, the model achieves a competitive BLEU score (Papineni et al., 2002) on the WMT 14 news test set (Bojar et al., 2014), which serves as a comparison to other non-autoregressive models that use this test set as the de facto standard benchmark. When evaluated on the WMT 19 news test set, our model obtains BLEU of 47.8, and a COMET score (Rei et al., 2020) of 0.1485. Compared to an similarly-sized autoregressive teacher model with 50.5 BLEU and COMET of 0.4110, we see a somewhat surprising gap between the COMET scores while BLEU scores are relatively close. We hypothesize that the errors that the non-autoregressive model makes are out of the training domain of the COMET models, which makes them more sensitive towards this kind of errors.

Decoding Time. We evaluated our models on the one million sentences benchmark used in the previous editions of this task (Heafield et al., 2021), and we tried to reproduce the official hardware setup to large extent. For CPU decoding, we measured time to translate the test set on an Intel Xeon 6354 server from Oracle Cloud, with 36 cores. We run the evaluation only in the batch decoding mode, as the models were too slow to decode with a single sentence in batch. With the submitted model, the translation on CPU took 7,434 seconds (using batch of 16 sentences).

We used a single Nvidia A100 GPU for GPU decoding. In the latency setup, the translation took 7,020 seconds, and the batched decoding ($b = 128$) took 782 seconds. When compared with other submissions to this task, we find that the smallest difference is indeed found in the GPU decoding latency setting. However, the optimized models submitted to last year's round still achieved significantly better decoding times.

4 Conclusions

We submit a non-autoregressive system to the Efficient Translation Shared Task to the WMT 22. The model is trained with connectionist temporal classification, which allows the generation of empty tokens and thus making generation of sentences of various length possible while retaining the conditional independence among output tokens without explicit length estimation.

The main motivation of this submission is to provide a reasonable baseline system for future research. We believe that the sub-field of non-autoregressive NMT cannot progress without controlled decoding speed evaluation, which is exactly what the shared task organizers provide.

Abstract

This paper describes the submission of the ROYALFLUSH neural machine translation system for the WMT 2022 translation efficiency task. Unlike the commonly used autoregressive translation system, we adopted a two-stage translation paradigm called Hybrid Regression Translation (HRT) to combine the advantages of autoregressive and non-autoregressive translation. Specifically, HRT first autoregressively generates a discontinuous sequence (e.g., make a prediction every k tokens, $k > 1$) and then fills in all previously skipped tokens at once in a non-autoregressive manner. Thus, we can easily trade off the translation quality and speed by adjusting k. In addition, by integrating other modeling techniques (e.g., sequence-level knowledge distillation and deep-encoder-shallow-decoder layer allocation strategy) and a mass of engineering efforts, HRT improves 80% inference speed and achieves equivalent translation performance with the same-capacity AT counterpart. Our fastest system reaches 6k+ words/second on the GPU latency setting, estimated to be about 3.1x faster than the last year's winner.

1 Introduction

Large-scale transformer models have made impressive progress in past WMT translation tasks, but it is still challenging for practical model deployment due to time-consuming inference speed (Wang et al., 2018b; Li et al., 2019). To build a fast and accurate machine translation system, participants in past WMT efficiency tasks developed and validated many efficient techniques, such as knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016), light network architecture (Kasai et al., 2020), quantization (Lin et al., 2020) etc. We noticed that all the above efforts are aimed at autoregressive translation (AT) models. In contrast, other translation paradigms, like non-autoregressive translation (NAT) (Gu et al., 2017) or semi-autoregressive translation (SAT) (Wang et al., 2018a) etc., have not been well studied.

In this participation, we restrict ourselves to the GPU latency track and attempt to investigate the potential of non-standard translation paradigms. However, replicating the vanilla non-autoregressive or semi-autoregressive models degrades the translation quality severely in our preliminary experiments. To this end, we explore hybrid-regressive translation (HRT), the two-stage translation prototype, to better combine the advantages of autoregressive and non-autoregressive translation (Wang et al., 2021b). Specifically, HRT first uses an autoregressive decoder to generate a discontinuous target sequence with the interval k ($k > 1$). Then, HRT fills the remaining slots at once with a non-autoregressive decoder. The two decoders share the same parameters without adding additional ones. Thus, HRT can easily trade-off between translation quality and speed by adjusting k [1]. Please see Table 1 for the comparison between different translation paradigms.

In addition to the change of translation paradigm, we have also made a mass of other optimizations. We use the widely used sequence-level knowledge distillation (Kim and Rush, 2016) and deep-encoder-shallow-decoder layer allocation strategy (Kasai et al., 2020) to learn effective compact models. Moreover, on the engineering side, we customized an efficient implementation of GPU memory reuse and kernel fusion for HRT following LightSeq (Wang et al., 2021c).

Putting all the efforts together, our HRT model achieves almost equivalent BLEU scores to the corresponding AT counterparts while improving the inference speed by about 80%. Our best-BLEU

[*] Corresponding author.

[1] A larger k implies that fewer autoregressive decoding steps are required, resulting in faster inference speed but lower translation quality.

model drops an average of 0.9 BLEU points compared to the teacher model, which ensembles four transformer-big models. Moreover, our fastest model decodes 6k+ source words per second, estimated to be 3.1x faster than the winner in last year [2].

2 Hybrid-regressive translation

One of the most important highlights is the introduction of the newly proposed two-stage translation prototype——HRT. In this section, we will detail the model, training, and decoding of HRT.

2.1 Model

HRT consists of three components: encoder, Skip-AT decoder (for stage I), and Skip-CMLM decoder (for stage II). All components adopt the Transformer architecture (Vaswani et al., 2017). The two decoders have the same network structure, and we share them to make the parameter size of HRT the same as the vanilla Transformer. The only difference between the two decoders lies in the masking pattern in self-attention: The Skip-AT decoder masks future tokens to guarantee strict left-to-right generation like an autoregressive Transformer (Vaswani et al., 2017). In contrast, the Skip-CMLM decoder eliminates it to leverage the bi-directional context like the standard conditional masked language model (CMLM) (Ghazvininejad et al., 2019). We note that there is no specific target length prediction module in HRT because HRT can obtain the translation length as the by-product of the Skip-AT decoder: N_{nat}=$k \times N_{at}$, where N_{at} is the sequence length produced by Skip-AT.

2.2 Training

Multi-task framework. We learn HRT through joint training of four tasks, including two primary tasks (SKIP-AT, SKIP-CMLM) and two auxiliary tasks (AT, CMLM). All tasks use cross-entropy as the training objective. Figure 1 illustrates the differences in training samples among these tasks. It should be noted that, compared with AT, SKIP-AT shrinks the sequence length from N to N/k, whereas the token positions follow the original sequence. For example, in Figure 1 (c), the position of Skip-AT input ([B$_2$], y_2, y_4) is (0, 2, 4) instead of (0, 1, 2). Involving auxiliary tasks is necessary because the two primary tasks cannot fully leverage all tokens in the sequence due to the fixed k. For example, in Figure 1 (c) and (d), y_1 and y_3 have no chance to be learned as the decoder input of either SKIP-AT or SKIP-CMLM.

Curriculum learning. To ensure that the model is not overly biased towards auxiliary tasks, we propose gradually transferring the training tasks from

[2] We obtained the best decoding speed in last year's competition according to Heafield et al. (2021): The fastest system *2.12_1.micro.rowcol-0.5* decodes 19,951,184 space-separated words in 13665 seconds. Therefore, we estimated its inference speed is 1460 words/second. We note that the acceleration ratio is not an accurate value because we use slightly different computation devices and test data to measure the speed.

auxiliary tasks to primary tasks through curriculum learning (Bengio et al., 2009). More concretely, given a batch of original sentence pairs $\mathcal{B}$, and the proportion of primary tasks in $\mathcal{B}$ is p_k, we start with p_k=0 and construct the training samples of AT and CMLM for all pairs. Then we gradually increase p_k to introduce more learning signals for SKIP-AT and SKIP-CMLM until p_k=1. In implementation, we schedule p_k by:

$$p_k = (t/T)^{\lambda}, \tag{1}$$

where t and T are the current and total training steps. λ is a hyperparameter, and we use λ=1 to increase p_k linearly for all experiments.

2.3 Decoding

HRT adopts two-stage generation strategy: In the first stage, the Skip-AT decoder starts from [BOS$_k$] to autoregressively generate a discontinuous target sequence $\hat{\boldsymbol{y}}_{at} = (z_1, z_2, \ldots, z_m)$ with chunk size k until meeting [EOS]. Then we construct the input of Skip-CMLM decoder $\boldsymbol{y}_{nat}$ by appending $k-1$ [MASK]s before every z_i. The final translation is generated by replacing all [MASK]s with the predicted tokens by the Skip-CMLM decoder with one iteration. If there are multiple [EOS]s existing, we truncate to the first [EOS]. Note that the beam size b$_{at}$ in Skip-AT can be different from the beam size b$_{nat}$ in Skip-CMLM as long as st. b$_{at} \geq$ b$_{nat}$: We only feed the top b$_{nat}$ Skip-AT hypothesis to Skip-CMLM decoder. Finally, we choose the translation hypothesis with the highest score S($\hat{y}$) by:

$$\underbrace{\sum_{i=1}^{m} \log P(z_i|\boldsymbol{x}, \boldsymbol{z}_{<i})}_{\text{Skip-AT score}} + \underbrace{\sum_{i=0}^{m-1}\sum_{j=1}^{k-1} \log P(\hat{y}_{i\times k+j}|\boldsymbol{x}, \boldsymbol{y}_{nat})}_{\text{Skip-CMLM score}} \tag{2}$$

where z_i=$\hat{y}_{i\times k}$.

3 Optimization

Sequence-level knowledge distillation. Overall, we use the teacher-student framework via sequence-level knowledge distillation (SEQKD) to learn our small HRT model (Kim and Rush, 2016). Specifically, the ensemble of provided four transformer-big models is our teacher, whose beam search results are used as our distillation data. There are 320M official distillation data composed of 80M parallel and 240M monolingual datasets. We directly use the distillation data without further data cleaning. We use the same sentencepiece vocabulary as the teacher model to encode the text.

Encoder	Newstest19	Newstest20	WPS
6	43.8	32.6	4.0k
12	45.6	33.9	3.8k
20	45.9	34.4	3.5k

Table 2: SacreBLEU and inference speed against the number of encoder layers in HRT with a single-layer decoder. All HRT models are trained with k=2. WPS refers to source words per second, measured by the average five runs with a batch size of 1. Unless otherwise stated, we measure WPS on Newstest20.

b$_{at}$	b$_{nat}$	Newstest19	Speedup
5	5	**45.9**	ref.
5	1	45.8	1.05x
1	1	45.6	**1.33x**

Table 3: Effects of different settings of beam size in HRT.

Deep-encoder-shallow-decoder architecture. Using deep-encoder-shallow-decoder network architecture has been widely validated effectiveness for transformer-based NMT systems (Wang et al., 2021a; Kasai et al., 2020). Our HRT also follows this guidance by using only one decoder layer. We use the pre-norm transformer following Wang et al. (2019) to learn deep encoder well. Intuitively, the single-layer decoder may be insufficient for HRT because the decoder is responsible for both autoregressive and non-autoregressive generation. However, as shown in Table 2, we found that HRT enjoys the deep-encoder-shallow-decoder architecture. For example, compared to HRT_E6D1 [3], HRT_E12D1 and HRT_E20D1 improve +1.6/+2.0 BLEU score points on average, while the inference speed decreases by 5% and 12.5%. Therefore, we mainly investigate HRT with a 12-layer and 20-layer encoder due to the high BLEU scores.

Fully greedy search. Prior work has validated that greedy search is sufficient for the autoregressive distilled model to work well (Kim and Rush, 2016). Since HRT refers to two beam sizes (b$_{at}$ and b$_{nat}$), we test three settings as shown in Table 3. It can be seen that using b$_{at}$=1 and b$_{nat}$=1 only decreases BLEU slightly but accelerates a 30%+ faster than that of b$_{at}$=5 and b$_{nat}$=5. Unless otherwise stated, we use b$_{at}$=1 and b$_{nat}$=1 in the following experiments.

[3] We use HRT_E{#1}D{#2} to denote the HRT model with {#1}-layer encoder and {#2}-layer decoder.

Model	Param.	Newstest19		Newstest20		Average		WPS

Table 4: Compare different model variants with regard to SacreBLEU (Post, 2018), COMET (Rei et al., 2020) and inference speed. $*$ denotes the number is not exactly comparable due to the difference in test data and GPU.

Maximum sequence length. We predefine the maximum source/target sequence length L as 200. Here the length is calculated based on the results of sentencepiece. Once the sequence length exceeds L, we truncate the source/target sequence. For HRT, we let the maximum decoding length in the Skip-AT stage as L/k. In this way, the maximum target length in the Skip-CMLM stage can be guaranteed not beyond L.

GPU memory reuse. Since we only participate in the GPU latency track, given the predefined maximum sequence length L, we can estimate the maximum GPU memory buffer used in the encoder, autoregressive decoder, and non-autoregressive decoder in advance, respectively. Then we only allocate the maximum buffer size among them because these three processes are memory-independent. This memory-reuse method helps us reduce our footprints and avoid frequent memory applications and releases.

Kernel fusion. Too many fine-grained kernel functions make modern GPU inefficient due to kernel launching overhead and frequent memory I/O addressing (Wang et al., 2021c; Wu et al., 2021). We follow the good implementation in LightSeq and use the general matrix multiply (GEMM) provided by cuBLAS as much as possible, with some custom kernel functions. Please refer to Wang et al. (2021c) for details.

FP16 inference. We also use the 16-bit floating-point to utilize modern GPU hardware efficiently. Previous study (Wang et al., 2021a) shows that FP16 can bring significant acceleration in batch decoding. In contrast, in our GPU latency task, we only observed about 15% speedup due to the smaller computational burden, as shown in Table 5.

Model	FP16	WPS
HRT_E12D1 (k=2)	no	3.3k
HRT_E12D1 (k=2)	yes	3.8k

Table 5: The effect of FP16 on HRT model in GPU latency task.

Docker submission. We use multistage builds to reduce the docker image size. Specifically, we first use static compilation to build our executable program with CUDA 11.2. Then we add the built result and model into the 11.2.0-base-centos7 docker. The model disk size is compressed by *xz* compression toolkit.

4 Experimental Results

Setup. We mainly compared HRT to the standard autoregressive baselines in Table 4. All models adopt transformer-base setting (Vaswani et al., 2017): d=512, d_{ff}=2048, $head$=8. We validated the following model variants:

- **AT:** We train three autoregressive baselines with the number of encoder layers of 6, 12, and 20, denoted as AT_E6D1, AT_E12D1, and AT_E20D1, respectively. All AT models are trained from scratch for 300k steps.

- **HRT:** HRT models are fine-tuned based on the pre-trained AT counterparts for 300k steps. We also try different chunk sizes $k \in \{2, 3, 4\}$ to trade off the translation quality and inference speed.

Other training hyper-parameters are the same as Wang et al. (2019). We ran all experiments on 8 GeForce 3090 GPUs. For decoding, the length penalty is 0.6, and the batch size is 1. We report the detokenized SacreBLEU score with the same signature as the teacher. Besides, we also follow Helcl et al. (2022)'s suggestion to provide COMET score (Rei et al., 2020) for the evaluation of non-autoregressive translation.

Translation quality. First, we can see that a deeper encoder improves about 0.5 BLEU points across the board. When using k=2 for HRT, both 12-layer and 20-layer HRT models have almost equivalent BLEU scores to that of AT counterparts. Our best HRT model HRT_E20D1 with k=2 only drops an average of 0.9 BLEU points than the teacher using model ensemble. However, in line with Helcl et al. (2022), we find that even when BLEU scores are close, HRT's COMET scores are significantly lower than those of AT, e.g., AT_E20D1 vs. HRT_E20D1 (k=2). Nevertheless, HRT_E20D1 (k=2) still achieves higher BLEU and COMET than AT_E6D1 with 60% acceleration.

Translation speed. We estimated the inference speed of the fastest system last year according to the data in Heafield et al. (2021). Supposing ignoring the difference in test data, our AT baselines run about 40%+ faster than it. It indicates that our AT engine is a strong baseline. Even so, we can see that both 12-layer and 20-layer HRT with k=2 achieve approximated 80% acceleration than AT without BLEU drop. Moreover, larger k further reduces the autoregressive decoding steps: Our fastest model, HRT_E12D1 (k=4), decodes 6k+ source words/second, which is 3.1 times faster than the fastest system last year.

5 Conclusion

This paper presented the RoyalFlush system to the GPU latency track of the WMT 2022 translation efficiency task. We proposed hybrid-regressive translation, a novel two-stage prototype to replace conventional autoregressive translation. With a lot of development optimization, we showed that our HRT with a chunk size of 2 achieves equivalent translation performance to the AT counterpart while accelerating 80% inference speed. By increasing HRT's chunk size, our system can further speed up 60% to 6k+ words/second, estimated to be about 3.1 times faster than the fastest system in last year's competition.

Abstract

This paper presents the submissions of Huawei Translation Services Center (HW-TSC) to WMT 2022 Efficiency Shared Task. For this year's task, we still apply sentence-level distillation strategy to train small models with different configurations. Then, we integrate the average attention mechanism into the lightweight RNN model to pursue more efficient decoding. We add a retrain step to our 8-bit and 4-bit models to achieve a balance between model size and translation quality. We still use Huawei Noah's Bolt[1] for INT8 inference and 4-bit storage. With Bolt's support for batch inference and multi-core parallel computing, we finally submit models with different configurations to the CPU latency and throughput tracks to explore the Pareto frontiers.

1 Introduction

Transformer and its variants (Vaswani et al., 2017; Shaw et al., 2018; So et al., 2019; Dehghani et al., 2019) have become benchmark models for machine translation. A lot of innovations and engineering optimizations (Tay et al., 2020) in this area are based on Transformer. However, with the increase of bilingual and monolingual data sizes used for training, the size of the model expands and the requirement of computing ability become higher. Taking T5 (Raffel et al., 2020), GPT3 (Brown et al., 2020) and a series of subsequent large models (Fedus et al., 2021; Smith et al., 2022) as examples, although they have achieved very good performances, it is still difficult for ordinary practitioners to reproduce or use these models for research and industry application. Especially in scenarios where hardware capability is limited, models that balance size, quality and power consumption is urgently needed. The WMT Efficiency task is performed under such constraints.

In this year's task, we still focus on CPU inference optimization and participate in CPU latency and multi-core throughput tracks.

We employ knowledge distillation (Hinton et al., 2015) to train small models. The teacher models and distillation data come from official website. We only perform simple data cleaning, and all of our experiments are conducted based on fariseq (Ott et al., 2019).

Deep encoder and shallow deocder models can balance quality and inference speed (Wang et al., 2019). We follow this configuration for pursuing extreme efficient decoding. Inspired by SRU++ (Lei, 2021) and AAN (Zhang et al., 2018), we integrate the average attention mechanism with a lightweight RNN for more efficient decoding.

We retrain our 8-bit quantisation model (Jacob et al., 2018), then compare its result with that of direct post-quantization (Sung et al., 2015) model. We finally find that in the distillation scenario, the difference between the two is not obvious. We apply 4-bit storage to obtain an extremely small model size. Although our training and inference strategies ensure basically the same model quality, the gap in overall quality is large and the model needs to be further optimized.

We still use Huawei Noah's Bolt as the inference library. This year, we implement batch inference and parallel computing on multi-core CPUs for the throughput track.

Finally, after performing some necessary engineering optimizations, we submit four models with different configurations to explore the Pareto frontiers.

2 Teacher to Student Knowledge Distillation

2.1 Data Process

The task is to translate English to German following the constrained news task from WMT 2021.

[1] https://github.com/huawei-noah/bolt

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 677 - 681
December 7-8, 2022 ©2022 Association for Computational Linguistics

The teacher model, as well as bilingual data and distillation data used in this task are provided by the organizer. It makes everyone on the same start line in the distillation experiment, avoiding the quality difference due to different teacher models. We download the data and find it pretty much the same as the data we used in the task last year. According to our distillation experiment last year, keeping the ratio of bilingual data and distillation data as 1:2 can ensure that the student model inherits the knowledge of the teacher model well. Except for the generation of distillation data, other processing strategies are the same as last year's. For details, please refer to our previous task report (Shang et al., 2021).

2.2 Vocabulary

We build a joint subword segmentation model from real parallel data using SentencePiece (Kudo and Richardson, 2018) as last year. The vocabulary size is set to 25k tokens.

2.3 Model Structure

The autoregressive module is based on the self-attention in the Transformer decoder layer. The decoding complexity increases as the decoding length increases. Therefore, special processing is required if we want to pursue extreme decoding performance. The commonly used strategy is to replace it with a fixed computational cost module, such as LSTM, other RNN variants (Lei et al., 2018), or AAN. These modules use a global cell to store sentence-level information and perform the same cell update actions as each token is decoded without relying on the decoded sequence.

SRU++ (Lei, 2021) further replaces the heavyweight multiplication operation outside the cell with a self-attention component to improve the representation ability of the model. We use the AAN to replace the standard self-attention module for faster decoding while ensuring the expression ability of the model. We call it the AASRU model.

The calculation formula in the cell is as follows:

$$\begin{aligned}
f[t] &= \sigma(U[t,0]) + V \odot C[t-1] + b) \\
r[t] &= \sigma(U[t,1]) + V^{'} \odot C[t-1] + b^{'}) \\
c[t] &= f[t] \odot C[t-1] + (1 - f[t]) \odot C[t,2] \\
h[t] &= r[t] \odot C[t] + (1 - r[t]) \odot x[t]
\end{aligned}$$

The formula for calculating U is as follows:

$$Q = W^q X^T$$

$$\begin{aligned}
V &= W^v X^T \\
A^T &= AVERAGE(V^T) \\
U^T &= W^o layernorm(Q + A)
\end{aligned}$$

where W^q and $W^v \in R^{d^{'} \times d}$, $W^o \in R^{3d \times d^{'}}$, d is the hidden state size, and $d^{'}$ is the attention dimension. The σ is the sigmode function, and $\odot$ is the element-wise multiplication, t refer to the time step, v and b are parameter vectors to be learnt during training, c and h are the cell states and the hidden states in RNN.

2.4 Training

Our distillation experiments are based on fairseq. We implement the AASRU module by referring to the open-source transformer-aan [2]. Also, we do not use regularization techniques such as dropout and label smoothing. All our models are trained using 8 Nvidia Tesla V100 for about two days. The maximum number of tokens vary from 4096 to 10240 according to the model size, as we try to keep the maximum GPU memory usage the same.

After that, we retrain our 8-bit quantization model, constrain all Linear and Matual operator's inputs to the interval [-1, 1], add quantization and inverse quantization operators to the model graph. The retrain is performed after the base model has been trained for 200K steps.

We compare the results of retrain and post-quantization on the Base.12 model, and find almost no difference in performances of the two models under the current distillation experiment setting. Therefore, we submit the post-quantized models.

Next, we apply 4-bit storage models to pursue extreme model sizes. In order to achieve better translation, we add retrain and verify the consistency between training and inference. The translation quality obtained via Bolt inference and training respectively is almost the same. However, the overall quality of our model declines greatly, requiring further optimization.

2.5 Evaluation

We still use WMT 2019 and 2020 News Task test sets to measure our models with SacreBLEU (Post, 2018) this year. We perform a simple post-processing (normalize the punctuation) on the German translations, so the BLEU scores are slightly higher than the officially provided one.

Small.9	384	1536	6	9/1	28	112	44.62	34.40
Small.6	384	1536	6	6/1	22	88	43.80	34.26
Tiny.12	256	1024	4	12/1	17	68	43.84	33.62
Tiny.6	256	1024	4	6/1	13	52	42.15	32.27
Tiny.6 + 4-bit	256	1024	4	6/1	13	52	34.75	26.30

Table 1: Results of Distillation Training. 8-bit and 4-bit refer to retraining.

Overall, the results of our distillation experiments are within our expectations. The Baseline model has about 25% parameters as the teacher model, and its performance is attenuated by about 1.5 BLEU. The 8-bit retraining model is basically the same as the direct training one. However, we observe over 5.0 BLEU decrease on our Tiny.6 model after adding 4-bit storage. The reason may be that we treat every parameter the same way, including embedding. As a result, more training tricks and experiments are required in the future.

We also analyze the effect of the encoder's height and width on the model. Comparing Base.6 to Small.12, and Small.6 to Tiny.12, we find that deeper networks almost have equal or better quality even with less parameters except for Tiny.12's 2020 test result.

Under the same height setting, models with different widths also perform differently. A wider model seems to perform better. Comparing 12-layer and 6-layer models, we observe less than 1 BLEU difference under the base setting, less than 1.2 BLEU difference under the small setting (and only 0.7 BLEU difference on the WMT20 test set), and only about 1.7 BLEU difference under the tiny setting. Wider encoder means more parameters and probably better quality.

Based on the above analysis and the quality gap between the models, We finally decide to submit four models including Base.12, Small.9, Tiny.12, and Tiny.6 to explore the Pareto frontiers better.

3 Inference Optimizations

We use Bolt acceleration library as CPU optimization backend to build the high-performance translation engine. Bolt has a standalone C++ runtime, therefore it can perform fast inference without any third-party dependencies. We use Bolt v1.4.0, which will be available in October 2022.

3.1 8-bit Quantization

We still apply the post-training quantization method this year. All parameters of the model except the bias are quantized to 8-bit intergers by absolute maximum quantization. All GEMM operations in the attention layer are in 8-bit and well optimized by Intel VNNI instructions, but the layernorm and softmax computations are back off to FP32.

3.2 4-bit Storage

For this year's submission, we employ 4-bit storage to achieve almost 8x model compression. With 4-bit storage, all parameters have to be converted to 8-bit integers for calculation because of the hardware limitations, so there is no performance advantage compared with 8-bit storage.

3.3 Batch and Thread

For the throughput track, we support batch inference and merge multiple matrix calculations in attention layer. Our experiments show an end-to-end speedup of up to 20% on a single core. To further increase the throughput, we divide the input text into specified sizes and assign them to multiple CPU cores for parallel computation. The input text is sorted first to prevent the performance waste due to the difference of data lengths within the batch. In the submitted systems, we uniformly set the batch size to 4.

3.4 Other Strategies

We apply some other commonly used strategies such as greedy decoding, caching and shortlist,

Model	Precious	Size	WPS	BLEU
Teacher	FP32	2000	-	36.29
Base.12	FP32	212	237	35.30
	INT8	53	815	35.20
+retrain	INT8	53	815	35.19
Small.9	FP32	112	468	34.40
	INT8	28	1129	34.29
Tiny.12	FP32	68	759	33.62
	INT8	17	1693	33.39
Tiny.6	FP32	52	996	32.27
	INT8	13	2001	31.92
+int4	INT8	6.5	1989	26.10

Table 2: Optimization results. The test set is WMT 2020 News test. The unit of size is MB. WPS refers to the source side. The test environment is Intel(R) Xeon(R) Gold 6278C CPU @ 2.60GH. We submit four models: Base.12, Small.9, Tiny.12 and Tiny.6 and the final Tiny.6+int4

which can improve the model decoding efficiency to a certain extent. Details can be found in our last year's report.

4 Optimization Results

Our final optimization results are shown in Table 2. We find that the inference speed of our models is significantly improved through int8 inference, and the overall improvement is 2-3 times that of FP32, which is basically the same as last year's results.

By analyzing the results of our comparative experiments on Base.12, we find that BLEU is only slightly decreased when we directly use the post-quantization inference version. So there is not much room left when optimizing the performance of models that employ retraining. The reason may be the limited diversity of the model under the distillation setting. The post-quantization model basically meet our requirement on quality.

We additionally employ 4-bit storage on the Tiny.6 model for pursuing extreme model size. After retraining, we successfully compress the model to almost 1/8 of the original size, and maintain a high degree of consistency between training (26.30 BLEU) and inference (26.10 BLEU) with slightly BLEU score decrease. We also submit the model for evaluation.

When preparing the model for the throughput track, we need to set the batch size for batch translation. We compare the impact of different batch sizes on throughput in detail using our Base.12 model. Results are shown in Table 3. When the batch size exceeds 3, the improvement becomes insignificant. Considering that the hardware used in the task may be different from our test environment, we set the batch size to 4 for all of our submissions for convenience.

Batch Size	BLEU	Costs	WPS
Base.12	35.30	-	-
1	35.20	53	815
2	35.23	45	978
3	35.17	44	1000
4	35.22	44	1000
8	35.38	45	978
16	35.26	45	978

Table 3: The effect of batch size on throughput. WPS refers to the source side.

5 Submitted Docker Images

Due to the simple runtime environment of Bolt, we can choose a very basic image to run our system. We still apply the ubuntu:18.04. Our inference project is inherited from last year's, adding support of batch inference and using a thread pool to run models in parallel on multiple CPU cores. Following the task requirements, our startup script is /run.sh. Our model is stored in the /model directory, which contains the converted Bolt model, vocabulary, and shortlist files. The compressed file is provided.

Our largest model volume is around 50M, and the base image volume is around 60M. The space occupied by our inference project is almost negligible, so the final image we submitted after compression still does not exceed 70M, and the smallest one is about 35M.

6 Concolusion

In this year's task, we follow some strategies from last year, including data processing, basic distillation training, etc. In addition, we explore a new and more efficient decoding structure, AASRU, this year, which reduces the amount of computation while maintaining quality. We add 8-bit and 4-bit retrain to distillation training, and verify the consistency of training and inference. Regarding engineering, we add the relevant features of Batch inference and multi-core parallel computing, and finally submit several models with balanced quality and speed for CPU latency and throughput tracks.

IIT Bombay, India
{sourabhdeoghare, pb}@cse.iitb.ac.in

Abstract

This paper describes IIT Bombay's submission to the WMT-22 Automatic Post-Editing (APE) shared task for the English-Marathi (En-Mr) language pair. We follow the curriculum training strategy to train our APE system. First, we train an encoder-decoder model to perform translation from English to Marathi. Next, we add another encoder to the model and train the resulting *dual-encoder single-decoder* model for the APE task. This involves training the model using the synthetic APE data in multiple training stages and then fine-tuning it using the real APE data. We use the LaBSE technique to ensure the quality of the synthetic APE data. For data augmentation, along with using candidates obtained from an external machine translation (MT) system, we also use the phrase-level APE triplets generated using phrase table injection. As APE systems are prone to the problem of 'over-correction', we use a sentence-level quality estimation (QE) system to select the final output between an original translation and the corresponding output generated by the APE model. Our approach improves the TER and BLEU scores on the development set by -3.92 and +4.36 points, respectively. Also, the final results on the test set show that our APE system outperforms the baseline system by -3.49 TER points and +5.37 BLEU points.

1 Introduction

Automatic Post-Editing (APE) is a post-processing task in a Machine Translation (MT) workflow. It aims to automatically identify and correct errors in MT outputs (Chatterjee et al., 2020). Läubli et al. (2013) and Pal et al. (2016) show that APE systems have the potential to reduce human effort by automatically correcting repetitive translation errors.

The initial years of the WMT APE shared task focused on correcting errors in Statistical Machine Translation (SMT) translations, where participants explored various statistical and neural APE approaches (Bojar et al., 2017). Although neural APE approaches showed high potential for significantly improving the quality of SMT translations, these approaches faced challenges in improving translations obtained from relatively-more-robust neural machine translation (NMT) systems (Chatterjee et al., 2018). A possible reason for this could be that correcting a high-quality translation requires fewer edits, and therefore APE approaches need to be precise in identifying and in correcting the errors. Also, the neural APE approaches use large neural networks that require significant training data. APE training data consists of 'triplets' in the form of source sentence (*src*), its translation generated using an MT system (*mt*), and a human post-edited version of the translation (*pe*). Obtaining *pe* is an expensive task in terms of time and money; therefore, there is a lack of large APE datasets.

To deal with this problem, various data augmentation techniques have been proposed (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018; Lee et al., 2020b). Wang et al. (2020) used imitation learning to filter the APE data for tackling the distributional difference between real and synthetic APE data. Wei et al. (2020) augmented the APE training data with translations generated using a different MT system. Inspiring from the work of Sen et al. (2021), we augment the APE data by generating phrase-level APE triplets using SMT phrase tables. To ensure the quality of the synthetic data, we use the LaBSE technique (Feng et al., 2022) and filter low-quality triplets.

Another effective approach for dealing with the problem of data sparsity is transfer learning in which pre-trained models are adapted to the APE task (Lopes et al., 2019). An APE system needs to understand both the source and target languages to obtain joint encoding of *src* and *mt*. Therefore, Lee et al. (2020a) uses a cross-lingual language model instead of a monolingual one. Unlike

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 682 - 688
December 7-8, 2022 ©2022 Association for Computational Linguistics

these approaches, Wei et al. (2020); Sharma et al. (2021) use a pre-trained NMT model and adapts it to the APE task. Oh et al. (2021) has proposed the Curriculum Training Strategy (CTS) that gradually adapts pre-trained models to the APE task.

Although recent APE systems use a single encoder to encode both the source sentence and its translation (Oh et al., 2021; Lee et al., 2020a), we use separate encoders for encoding *src* and *mt* as English and Marathi do not share much vocabulary; and belong to different language families. We use IndicBERT (Kakwani et al., 2020) to initialize weights of our the *src* encoder and *mt* encoder. We train and fine-tune our models using the CTS over the good-quality APE data. The training data is also augmented with external MT candidates and phrase-level APE triplets. It is known that APE systems are prone to making unnecessary edits to translation output (Chatterjee et al., 2020). To mitigate this issue of over-correction, we use a sentence-level QE system to select the final output. When evaluated on the development set, our approach improves the TER (Snover et al., 2006) by -3.92 points and the BLEU (Papineni et al., 2002) by +4.98 points. Similarly, the final results on the test set show that our APE system outperforms the baseline system by -3.49 TER points and +5.37 BLEU points. We summarize the main features of our approach as follows:

- We use two separate encoders to generate representations for *src* and *mt*. We also use the IndicBERT language model to initialize the weights for both our encoders.

- We filter low-quality APE triplets from the synthetic data using LaBSE-based filtering.

- We divide the APE training step using CTS into two phases. We train the APE model in the first phase using out-of-domain synthetic APE data. In the next phase, we train the APE model using only the in-domain APE data.

- We follow two approaches for data augmentation: (1) As per the recent trend, we use external MT candidates. (2) We generate phrase-level APE triplets using SMT phrase tables.

- APE systems are prone to the problem of over-correction. Therefore, we use a sentence-QE system to select the final output between the APE output and the original translation.

2 Approach

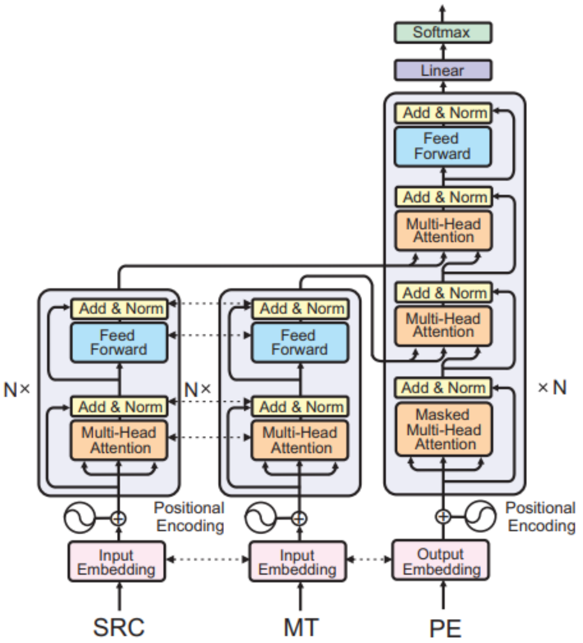

Figure 1: Dual-encoder Single Decoder Architecture. Dashed arrows represent tied parameters and common embedding matrices for encoders and decoder.(Junczys-Dowmunt and Grundkiewicz, 2018)

Our APE model is based on the transformer (Vaswani et al., 2017) architecture. Figure 1 shows the architecture of our APE model. In this section, we discuss the details of our approach.

2.1 Dual-Encoder Single-Decoder APE Model

The APE task is usually treated as an NMT-like task. Recent approaches use a single encoder to encode a source sentence and its translation (Oh et al., 2021; Lee et al., 2020a). Such an approach may work well when the source and target languages share the vocabulary (Kanojia et al., 2021). However, for English and Marathi, there is no vocabulary overlap, and also, the script used in both languages is different (Kanojia et al., 2020). Therefore, for developing an English-Marathi APE system, we use two separate encoders to encode *src* and *mt* (Junczys-Dowmunt and Grundkiewicz, 2018).

We apply transfer learning by using IndicBERT to initialize weights of the *src encoder* and the *mt encoder*. We choose IndicBERT as it is trained over text in Indian languages and English. We use a single transformer-based decoder that attends to representations of both *src* and *mt* and generates a post-edited version of the *mt*. We add one more cross-attention layer above the available cross-attention layer in the decoder. We pass the representation generated by *mt encoder* to the first cross-attention layer. The newly-added cross-attention layer receives two inputs: output of the first attention layer and representation generated by the *mt encoder*. Such placement allows the decoder to first attend to *mt*, which is prone to mistakes, and then it attends to *src*, which doesn't involve any errors. We share parameters between encoders, but the encoders generate different activations, and different attention layers receive the outputs of these encoders in the decoder. During the fine-tuning phase, we concatenate *mt* and *external MT candidate* using a special token '[SEP]' and pass this concatenated sequence to the *mt encoder*.

2.2 Sentence-Level Quality Estimation

In the Sentence-level Quality Estimation (QE) task, the machine-translated sentence is evaluated by human annotators by providing each instance with a Direct Assessment (DA) score (ranging from 0 to 100). These scores are then normalized using *z-score normalization*. A source sentence and the corresponding machine-translated output are passed to the sentence-level QE (sentence-QE) system as inputs, and it predicts a z-standardized DA score denoting the quality of translation.

We use the MonoTransquest (Ranasinghe et al., 2020), a XLM-R (Conneau et al., 2020) based model to obtain representations of the inputs. The XLM-R model is trained using a 2.5TB multilingual dataset retrieved from the CommonCrawl databases, which includes 104 languages. It is trained using the RoBERTa's masked language modelling (MLM) objective (Liu et al., 2019). We use the training (18K samples), and development (1K samples) sets shared in the WMT-22 Sentence-QE English-Marathi sub-task to train our sentence-QE model.

We use this sentence-QE model to rate the original translation and the output generated by our system. We then compare the ratings for both these sequences and select the one with a higher rating as the final output.

2.3 Curriculum Training Strategy (CTS)

We follow the CTS (Oh et al., 2021) to train our APE model. It involves gradually adapting a model to more complex tasks. In the first step, we train an encoder-decoder model for performing English to Marathi translation. We then add another encoder to the encoder-decoder model and train the resulting *dual-encoder single-decoder* model for the APE task using synthetic APE data in two phases. In the first phase, we train the APE model using APE triplets belonging to any domain except the General, News, and Healthcare domains. In the second phase, we train the model using synthetic APE triplets of the General, News, and Healthcare domains. Finally, we fine-tune the APE model using in-domain real APE data and external MT candidates.

2.4 Data Augmentation

Before using the synthetic APE data during the training steps of the CTS, we filter the low-quality triplets by using the LaBSE-based filtering (Feng et al., 2022). We do this to ensure adequate quality of the synthetic APE data. To do so, we first generate embeddings of the *src* and *pe* using the LaBSE model and normalize them. Then, we compute the cosine similarity between these normalized embeddings. If the cosine similarity is less than 0.91, we discard the corresponding APE triplet. Our experimental results show the importance of using good-quality APE data to train APE systems.

We also generate the phrase-level APE triplets using the good-quality synthetic APE data and the real APE data. We follow the procedure described by Sen et al. (2021) and extend it for the phrase-level triplet injection for APE. First, we use the Moses (Koehn et al., 2007) SMT system and train *src-mt* and *src-pe* phrase-based SMT systems. We then extract these phrase pairs from both SMT systems. In the next step, we collect pairs of phrase-pairs having same *src* from the *src-mt* and *src-pe* phrase tables. Finally, we follow the steps used in the LaBSE-based filtering and get cosine similarity scores for both the phrase pairs having the same *src*. If both the scores are more than 0.91, we combine these two phrase pairs to form a triplet and add it to the APE dataset.

To generate the external MT candidates, we train an mT5 (Xue et al., 2021) based English-Marathi NMT model over a publicly available English-Marathi parallel corpora (Samanantar (Ramesh et al., 2022), Anuvaad[1], Tatoeba[2], and ILCI (Bansal et al., 2013)) of around 6M parallel sentence pairs. We use the external MT candidates during the fine-tuning phase.

3 Experimental Setup

3.1 Dataset

This year's APE shared task focused only on the English-Marathi language pair. The real APE training data contains 18K APE triplets, and this APE data belongs to the General, Healthcare, and Tourism domains. The organizers also shared the synthetic APE data of various domains totaling around 25M APE triplets. As participants, we were permitted to use external data for this task.

To train a translation model, we use the publicly available English-Marathi parallel corpora of size around 6M parallel sentence pairs. For data augmentation, we first generate phrase-level APE triplets using synthetic and real APE data and then randomly select 50000 phrase-level APE pairs for augmenting with the synthetic APE data and 10000 for augmenting with real APE data.

3.2 Training Hyperparameters

We used NVIDIA DGX A100 GPUs for our experiments. We trained our models with a batch size of 32. We set the number of maximum epochs to 1000 with early stopping patience of 5. We used the Adam optimizer with a learning rate of 5 x 10^{-5}, $\beta_1 = 0.9$, and $\beta_2 = 0.997$. We set the number of warmup steps to 25K. On the decoder side, We used beam search with the beam size set to 5. For the LaBSE-based filtering, we used a threshold value of 0.91 for cosine similarity to ensure that *mt* and textitpe are similar to each other.

4 Results

In Table 2, we report the results of our APE system by evaluating it on the development set. To estimate the quality of our APE system output compared to the human-generated references, we use BLEU and TER score between the APE output and *pe*. Table 2 compiles the results of our experiments performed on the development set.

We compare the results of our experiments against a 'Do Nothing' APE baseline that simply outputs *mt* without any modification. When we trained our model using CTS and external MT candidates to increase feature diversity, the TER and BLEU scores improved to 20.08 TER points and 67.39 BLEU points from the baseline TER and BLEU scores of 22.93 and 64.51, respectively. The third row in the 2 shows the results of an experiment where we use a good-quality synthetic dataset for APE training obtained by filtering low-quality triplets using LaBSE-based filtering. The experiment also involves training the APE model in two phases: first, the model is trained on out-of-domain synthetic data and then on in-domain synthetic data. This setting brings -3.2 and +3.35 TER and BLEU score improvements over the baseline, and *underlines the importance of using good-quality in-domain APE data.*

The only change we make for performing the next experiment is augmenting the synthetic and real APE data using phrase-level APE triplets. Results of this experiment show that performance improves over the baseline by -3.54 TER points and +3.84 BLEU points. Towards the end, we also used a sentence-QE system to rate the original translation and the APE output. We then select one of them with a higher rating as the final output of our APE system. With the combination of the APE model and sentence-QE system, we see that the TER score improves to 19.01 points, and BLEU score increases to 68.87 points; which *shows that using the sentence-level QE system is an effective* *approach to discard APE output, in cases of over-correction.*

As per the information received by the shared task organizers, our APE system achieves a TER score of 16.79 points and a BLEU score of 72.92 when evaluated on the official test set, which is -3.49 TER points and +5.37 BLEU points improvement over the baseline.

5 Conclusions and Future Work

This paper presents our APE system submitted to the WMT-22 APE English-Marathi Shared task. We use a dual-encoder single-decoder model where both encoders are initialized using IndicBERT. We propose a new way to generate artificial phrase-level APE triplets by extending the phrase-pair injection method used in MT for APE. We show that augmenting APE training data with these phrase-level triplets and training the model with the CTS on good-quality in-domain APE data improves the performance of the APE system. Furthermore, we also explore using the sentence-level QE system to discard low-quality APE outputs. Evaluation of our APE system shows that our approach achieves significant gains on the WMT-22 APE development and test sets.

In future, we would like to extend this approach for automatic post-editing with the help of word-level quality estimation and come up with a single architecture for performing both the QE tasks along with APE. We would also like to attempt a multilingual APE system with a shared decoder across multiple languages.

6 Limitations

We use in-domain data to train the APE model in the last training stage and the fine-tuning stage. It makes the APE system robust in post-editing in-domain translations, but it also makes it sophisticated. We observe that the system's performance worsens when we pass out-of-domain translations to the system. Similarly, we observe poor performance when translations with distributional differences from the real APE data are passed to the APE system. We use a sentence-level QE system to compare the quality of the APE output and the original translation. Even though it helps us to get rid of poor-quality APE outputs, the APE system itself does not get benefited from it.

Abstract

By learning the human post-edits, the automatic post-editing (APE) models are often used to modify the output of the machine translation (MT) system to make it as close as possible to human translation. We introduce the system used in our submission of WMT'22 Automatic Post-Editing (APE) English-Marathi (En-Mr) shared task. In this task, we first train the MT system of En-Mr to generate additional machine-translation sentences. Then we use the additional triple to bulid our APE model and use APE dataset to further fine-tuning. Inspired by the mixture of experts (MoE), we use GMM algorithm to roughly divide the text of APE dataset into three categories. After that, the experts are added to the APE model and different domain data are sent to different experts. Finally, we ensemble the models to get better performance. Our APE system significantly improves the translations of provided MT results by -2.848 and +3.74 on the development dataset in terms of TER and BLEU, respectively. Finally, the TER and BLEU scores are improved by -1.22 and +2.41 respectively on the blind test set.[1]

1 Introduction

Automatic Post-Editing (APE) is the task of automatically editing the translations of MT system. By using APE models, we can transfer MT system from general domain to specific domain and then reduce the workload of human post-edits. WMT has been holding APE task competitions in different languages and fields since 2015. Now the APE models are often based on transformer and improved on this basis.

WMT 2022's Automatic Post-Editing task focused on English-Marathi language pairs. The difference from the previous competition is that the target language is changed to Marathi. Besides, two new fields, medical care and tourism, are added. Participants are provided a training set with 18000 instances, a development set and a test set with 1000 instances respectively. Each dataset consists of source, machine-translation and post-edit triplets. The source sentences in English come from the healthcare, tourism, and general/news domains. The MT outputs are automatic translations to Marathi. The post-edits are human revisions of the target elements. This synthetic training data is prepared as a part of the 2022 APE shared task. The data is created by taking a parallel corpus, where the source data is translated using an MT system, and the references are considered as post-edits. Participants are also allowed to use any additional data for systems training.

Last year's research mainly focused on transfer learning and data augmentation. Sharma et al. (2021) utilizes the most advanced En-De machine translation model and further fine tune the APE dataset on this basis. We adopted the same strategy to train our baseline model with transfer learning and data augmentation. Due to the lack of a ready-made machine translation model of En-Mr as the basis of the APE model, we trained an APE model by using synthetic data and additional data. The APE model is then further fine-tuned with the APE dataset, which is data enhanced. In order to make use of the domain information in the training dataset, we use the mixture of experts structure and add adapter modules in the transformer, so that different adapters can learn the distribution of different domain information, thus improving the translation performance. The contributions of this work are as follows. (1) Data augmentation. We trained an external MT to obtain more data sets consistent with ape tasks. At the same time, we use Google translation to back translate the post-edits in the training set. The dataset is composed as follows: back translation <s> machine translation as input and post-edits as reference output. On the other hand, we take source <s> post-edits as

[1] Work performed during internship in Samsung Research China - Beijing

input and post-edits as reference output. (2) Mixture of adaptors. We implement the mixture of experts structure to deal with inputs from different domains, in which we use lightweight adapters as experts and introduce a classifier for expert routing. Considering the effect of directly initializing the adapter for training is not good enough, so we first set an adapter in the model and pre-train the model to obtain the adapter weight W_0. Since the training set comes from three different fields, we add two additional adapters, which will read W_0 as a parameter for initialization. We freeze all model parameters when training the model, and only fine tune the weights of the three adapters.

2 Related Work

Last year's WMT'21 APE shared task proved that both transfer learning and data augmentation were very effective. Facebook Fair's WMT19 news translation model was used in Shinhyeok's system (Oh et al., 2021). By continuously adding different levels of datasets, the model gradually understood APE tasks. For further improvement, Oh et al. (2021) used a multi-task learning strategy with dynamic weight average. By adding related subtasks, the model can learn unified representation. In addition, they also used the data set provided by ape shared task in previous years. Finally, their TER and BLEU scores were 17.28 and 71.55, respectively. Oh et al. (2021) used the most advanced machine translation model as the pre-trained model. The WikiMatrix dataset was uesd to make the model distribution tend to match the field. After that, APE samples from former years were added for fine adjustment. Finally, their model's TER and BLEU scores were 17.85 and 70.5, respectively.

Considering the experience of previous competitions, we used the existing data to train an En-Mr translation model as a data augmentation method due to the lack of advanced En-Mr translation model. Inspired by the MoE, the built-in adapter module enables the model to learn three data distributions at the same time to improve the performance of translation.

3 Dataset

3.1 Data Source

We used the WMT22 official English-Marathi APE dataset which consisted of a training and development set. We also used synthetic training data, which was prepared as a part of the 2022 APE shared task. In addition, we collected LoResMT2021 Shared Task (mac) data, CVIT PIBv1.3 (Philip et al., 2021), bible-uedin (Christodouloupoulos and Steedman, 2015) as some additional data to train our models. The LoResMT2021 Shared Task focused on machine translation of COVID-19 data for both low-resource spoken and sign languages. The LoResMT2021 dataset contains three parts: English-Irish, English-Marathi, and Taiwanese Sign language-Traditional Chinese. We only use its English-Marathi parallel corpora. CVIT PIBv1.3 is used in this work as a source for articles published in several Indian Languages to extract a multiparallel corpus. Sentences in CVIT PIBv1.3 aligned parallel corpus between 11 Indian languages, crawling and extracting from the press information bureau website. Bible-uedin is a multilingual parallel corpus created from translations of the Bible compiled by Christos Christodoulopoulos and Mark Steedman. The summary of the corpora used is provided in Table 1.

3.2 Data augmentation

As shown in Table 1, we have collected lots of parallel corpus but these corpus lack the MT part (LoResMT2021, CVIT PIBv1.3, Bible-uedin, and some synthetic training data). Following the method of generating synthetic training data, we first train a machine translation system, and then use this system to translate the source data. To generate translation similar to synthetic training data as much as possible, we did not use *src-pe* pairs but *src-mt* pairs when training MT models. We use all parallel corpus to train MT model. We are able to achieve a BLEU score of 25.3 with our MT model. Finally, we translate the sources we collected by our MT model and achieve approximately 2500000 triplets.

Yang et al. (2020) utilized data augmentation with external MT to generate the external translated sentence, which could help generate the post-editing sentence. We take a similar line of approach by leveraging external MT to generate the external translated sentence but the result is not satisfactory. So we utilize external MT to generate the external back-translations. We'd like to use back-translations to add a set of parallel corpora for the model to learn the rules of post-edits. In addition,

Source	pairs	type
APE dataset	18k	*src-mt-pe*
Synthetic training data	2.57m	*src-mt-pe*
LoResMT2021	21k	*src-pe*
CVIT PIBv1.3	117k	*src-pe*
Bible-uedin	60k	*src-pe*

Table 1: Publicly available corpuses for Indian languages.

we also use sentence X that contains a source sentence (*src*) and a post-editing sentence (*pe*) as input. We assume that the model can learn the invariance in post-editing rules by leaking some information of *pe*.

In this paper, we use D_{ape} for [*src*, <*s*>, *mt*], D_{bac} for [*src'*, <*s*>, *mt*] and D_{pe} for [*src* and <*s*>, *pe*].

4 Model

We describe our baseline model followed by the details of domain and task adaptation in this section.

4.1 Fine-tuned Transformer

Compared with previous APE tasks, this task focuses on English-Marathi language pairs. It is impossible to fine tune APE dataset on the basis of MT model. We decided to solve the APE task as NMT alike task. To adapt this idea with Transformer, we use a special token <*s*> to concatenate *src* and *mt* to generate input sentence: [*src*, <*s*>, *mt*]. We first trained the APE model with the standard Transformer (Vaswani et al., 2017) structure using synthetic training data and additional data. In order to fix the mismatch between the APE model training data and the distribution in our task, we further fine-tuned the APE model on the APE dataset.

To further solve the problem of limited data, we use the data collected in the Data section to adopt three data augmentation methods. First, we use Google translation system to create the *src'* from the provided *pe* text. We simply concatenate the *src'* with *mt* to form the new input: [*src'*, <*s*>, *mt*]. After this, the model input consists of [*src*, <*s*>, *mt*] and [*src'*, <*s*>, *mt*], which contains 36000 triplets. The second method is to add [*src*, <*s*>, *pe*] as the input on the basis of the original input and the third method is to add the first two as input at the same time. In the first way, we'd like to add a group of parallel corpora for the rules in editing after model learning. The second way is to think that by adding PE, the model can learn the rules of human post editing from SRC, MT and PE. The purpose to adopt the third method is to combine the first two methods for a better model performance.

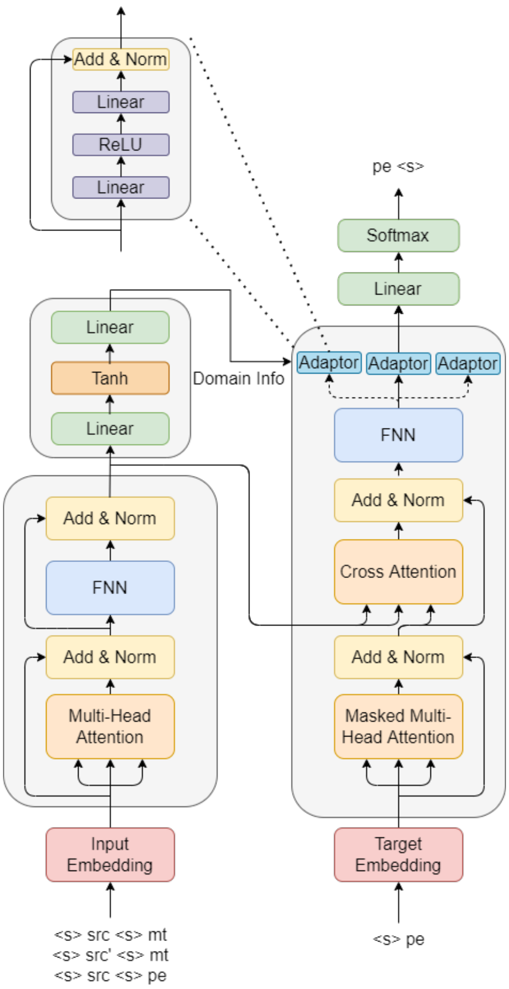

Figure 1: Adapter overall framework.

4.2 Adapter

We found that the APE dataset contains medical, tourism and general/news data. Inspired by the mixture of experts (Jacobs et al., 1991), we introduce adapters (Bapna and Firat, 2019; Pham et al., 2020) to handle different domains. We suppose that different adapters can process different domain data, so as to keep other parameters unchanged to improve the translation performance of the model for each domain, thus improving the overall TER and BLEU.

The structural diagram of the adapter is shown in Figure 1, which is similar to the FFN layer in transformer, but has a low dimensional hidden layer for nonlinear activation. In the experiment, we add the adapter layer after the FFN layer for each block in the decoder. Each adapter layer consists of three adapters. A classifier is introduced after the encoder to generate domain information (Domain Info) and it decides which adapter is activated during inference. Overall, in the inference phase, the classifier first generates domain information (Domain Info) by the encoder output, and then the corresponding adapter in each decoder is activated by the domain information. Finally, same with a general NMT model, the output is generated with an auto-regressive process.

The adapter model is trained with a pipe-line training process. First, an APE model is trained as the base model. Different from the original baseline model, an adapter is injected to each decoder layer and will be used to initialize the other two adapters in the same decoder layer. Then the classifier is trained by using a multi-classification task. Finally, with all other parameters are frozen, the parameters of the adapters are optimized by using the NMT task.

5 Experiment and Results

5.1 Experimental Settings

Both our En-Mr MT model and APE model are implemented with Fairseq framework (Ott et al., 2019). The Transformer model used for both models is Transformer-base with 6 encoders and 6 decoders, and the hidden size is 2048 for FFN layers and 512 for all other layers. The adapter used in our model is also modified to have a larger parameter size, where the hidden size of the inner layer is set to 2048.

Because we lacked the MT model, we learned the vocabulary of En and Mr by BPE. Specially, for English, we use token first and then BPE, while for Marathi, we directly conduct BPE. We believe that if token is used for Marathi before BPE, the model cannot learn the rules for punctuation after manual post-edits. The thing we should notice that the vocabulary of the En-Mr model cannot be shared which contains 31K and 31K sub-tokens for En and Mr respectively. Since the input of APE model contains En and Mr, the joint vocabulary of APE should be the total number of tokens in both languages, about 58K sub-tokens. All models were trained on NVIDIA Tesla V100. We use Adam optimizer to optimize with a fixed learning rate of 5e-4. The max tokens are set to 4096, about 64 batch sizes.

System	BLEU	TER
baseline	64.62	19.93
+Fine-tuning (D_{ape})	66.19	18.71
+Fine-tuning (D_{ape}+D_{bac})	66.44	18.56

+Fine-tuning (D_{ape}+D_{pe})	67.24	18.09
AVG_FT (D_{ape}+D_{pe})	**67.37**	**17.91**
+Fine-tuning (D_{ape}+D_{bac}+D_{pe})	66.93	18.30
AVG_FT (D_{ape}+D_{bac}+D_{pe})	67.22	17.93

Table 2: This is the experimental result of fine-tune. AVG represents the weighted average of the model.

System	BLEU	TER
baseline	64.62	19.93
Adpt (D_{ape}+D_{bac})	66.89	18.34
AVG_Adpt (D_{ape}+D_{bac})	66.84	18.36
Adpt (D_{ape}+D_{pe})	67.55	17.90
AVG_Adpt (D_{ape}+D_{pe})	67.55	17.89
Adpt (D_{ape}+D_{bac}+D_{pe})	**67.71**	**17.85**
AVG_Adpt (D_{ape}+D_{bac}+D_{pe})	67.67	17.89

Table 3: This is the experimental result of adapter. AVG represents the weighted average of the model.

5.2 Fine-tuned Transformer

Table 2 shows the experimental results of APE finetune model, where the baseline result is produced by directly calculating scores between the provided *mt* and *pe*. The first experiment is performed by fine-tuning all parameters of the pre-trained Transformer on the official training set. The TER and BLEU on the 2022 dev set were 18.71 and 66.91, which were -1.2 and + 1.57 better than baseline. This demonstrates that fine-tuning the pre-trained NMT model on the limited dataset can be useful.

The experiment of training model on D_{ape}+D_{bac} and D_{ape}+D_{pe} for data augmentation shows significant improvements on the performance. However, after performing experiments with different checkpoints of APE model, we find that the best checkpoint is not the best saved checkpoint for translation, which motivates us to average model weight parameters near the best checkpoint. The avg model results show averaging the model weight parameters near the best checkpoint can help the model to be closer to the convergence point locally. The performance of the model is improved well.

5.3 Adapter

Table 3 shows the experimental results of APE adapter model. For D_{ape}+D_{bac} dataset, adding the

System	BLEU	TER
baseline	67.55	20.28
Finetune_PRIMARY	69.66	19.36
Adapter_CONTRASTIVE	69.96	19.06

Table 4: Results on test dataset.Finetune_PRIMARY ensembles AVG_FT (D_{ape}+D_{bac}) and AVG_FT (D_{ape}+D_{pe}). Adapter_CONTRASTIVE ensembles AVG_Adpt (D_{ape}+D_{bac}) and AVG_Adpt (D_{ape}+D_{pe}).

adapter does not improve the APE performance of the model, but for D_{ape}+D_{pe} dataset, adding adapter makes the model reduce TER and improve BLEU, reaching the lowest TER and the highest BLEU respectively. The experimental results show that the rough classification of data and the learning of their respective distributions are more conducive to the better APE performance of the model.

5.4 Results on Test set

Table 4 shows the official results of our proposed methods on WMT22 test dataset with a baseline scores of 20.28 and 67.55, which is higher than the development dataset with 19.93 and 64.62 in terms of TER and BLEU. Despite its high quality, our proposed methods show effectiveness on this test dataset. We find that there are some Arabic numerals and Devanagari numerals in post-edits. However, because we are not familiar with Marathi, we do not know the number modification rules. Therefore, we replace all Arabic numerals in test results with Devanagari numerals to get the final post-edits.

6 Conclusion

In this paper, we first use the data augmentation method to build the *src' <s> mt* and *src <s> pe* as two additional training datasets. We suppose that the enhanced datasets can effectively improve the performance of the APE model. The experimental results show that the data augmentation method we used is effective. At the same time, it also shows that adding *pe* can make the model automatically learn the rules of human post-edits. After that, we draw lessons from mixture of experts. We add adapters in the APE baseline model. And we let the training data be sent to different adapters through the trained classifier so that the model can further learn the post-editing rules in different translations. The experimental results confirm that our system can modify the output of MT system with high efficiency and quality. Compared with baseline, the TER and BLEU scores are improved by -1.22 and + 2.41 respectively.

Abstract

In the seventh edition of the WMT Biomedical Task, we addressed a total of seven language pairs, namely English/German, English/French, English/Spanish, English/Portuguese, English/Chinese, English/Russian, English/Italian. This year's test sets covered three types of biomedical text genre. In addition to scientific abstracts and terminology items used in previous editions, we released test sets of clinical cases. The evaluation of clinical cases translations were given special attention by involving clinicians in the preparation of reference translations and manual evaluation. For the main MEDLINE test sets, we received a total of 609 submissions from 37 teams. For the ClinSpEn sub-task, we had the participation of five teams.

1 Introduction

This is the seventh edition of the biomedical translation task offered under the umbrella of the Conference on Machine Translation (WMT22).[1] This shared task builds on the six previous editions of the biomedical translation task (Bojar et al., 2016; Jimeno Yepes et al., 2017; Neves et al., 2018; Bawden et al., 2019, 2020; Yeganova et al., 2021). Similar to previous years, we addressed seven language pairs, in both directions, namely: German/English (de2en and en2de), Spanish/English (es2en and en2es), French/English (fr2en and en2fr), Italian/English (it2en and en2it), Portuguese/English (pt2en and en2pt), Russian/English (ru2en and en2ru), and Chinese/English (zh2en and en2zh).

In the biomedical translation task this year, participants were asked to translate shared test sets (described in Section 2) comprising documents belonging to three different text genres: scientific abstracts, clinical cases and terminology items. In total, seven language pairs (14 translation directions) were included this year, with both low-resource and high-resource pairs. For each language direction, we provide baseline systems relying on pre-trained

[*] The contribution of the authors are the following: MN prepared the MEDLINE test sets, performed test set validation, manual validation, and organized the task; AJY performed test sets validation, manual validation and the automatic evaluation; RR, PT, MVN, LY, DW. GMDN, FV performed test sets validation and manual validation; CGn created reference translation and performed manual validation; RB performed manual validation; DJE, SLL, EFM, MK organized the ClinSpEn sub-task; CGa created the baselines; and AN collected information on participants' methods, performed test sets validation, manual validation and created reference translation. All authors approved the final version of the manuscript. E-mail for contact: mariana.lara-neves@bfr.bund.de

neural translation models (described in Section 3). In order to help gain insight into the system performance, we collected information on the specific material and methods used in the systems from the participants (Section 4). System outputs for each task were evaluated both automatically and manually (as described in Section 5 and 6, respectively). One particular growth direction that we explored this year was the inclusion of full clinical case descriptions. A small set of five clinical cases in English were included in the MEDLINE test sets from English and a larger clinical corpus corpus was also included in the ClinSpEn track. We also involved clinicians in the preparation of gold standard translations and manual evaluation of clinical cases for en2fr and en2es.

Two types of submissions were received for the MEDLINE test sets: those submitted using (i) our submission system (hereafter called BioWMT), as in previous years, and (ii) the OCELoT submission system,[2] which was also used in the WMT general task.

In addition, an independent subtask was held as part of the Shared Task: ClinSpEn.[3] ClinSpEn focuses on the automatic translation of clinical content in both English and Spanish. Three subtracks are proposed based on different possible use cases: clinical case reports, clinical terminology obtained from literature and Electronic Health Records (EHR) and ontology concepts. Unlike the rest of the tasks, ClinSpEn's evaluation was done through CodaLab[4] and new submissions can still be made.

2 Test sets

In this section we describe the various test sets that we released for this year's edition of the WMT Biomedical task.

2.1 MEDLINE test sets

The MEDLINE test sets consisted of abstracts and case reports from the MEDLINE database. We aimed to retrieve 50 articles for each language direction. For the directions into English, the test sets consisted only of parallel abstracts. For the directions from English, we manually selected five clinical case reports, which were only available in English and which were the same across all language pairs. We completed each of these test sets with parallel abstracts. Table 1 summarizes the MEDLINE test sets as released in our submission system and in OCELoT. The only difference between the test sets released in our submission system and in OCELoT was that the latter contained aligned sentences, as provided by the automatic alignment. We describe the construction of the parallel abstracts and clinical case reports below.

2.1.1 Parallel abstracts

For the parallel abstracts, we downloaded the MEDLINE database[5] around the end of February and selected parallel abstracts for each language pair. We targeted publications whose PMID (PubMed identifier) was not included in any of our previous test sets and training data. We processed the abstracts using the same tools for sentence splitting and sentence alignment as in previous years (Yeganova et al., 2021). We manually checked the quality of the alignment using the Appraise tool (Federmann, 2010) and present results in Table 2.

2.1.2 Clinical case reports

For test sets *from English*, we decided to select clinical case presentations in order to include documents that would be closer in genre to clinical narratives found in patient records. Five clinical cases[6] were selected from publications of the *Journal of Medical Case Reports* (an open access publication) according to the following criteria:

- Reports a case related to oncology (based on the expertise of clinicians that agreed to contribute to the evaluation);
- Reports containing specific values such as lab results;
- Reports containing a limited amount of references to images and tables (to maximize resemblance with EHR narrative);

Both the abstract of the article and the full case presentation were included in the test set.

A gold standard translation of the clinical cases (both abstract and full case presentations) was created for French. We used the free version of

Table 2: Statistics (number of sentences and percentages) of the quality of the automatic alignment for the MEDLINE test sets. § Results after manual correction of sentence segmentation and/or alignment.

DeepL[7] followed by two rounds of post-edition: first, a native French speaker with formal translation training and knowledge of clinical text (AN) post-edited the machine translation (MT) focusing on linguistic quality and fluidity of the translation; second, a clinician (CG) post-edited the revised text focusing on clinical correctness and adequacy of the text with the French clinical narrative genre. In this second step, special attention was given to values such as lab results, which can be expressed using different units in English vs. French. The goal was to produce a translation that would convey properly processed information for direct use by a clinician. We computed BLEU scores between the original machine translated text and successive rounds of post-edition. BLEU between MT and the final gold standard translation was 38 for abstracts and 42 for full texts, while BLEU between the translator post-edited text and final gold standard translation was 63 for abstracts and 85 for full texts.

2.2 ClinSpEn test sets

For each of the ClinSpEn sub-tracks, a gold standard dataset was prepared with human translations created by domain experts. Additionally, a big collection of monolingual background data was provided for each subtrack so that participants could test the scalability of their systems or use them for other purposes.

Sub-track 1: Clinical case reports. This subtrack deals with the translation of clinical case reports. Clinical cases are a text genre where a patient's current condition, medical history, clinical presentation, examinations, treatment and diagnosis are described. They can be pretty similar to EHR both in form and content. However, unlike EHR, clinical cases are often free of privacy-related issues. This means that they can be used as substitute to train NLP systems for the clinical domain.

The gold standard dataset's clinical cases were carefully selected to cover a wide range of aspects related to COVID-19: different types of patients (children, adults, elderly and pregnant people, babies), different comorbidities (cancer, mental health issues, immunosuppressed patients) and symptomatology (mild and severe presentations, dermatologic, immunologic and psychiatric manifestations, thrombosis, etc.). The reports were translated from English to Spanish by a professional medical translator in a first step and revised by a clinical expert in a second step. The background set includes around 3,800 clinical case reports in English extracted from PubMed Central.

The dataset includes a total of 202 COVID-19 clinical case reports (50 for the dev set, 152 for the test set) and the direction of this sub-track is en2es.

Sub-track 2: Clinical terminology. This subtrack deals with the translation of clinical terminology. Translating clinical terminology is very relevant due to the existence of many established concepts and multi-word expressions (MWE) that need to be translated not only correctly but also consistently. Systems able to consider not only full sentences but also specific terms are able to provide more accurate translations, something fundamental in the clinical domain.

The gold standard terms were extracted from biomedical literature and electronic health records using information retrieval systems, filtered and translated and revised by professional medical translators. Amongst other semantic classes, the selected terms include diseases, symptoms and findings, procedures, drugs and species. The background set includes over 200,000 concepts in Spanish from the same sources.

The dataset includes a total of 19,128 terms (7,000 for the dev set and 12,128 for the test set). The direction of this sub-track is es2en.

Sub-track 3: Clinical terminology. This subtrack deals with the translation of concepts extracted from ontologies. Ontologies are one of the main ways of structuring knowledge. In the clinical domain, they are widely used mainly to normalize the content of electronic health records. However, their everyday use can be greatly limited by their unavailability in languages other than English. MT systems specifically trained for this type of data can be of great help to improve the impact of these ontologies or to ease a manual translation process.

The gold standard for this task is made up of concepts extracted from various free-access biomedical ontologies and taxonomies and then manually translated by a professional medical translator. Due to their origin, these concepts may present different challenges than terms extracted from free text, such as semi-structured concepts. The background set includes 300,000 concepts in English extracted from the same sources.

The dataset includes a total of 2,189 concepts (300 for the dev set and 1,789 for the test set). The direction of this sub-track is en2es.

3 Baselines

The baselines for en2de, en2fr, en2es, en2pt, de2en, fr2en, es2en, and pt2en were computed using models we trained ourselves in the previous years using Marian NMT (Junczys-Dowmunt et al., 2018). The baselines for en2zh, en2it, en2ru, zh2en, it2en, zh2en were computed using pre-trained Marian models distributed as HuggingFace "Transformers" library models,[8] without trying to increase their performance on the biomedical texts through further fine-tuning. The computation was performed on a single Nvidia A5000 GPU card.

The baselines are strongly outperformed by the participants of the biomedical task, with the exception of **en2it** where all reach similar and very high levels, in excess of 47 BLEU. Especially our zh2en baseline needs improvement.

[8] https://huggingface.co/Helsinki-NLP

4 Teams and systems

In this section we describe the teams and the number of submissions that we received from our two submission systems. When considering both the MEDLINE and the ClinSpEn sub-task, we had a total of 40 participating teams. We describe the submissions for each of them below.

4.1 MEDLINE participation

This year, we received a total of 609 submissions from 37 teams (see Table 3), from the following countries: China (7), France (2), Poland (1), Russia (1), and South Korea (1). Most teams (N=25), however, did not report a country of affiliation.

The number of submissions for each of the MEDLINE test sets are split into to parts: from English in Table 4 and into English in Table 5. We received around 100 more submissions for the test sets into English (354 vs. 255).

As in the 2020 and 2021 editions, we asked participants to fill out a survey with key information regarding the specific material and methods used in their self-identified primary runs used for manual evaluation. The survey comprised 15 questions covering the translation methods and corpora used. For consistency with previous years, the only change to the questionnaire was the addition of a question regarding the method used by teams to estimate the environmental impact of their experiments. We included the CO2 measurement methods identified in (Bannour et al., 2021) as options.

Only six teams supplied information about their "best run", and none reported measuring the environmental impact of their participation to the task. On average, the time spent by participants to supply information for one language pair was 7 minutes and 13 seconds (median: 3 minutes and 27 seconds). This is consistent with the previous survey statistics and suggests that the time commitment for supplying this information is limited, even for teams addressing more than one language pair.

All teams used transformer-based neural MT (NMT), relying mostly on existing implementations. Contrarily to last year, teams addressing several language pairs adapted their setup across them. See Table 6 for details of the teams' methods.

For in-domain data, teams used the training data distributed as part of the task as well as many of the sources described in (Névéol et al., 2018). Additional corpora used for Chinese were prepared by the teams but are not always available or described in detail, except for ParaMed, which relied on the New England Journal of Medicine to create a parallel corpus (Liu and Huang, 2021). Terminologies used by team Summer are available online.[9] The in-domain monolingual corpora used often use different selections of MEDLINE. We can also notice that the use or pre-processing of the same resources can differ between teams as the size reported for seemingly similar data can differ significantly. Table 7 provides details of the in-domain data used by the teams.

For relevant language pairs, parallel data from other WMT tracks (e.g. General or News Task) was used. Out-of-domain data was also used in the form of pre-trained base models. Table 8 shows details of the out-of-domain data used by the teams.

4.2 ClinSpEn Participation

In total, 11 different teams both from academia and industry registered for the ClinSpEn subtask, although only 5 teams ended up submitting their predictions. Four of them participated in all subtracks, with one of them participating only in subtrack 2 (clinical terminology translation). Table 9 presents an overview of the teams who submitted their predictions to the task.

5 Automatic evaluation

In this section we present the automatic evaluation that we performed for the MEDLINE and the ClinSpEn test sets.

5.1 MEDLINE test sets

For the MEDLINE test sets, we calculated the BLEU scores in the same way as previous years (Yeganova et al., 2021). We split the runs that we received into three groups: (i) runs to our BioWMT submission system; (ii) runs to the OCELoT Biomedical Task; and (iii) runs to the OCELoT General Task. As already discussed above, the only difference between the test sets in OCELoT and the ones in our submission system is that the sentences are aligned in OCELoT.

Results for runs to our BioWMT submission systems are presented in Tables 10 and 11. Runs for the Biomedical Task in OCELoT are shown in Tables 12 and 13. The run identifiers were mapped to names (e.g. run1, run2), and the mapping is presented in the Appendix (Tables 23 and 24). Finally,

Table 3: List of the participating teams.

due to the large number of teams and runs, we split the General Task runs into various results tables. The from-English submissions are split into two parts in Tables 14 and 15, while the identifier mapping is provided in Tables 25 and 26. Similarly, the into-English submissions are split into two parts in Table 16 and 17, while the identifier mapping is provided in Tables 27 and 28.

In general, the scores were much higher for runs to the BioWMT submission system than for the ones from the OCELoT test sets. All runs for the BioWMT submissions system outperformed our baseline. We did not provide a baseline for the OCELoT test sets.

5.2 ClinSpEn - CodaLab

The ClinSpEn subtask was evaluated in the CodaLab platform (Pavao et al., 2022). CodaLab is an open-source platform for running competitions, with some of its main advantages being automatic scoring and leaderboard building.

ClinSpEn submissions were evaluated using five common MT metrics: COMET (Rei et al., 2020), METEOR (Banerjee and Lavie, 2005), SacreBLEU (Post, 2018), BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). The main metric used for comparison is SacreBLEU, which is the same as OCELoT uses, and the other metrics are given so that participants are able to evaluate their systems from different perspectives. Part of the evaluation scripts were shared by the MedMTEval organizers

Table 4: Overview of the submissions from all teams and test sets translating from English. We identify submissions using the WMT Biomedical Submission System (WMTBio) with a "B", the ones for OCELoT Biomedical Task with an "O", and the ones for OCELoT General Task with an "G". The value next to the letter indicates the number of runs for the corresponding test set, language pair, and team.

[CITE], who used the HuggingFace datasets library (Lhoest et al., 2021). Multiple tests were performed to check that the results of our evaluation scripts are comparable to those returned by OCELoT and the WMT submission system. In total, participants were allowed to upload up to 7 predictions for each sub-track.

Tables 18, 19 and 20 show the overall results of each of the three sub-tracks. Only each team's best run is presented.

6 Manual evaluation

For the MEDLINE test sets, we performed a manual evaluation for some selected runs from some of the teams. In this section we describe how the teams and runs were selected, the results of the manual evaluation, and our observations on the quality of the translations.

6.1 Selected teams and submissions

A team qualified for manual evaluation if the participants either submitted a survey or a publications with details about their submission (see Section 4). Only the following six teams complied with this requirement: ECNU-MT, Huawei-BabelTar, Huawei-TSC, SPECTRANS, SRT, and Summer.

During the submission, we asked the participants to identify a primary submission for each language pair, as indicated in Tables 10, 11, 12, 13, 14, 15, 16, and 17. For those teams who submitted runs to both submission systems, we chose the ones sent to the BioWMT submission system. The Huawei-

Table 5: Overview of the submissions from all teams and test sets translating into English. We identify submissions using the WMT Biomedical Submission System (WMTBio) with a "B", the ones for OCELoT Biomedical Task with an "O", and the ones for OCELoT General Task with an "G". The value next to the letter indicates the number of runs for the corresponding test set, language pair, and team.

Table 11: BLEU scores for “OK” aligned MEDLINE test sentences, into English, for submissions to the BioWMT Biomedical system. Primary runs are marked by *.

BabelTar did not not indicate their primary run for some languages, and so we chose the ones with the highest scores, namely: run1 for en2de, en2fr, pt2en, and en2pt; run2 for de2en and es2en; and run3 for en2es, fr2en, it2en, en2it, ru2en, en2ru, zh2en, en2zh.

For submissions into English, we randomly selected the abstracts until we achieved at least 100 perfectly aligned (OK) sentences (see Table 2). We performed pairwise comparison between the reference translation and the selected submissions. The results from the manual validation are presented in Table 21. Unfortunately, we could not perform manual validation for submissions for de2en and

Table 12: BLEU scores for the OCELoT Biomedical Task, from English. An asterisk * indicates the primary run.

it2en.

For submissions from English, we manually selected 19 sentences from one of the clinical case reports, namely, PMID 35144678. Subsequently, we completed the sets with abstracts from the respective test sets. For the abstracts and exclusively for en2fr, for which a reference translation for the clinical case reports is available, we carry out a pairwise comparison between the reference translation and the selected submissions. For the case report for the remaining languages, we could only perform pairwise comparisons between teams' submissions. The results from the manual validation are presented in Table 22.

In both tables, we show in bold the comparisons in which one of the teams (or the reference translation) was statistically significant, according to the Wilcoxon test. The reference translation had a similar quality to many of the submissions. However, none of the teams was (statistically significant) superior than the reference translation.

6.2 Quality of the translations

Here we discuss the quality of the translations after manual validation of the selected abstracts and clinical case report.

en2fr As in previous years, the overall translation quality was high, with many automatically produced sentences exhibiting only small differences with the reference translation. In the examples shown below, correct translations are shown in black font while incorrect ones appear in red fond. Passages underlined within the same example block mark text that should carry the same meaning across statements.

(1) **en:** risk of short-term stroke
fr$_1$: risque d'AVC à court terme
fr$_2$: risque d'accident vasculaire cérébral de courte durée

(2) **en:** the long-term stroke ARD
fr$_1$: la DRA de l'AVC à long terme
fr$_2$: la maladie d'Alzheimer et les démences apparentées à long terme

However, longer or more complex sentences seemed more difficult to address for automatic systems. For examples, acronym modifiers were sometimes translated erroneously 1. We also noticed recurring issues pertaining to acronym translation (Example 2) as well as consistency throughout an entire document.

Table 13: BLEU scores for the OCELoT Biomedical Task, into English. An asterisk * indicates the primary run.

For example, the acronym *POAF*, corresponding to the term *Perioperative atrial fibrillation*, was translated as *POAF*, *FOPA*, *FPO* or *FAPO*. Systems commonly used a combination of two or more of these solutions throughout a whole document, while the reference translation consistently used the correct translation, *FAPO*.

This year, manual validation for en2fr was performed by one evaluator with translation training and one clinician. The overall agreement on individual pair comparison was moderate at 64%. However, the overall ordering of systems and reference according to both annotator remained unchanged.

fr2en As in previous years, translation quality was high, resulting in many automatically produced translations whose quality was indistinguishable from that of reference translations. Concerning the quality of this year's references, they generally corresponded better to direct (as opposed to approximate) translations of the source abstracts, with respect to previous years. This is reflected by the pairwise comparison, which shows that the reference translation is systematically preferred over automatic translations. The most common translation errors were in term and acronym translation (Examples 3-6), prepositional and adjectival attachment (Examples 7 and 8 and in lack of capitalisation (of terms and in particular of acronyms). Term translation was particularly important for overall translation quality, often counterbalancing other more minor errors such as the naturalness of lexical and syntactic choices and correct capitalisation.

(3) **fr:** polyradiculonévrite inflammatoire démyélinisante chronique
en$_1$**:** chronic inflammatory demyelinating polyradiculoneuropathy
en$_2$**:** *chronic inflammatory demyelinating polyradiculoneuritis

(4) **fr:** défaut de croissance staturo-pondérale
en$_1$**:** failure to thrive

[10] This example is interesting, since the original French uses English acronyms rather than French ones, presumably as they are well-known terms that have been borrowed into scientific French. The correct English translation is therefore to use the same acronyms as the French.

Table 21: Pairwise manual evaluation results for the MEDLINE abstracts test set (into English). We show in bold the values which were statistically significant (Wilcoxon test). We only show the team (or reference) in bold, if both the abstracts and sentences were statistically significant (bold).

Nevertheless, most systems struggled to deal with the ambiguity linked to the translation of personal pronouns *sa*, *son*, *ses* 'his/her' in a context where it refers to an unspecified individual (e.g. *the teenager, the child*, etc.); most systems chose the masculine 'his', whereas the correct translation would either be gender neutral 'they' or 'his or her'.

From the manual evaluation results (cf. Table 21), it appears that Huawei-TSC is the superior system; although results are not significant for comparisons against the other two systems), it is the only system of the three that is not significantly worse than the reference translation. Results for abstracts and for sentences appear to correlate, although it was possible on occasions for an abstract to be of better quality than another despite having fewer better individual sentences (due to the differing importance of different errors).

Table 22: Pairwise manual evaluation results for the MEDLINE abstracts test set (from English). We show in bold the values which were statistically significant (Wilcoxon test). We only show the team (or reference) in bold, if both the abstracts and sentences were statistically significant (bold).

en2pt As shown in Table 22, the translations from the Huawei-BabelTar team achieved a similar quality as the reference translation. Similar to previous years, the translations had a good quality and we found just some few mistakes. For instance, errors in acronyms are still present, e.g. "Reforma Psiquiátrica Brasileira (RBP)" instead of "Reforma Psiquiátrica Brasileira (RPB)". Some translations might not include mistakes, but we thought that one of them was clearer than the other, e.g. "desfechos desfavoráveis tanto para a mãe quanto para o feto" (unfavorable outcomes for both mother and fetus) instead of "maus desfechos maternos e fetais" (poor maternal and fetal outcomes). Finally, we found it interesting that all query terms remained in English, namely "status epilepticus", "refractory", "treatment" and "topiramate", for both translations, in one particular sentence that discussed queries to a search tool.

pt2en As shown in Table 21, the translations from the Huawei-BabelTar team achieved a similar quality as the reference translation. The quality of both translations were usually good, but we found some differences in some situations in which we preferred one translation over the other. For instance, in cases such as "out of 100" instead of "of 100". Further, in one particular sentence, "rule out" was used as a translation for "discutir", while the other used "discuss". In many situations, we preferred translations that placed the verbs at the beginning of the sentence, such as in "We examined the absenteeism parameters..." instead of at the end, such as in "the parameters for granting time off work .... were analyzed". Further, we find that the use of a specific and more suitable terms, such as "absenteeism", "productivity", and "control" are preferred to a longer or informal expression, such as "granting time off work", "being productive" and "combat", respectively.

en2es This year the overall quality of the translations was mixed. Both SRT and reference translations were of very good quality, and SRT was in many occasions indistinguishable to reference translations in the manual evaluation when it came to quality. However, the Huawei-BabelTar system had a mixed result with very good translations and translations of doubtful quality that clearly affected the fluency and readability of the output.

Capitalization and word separation were the main issues encountered when evaluating Huawei-BabelTar's output at a sentence level e.g. "La pandemia de covid-19 ofreció a la humanidad un portal a través del cual podemos romper con el pasado e imaginar nuestromundo de nuevo."

As in past years, the translation of acronyms and out-of-dictionary terminology remains a challenge for MT systems, Huwaei-BabelTar being a perfect example of such issues: "Describimos el caso de una cirrosis descompensada que desarrolló hpp y se resolvió con trasplante hepático, permaneciendo asintomática tras diez años de seguimiento."

When dealing with long named entities, word order remained a challenge for both SRT and Huawei-BabelTar, as in the following example where the numbers relate to the acronym "MMPs", and not to the noun "haplotypes":

(9) **Source**: To evaluate MMPs 7, 8, 12, and 13 haplotypes and their association with CRC.

Reference: Evaluar haplotipos de las MMP 7, 8, 12, y 13 y su asociación con CCR.

Huawei-BabelTar: Evaluar los haplotipos 7,8, 12 y 13 (incorrect word order and word separation) delmmp (word separation and capitalization) y su asociación con el ccr (capitalization of acronyms).

SRT: Evaluar los haplotipos 7, 8, 12 y 13 (incorrect word order) de MMP y su asociación con el CCR.

The reference translations were of very high quality overall, creating readable and fluent outputs at the level of sentences and abstracts. The main thing that differentiated reference translations from machine translations was the fact that they were less literal and followed writing conventions in Spanish for the domain, such as the use of passive reflexive tense which is more common in Spanish medical and scientific writings. However, the reference translation omitted relevant information or added implicit information from the text, which affect the overall quality of those translations when compared with the MT systems.

es2en This year the overall quality of the translations was mixed, with some very good quality translations coming from the MT systems (which made them nearly indistinguishable from the reference translations) to poorly written translations (including reference translations). Such is the case as well for the source text, which included some very high quality abstracts and also some poorly written abstractsn which contained grammatical errors such as lack of capitalization, wrong punctuation or word separation as in the following example:

(10) estudio observacional, relacional, transversal, en 185 derechohabientes de una unidad de medicina familiar del 15 de junio al 15 de agosto de 2020

This affected the quality of the output of both MT systems, Huwaei-BabelTar and SRT, which closely followed the source text:

(11) **Huawei-BabelTar**: observational, relational, cross-sectional study in 185 beneficiaries of a family medicine unit from June 15 to August 15, 2020.

SRT: observational, relational, cross-sectional study in 185 beneficiaries of a family medicine unit from June 15 to August 15, 2020.

On the other hand, SRT proved to be more robst than Huwaei-BabelTar and the reference translation, and was able to deal with poor source text much more consistently such as in the example:

(12) **Source**: Existen múltiples causas delesiones ureterales, siendo la principal yatrogénica.

SRT: There are multiple causes of uretral injuries, the main one being iatrogenic.

Word order in longer sentences still remains a challenge for MT systems, which do not always correctly identify adverbs modifying long named entities as seen the following example, where "muchos" modifies the noun "biomarcadores":

(13) **Source** : La expansión y el descubrimiento de nuevas posibilidades de diagnóstico para el uso de muchos biomarcadores de enfermedades cardiovasculares (ECV), incluidas las isoformas de troponina cardioespecíficas (cTnI, cTnT), se debe a la mejora de los métodos de laboratorio para su determinación.

Huawei-BabelTar: The expansion and discovery of new diagnostic possibilities for the use of many cardiovascular disease (CVD) biomarkers, including cardio-specific troponin isoforms (cTnI, cTnT), is due to improved laboratory methods for their determination.

> **SRT**: The expansion and discovery of new diagnostic possibilities for the use of many cardiovascular disease (CVD) biomarkers, including cardio-specific troponin isoforms (cTnI, cTnT), is due to improved laboratory methods for their determination.

Both SRT and Huawei-BabelTar create sentences where “many” modifies “cardiovascular diseases”, which changes the meaning of the translation in both cases.

However, the reference translations also had a mixed quality when compared to the MT systems, and presented issues such as poor capitalization or incorrect word separation, as seen in the following example: “There are many causesof ureteral injury being the main one iatrogenic”.

Unlike previous years, SRT performed best in the three-way manual evaluation, coming close to the reference translation, due to the references’ varied quality.

en2de Similarly to the last few years, the quality of the translations into German was very high. Both participants provided mostly convincing translations - partially including slight restructurings of the sentences. However, although the Huawei-BabelTar team performed lower in comparison to Huawei-TSC, the translations were in most cases not necessarily of lower quality. Instead, the Huawei-BabelTar system made two crucial errors, namely a) translations tend to ignore the capitalization of some German words, as well as b) single words were sometimes written together (without whitespace). Without those two error patterns, the quality of both translation systems would be closer to each other. Sometimes the systems used literal translatations, which impacted the quality of the translated text. For instance, “real-data” was translated into “reale Daten” (instead of “Daten aus der Praxis”) or “essential” was translated into “essentiell” instead of “unerlässlich”.

en2zh The translation quality this year was high. Unlike last year where few sentences were so awkwardly translated that a reader could hardly guess the original meaning, there were essentially no such sentences this year.

The biggest factor that reduced translation quality was the treatment of biomedical terms. This phenomenon came in two categories. The first category was straightforward, where the correct Chinese term was imprecise or downright wrong. For instance, *poor outcomes* of medical treatments was imprecisely translated as 不良结局 (poor end results), when the precise Chinese medical term was 不良预后 . In another example, *Rights-based Approaches (RBAs)* was translated as 基于权利的方法（非洲区域局） in which the full name of the term was correctly translated, but the abbreviation in brackets was incorrectly translated as *Regional Bureau Africa*.

The second category is more subtle, where the translated Chinese term was correct, but the presence of the original English term (or lack thereof) impacted readability. As an example, *Diabetic Retinopathy (DR)* was ideally translated as 糖尿病视网膜病变 *(Diabetic Retinopathy, DR)*, where the Chinese term, the English term, as well as the English abbreviation in the source text were all present. Another translation omitted the full English term, yielding 糖尿病视网膜病变 *(DR)*, which was still easily understandable. In another case, however, *healthcare workers (HCWs)* was translated to 医护人员 *(HCW)*. Here, the abbreviation was translated in singular form, conflicting with the plural form in the source text.

An interesting observation was that conventional, typical wording and punctuation in the translation significantly improved its quality. As a simple example, *experts disagreed* was translated by one system as 专家意见有分歧 (expert opinions differ) and by another as 专家们持不同看法 (experts have different opinions) . Both translations conveyed the same information, but the first translation was much more typical – refined even, as one would expect in a scientific publication. In terms of punctuation, the 、 is unique to the Chinese language when listing items. Hence when given *three overall reactions (positive, negative, and ambivalent)*, the translation 三种总体反应（积极、消极和矛盾） (note the punctuation between the first and second items) read much more naturally than 三种总体反应（积极，消极和矛盾） (exactly the same text, but a comma was used instead). In these cases, the less typical writing style was strictly speaking not wrong, but immediately hinted at the possibility that the text was not written by a native speaker.

Finally, the conversion between Western and Chinese number systems remained a challenge for some systems. The amount *598.851 billion yuan* referred to a billion as 10^9. The closest Chinese word to *billion* is 亿 , which is one order of magnitude smaller at 10^8. This particular amount (598,851,000,000) was incorrectly converted to *598851* 亿元 (59,885,100,000,000) by one system, and correctly though confusingly converted to *558851 m* 元 (558,851 million) by another.

zh2en Continuing the trend from the previous two years, the translations this year are again of high quality. Nevertheless, a few common types of error still provide room for improvement.

Presumably, when a technical or medical term is missing from the system's dictionary, the individual Chinese characters in the term are translated literally. For instance, 清零 (zero-COVID policy) was translated by multiple systems as *zeroing*, which, despite the context of a COVID-related abstract, was hardly guessable. In another instance, 增强现实 (augmented reality) is arguably a technical term outside of the biomedical domain, but was still successfully translated as *augmented reality* by most systems and only one system produced *augmented real-world*.

In other cases, when a Chinese word has a general, non-biomedical meaning as well as a biomedical one, a system might incorrectly opt for the biomedical meaning. 服务阵地不断萎缩 (the continuous shrinking/decline of the service locations) is an example, where 萎缩 should be given the general translation of *decline* instead of the biomedical translation of *atrophy*.

When a translation overly preserves the fidelity of the source phrase, the resulting translation can be awkward. Take 在明确针刺可调节神经、血管这一共识的基础上 as an example. A more readable and thus preferable translation was *based on the consensus that acupuncture can regulate nerves and blood vessels*, even though a word-for-word translation would produce *on the basis of the consensus that acupuncture can regulate nerves and blood vessels* instead.

Similar to en2zh translations, numerical values also proved challenging for some systems in zh2en. 4.26 万 (one 万 is 10,000) is equivalent to 42,600, but the systems translated that variously to *4.26,000* or even *426 million*.

6.3 Targeted evaluation in clinical cases

This year, special attention was given to the evaluation of translations submitted by systems for the clinical case reports, from English into French.

The manual evaluation focused on the criteria that were used to select the clinical case: (1) acronyms; (2) numeric values including lab values; and (3) clinical correctness. Examples 14 and 16 illustrate erroneous translations produced by automatic systems while example 15 illustrates a case of an untranslated value. In the examples correct translations are shown in black font while incorrect ones appear in red fond. An asterisk indicates ungrammatical segments. Passages underlined within the same example block mark text that should carry the same meaning across statements.

(14) **en:** screening test for SARS-CoV-2
fr$_1$: dépistage systématique du SARS-CoV-2
en$_2$: *dépistage systématique du CoV-2 du SARS

(15) **en:** the platelet count was 113 × 10E9/L
fr$_1$: les plaquettes sont à 113 000/mm^3
en$_2$: numération plaquettaire de 113 10E09/L

(16) **en:** General examination revealed a wasted man
fr$_1$: L'examen clinique objective une dénutrition
en$_2$: L'examen général a révélé un homme obèse

Specifically, the translations were annotated using BRAT[11] and aimed to assess the systems' performance on the specific aims. Annotations were produced independently by one annotator with formal translation training (AN) and one clinician (CG). For annotations on the full-text case descriptions, inter-annotator agreement on entities was high overall (above 0.75 F-measure) for "values" and "acronyms" and lower for "errors" (above 0.35 F-measure), mainly due to the identification of more errors by the clinician, which was expected. Inter-annotator agreement on attributes was medium overall (above 0.55 F-measure) mainly due to disagreements on "unclear" and "erroneous" translations, while agreement was much higher for "correct" and "untranslated" cases.

While the "correct" translation category was the most prevalent for all systems for values and acronyms, it can be noted that SPECTRANS produced more "Untranslated" occurrences. Overall, Huawei-BabelTar produced more "Errors" than the other two systems.

This analysis suggests that, in spite of high BLEU scores, the automatic translations can contain serious translation errors (e.g. Example 16)

[11] Brat Rapid Annotation Tool https://brat.nlplab.org/(Stenetorp et al., 2012)

and information that is not directly actionable for clinicians (e.g. Example 15).

7 Conclusions

We presented an overview of this year's edition of the WMT Biomedical Task. We released test sets for seven language pairs, and addressed a variety of textual sources, such as scientific abstracts, clinical case reports, and terminologies. We had a record number of participating teams and of submissions. All submissions were automatically evaluated in terms of BLEU scores, with respect to reference translations, whenever available. We also manually evaluated a selection of the submissions, and similar to previous years, the translations from some teams achieved a similar quality to the reference translations.

Limitations

The scope of the biomedical task has been growing over the years. While each new edition builds on the experience of the previous one, the scale of operations implies a number of limitations from operational and theoretic perspectives. One major limitation is the comparison between translation approaches used by the teams. The information we collect through the participant survey attempts to document the material and methods used by the participants' systems. However, it can be noted that only a subset of teams do supply details of their systems. Furthermore, some descriptions such as the training corpus size or content could be clarified. A closed task, where all participants are limited to using specific training material, could help improve comparability but would require additional work from participants and organizers. Another limitation is the imbalance between language pairs, which attracts different levels of effort from both participants and organizers.

MT can be computationally intensive and the environmental impact of experiments should be measured. While no measure of impact was conducted this year, we included this aspect in the participant survey, which included a list of tools that can be used to measure impact. A future growth direction to increase awareness of impact can be to ask participants to supply a measure of CO2 impact along with their results.

Ethics Statement

This task mainly focuses on translation using the MEDLINE corpus, which is openly available for research. The test corpora used in the task were selected based on publication date and linguistic criteria. Any imbalance regarding the demographics of populations represented in the corpus is involuntary.

The intended use of this task is to contribute to the evaluation and training of MT systems in the biomedical domain. We do not recommend the use of MT without expert validation in a medical context, as machine translated text could contain errors impacting patients' health outcomes.

Acknowledgements

The ClinSpen sub-task was supported by the Spanish Government's Encargo of Plan TL (SEAD) to BSC and BIOMATDB project of European Union's Horizon Europe Coordination & Support Action under Grant Agreement No 101058779, as well as AI4PROFHEALTH project (PID2020-119266RA-I00).

Rachel Bawden's participation was funded by her chair position in the PRAIRIE institute funded by the French national agency ANR as part of the "Investissements d'avenir" programme under the reference ANR-19-P3IA-0001.

Abstract

This paper reports the findings of the second edition of the Chat Translation Shared Task. Similarly to the previous WMT 2020 edition, the task consisted of translating bilingual customer support conversational text. However, unlike the previous edition, in which the bilingual data was created from a synthetic monolingual English corpus, this year we used a portion of the newly released Unbabel's MAIA corpus, which contains genuine bilingual conversations between agents and customers. We also expanded the language pairs to English↔German (en↔de), English↔French (en↔fr), and English↔Brazilian Portuguese (en↔pt-br).

Given that the main goal of the shared task is to translate bilingual conversations, participants were encouraged to train and test their models specifically for this environment. In total, we received 18 submissions from 4 different teams. All teams participated in both directions of en↔de. One of the teams also participated in en↔fr and en↔pt-br. We evaluated the submissions with automatic metrics as well as human judgments via Multidimensional Quality Metrics (MQM) on both directions. The official ranking of the systems is based on the overall MQM scores of the participating systems on both directions, i.e. *agent* and *customer*.

1 Introduction

With the significant translation quality improvements brought by newer machine translation (MT) approaches in the last years, we can start using MT to translate non-conventional content types such as bilingual and multilingual conversations. These new applications pose new challenges to MT systems and require new solutions to deal with them. In this shared task, we focus on the automatic translation of conversational text, in particular customer support chats, an important and challenging content due to their particular characteristics (Gonçalves et al., 2022; Wang et al., 2021; Farajian et al., 2020): In contrast to content types such as news articles and software manuals, among others, in which the text is carefully authored and well formatted, chat conversations are less planned, more informal, and often present ungrammatical linguistic structures. Furthermore, such conversations are usually on-the-fly production of text with very fuzzy frontiers with speech and mimicking speech production. Due to time requirements, since in dialogues turn-exchange need to be dynamic, the conversations may also have typos, abbreviations and ellipses. The conversations are also characterized by stressful moments, which in turn is represented by the capitalization of the entire word or turn, emoticons or emojis, and multiple punctuation marks.

Furthermore, Gonçalves et al. describe several factors that often lead to poor quality of the written text in this content type, resulting in lower quality of the MT outputs. They highlight the fact that the clients requiring customer support usually demonstrate high levels of impatience and frustration, resulting in typos, profanities, as well as variable capitalization and punctuation. They also mention that text is often times left unstructured, informal and agrammatical, factors that further increase the challenges of dealing with this particular content.

Given the limited number of parallel data for this domain, the main motivation for the Chat Translation Shared Task is to provide a common ground for evaluating and analyzing the challenges posed by conversational data as a content type, which has broad application in industry-level services. Following the success of the first edition of the Chat Translation Shared Task (Farajian et al., 2020), this

Table 1: Excerpt of a en↔pt-br conversation between a *customer* and an *agent*.

year we organized the second edition of the task with the following improvements:

- We released a genuine bilingual corpus, the Unbabel's MAIA Dataset. This consists of customer support dialogues in which the speakers (i.e. *customer* and *agent*) speak in their own language.

- We expanded the number of language pairs to three: English-German (en↔de), English-French (en↔fr), and English-Brazilian Portuguese (en↔pt-br).

- We performed manual evaluation on both directions of agent and customer, and we ranked the systems based on their overall performance in both directions, by using an adaptation of the multidimensional quality metrics (MQM) (Lommel et al., 2014) that is tailored to assess customer support translated content.

Similarly to the first edition of the task, we asked the participants to translate dialogues between two parties (i.e. *customer* and *agent*), where the *agent* writes in English and the *customer* writes in either German, French, or Brazilian Portuguese, depending on the language pair.

In order to evaluate the translation quality of the participating systems we used both automatic evaluation metrics and human judgement through MQM annotations. For the automatic evaluation metrics we used COMET (Rei et al., 2020), chrF (Popović, 2015), and SacreBLEU (Post, 2018), and for the human evaluation we used MQM (Lommel et al., 2014) performed with annotators specialized in explicit knowledge of translation errors and linguistics. Compared to the direct assessment evaluation (Graham et al., 2013, 2014, 2015) used in the previous edition, MQM annotations provide a more detailed analysis of the types and severities of the errors produced by the MT systems. MQM has also been shown to have a higher correlation with state-of-the-art metrics than direct assessments (Freitag et al., 2021).

This year, 18 submissions were received from 4 different teams, which have submitted outputs for both directions (i.e. *agent* and *customer*). Among these 4 teams, one team participated in all the three available language pairs, while the others focused only on en↔de. Details of their submissions and evaluation are described in §4 and §5.

2 The MAIA corpus

One of the biggest challenges of bilingual conversation translation, especially for Customer Support conversations, is the lack of appropriate publicly available datasets. To alleviate this issue, in the first edition of the Chat Translation Shared Task, Farajian et al. introduced the BConTrasT corpus that was based on a monolingual English corpus, Taskmaster-1 (Byrne et al., 2019). They translated the selected conversations into German mimicking a scenario in which an agent and a customer are communicating in their native languages. However, even this dataset was just an approximation of a real Customer Support conversation due to the fact that: 1) the original conversations in the Taskmaster-1 corpus were created by using crowdsourced workers interacting with each other to complete a specific task; and 2) the conversations were not truly genuine bilingual conversations since German segments were all just translations of the original English sentences.

This year, we made advancements by releasing the Unbabel's MAIA Dataset: a corpus that is truly composed of entire, genuine and original bilingual conversations from four different clients of the Unbabel database. The conversations are from clients that gave written consent on using this data for research purposes as long as in accordance with the General Data Protection Regulation (GDPR). In this corpus, the original segments of *customers* and *agents* are translated into their corresponding target languages via the MTPE process[1], done by the experienced translators of the Unbabel Community that have demonstrated consistently high quality within the respective language pair. MT segments were produced with a mixed of online MT services and internal ones. The corpus is released under the Creative Commons public license Attribution-NoDerivatives 4.0 International (CC BY-ND 4.0) and can be freely used for research purposes only. Please note that, as the license states, no commercial uses are permitted for this corpus. This data was collected within the MAIA Project (Martins et al., 2020).

The Unbabel's MAIA Dataset[2] contains more than 40k segments from more than 900 conversations in three language pairs (and a total of 6 language directions): English ↔ German (en↔de), English ↔ French (en↔fr) and English ↔ Portuguese (Brazil) (en↔pt-br). The breakdown of the corpus by language pair and direction is presented in Table 2. A sample conversation is presented in Table 1 and it shows that a conversation usually starts by the customer explaining the problem that led them to contact the *customer* support and is followed by the *agent* asking for more details in order to provide the necessary assistance.

Anonymization process. To make the conversations publicly available and in accordance with the General Data Protection Regulation (GDPR), we anonymized them first automatically by using the Unbabel proprietary anonymization tool and then by manually verifying the data. This resulted in 12 different anonymization categories, each presented by a specific token that are presented in Table 3. Importantly, Unbabel is also certified for ISO/IEC 27001:2013 Information Security Management Certification[3].

3 Task Description

Similarly to the first edition of the Chat Translation Shared Task, in this edition we focused on a critical challenge faced by international companies that are providing customer support in several different languages. One common approach to deal with this challenging requirement is centralizing the customer support with English speaking agents and having a translation layer in the middle to translate from the customer's language into the agent's language (e.g. English) and vice versa. The ideal solution for this environment needs to be able to properly handle all its aforementioned issues including the context-related challenges, the noisy inputs and multilingualism, among others.

In the second edition of the Chat Translation Shared Task we provide real genuine bilingual data for three different language pairs and encouraged the participants to make use of the bilingual context present in the conversations and to submit translations for both directions of the three language pairs. To emphasize on the importance of this aspect, we decided to rank the participating teams based on the overall quality of their primary submissions on both directions using a manual quality evaluation methodology through MQM annotations.

And, finally, we asked the participants to submit a maximum of three MT outputs per language pair direction, one primary and a maximum of two contrastive outputs. Due to time and budget constraints we performed the manual evaluation only for the primary submissions, while all the systems are evaluated using the automatic evaluation metrics (COMET, chrF, and SacreBLEU). For more details on the evaluation process please see §5.

3.1 Data

In the domain of customer support usually there is a very small amount of publicly available par-

[1] Machine Translation followed by a Post-Editing step.

Table 3: Anonymization tokens and their description.

allel data because of privacy and copyright issues that make releasing this kind of data difficult. In order to provide a more realistic setting, and due to the constraints outlined above, in this edition of the shared task, we provided participants with development and test sets only. The development sets can be divided into two types: SOURCE-ONLY, which that contains conversations without the human translations and PARALLEL, which that contains a smaller set of conversations with their corresponding human post-edited translations. The number of conversations and segments of the test and development sets per language pair and direction are presented in Table 4.

For training and validation purposes, participants were also allowed to use the training data of the general task (including the data of the previous editions), the data of the other tracks (eg. biomedical) and the other corpora (either parallel or monolingual) that are publicly available for research purposes including the data of the previous edition of the Chat Translation Task, BCONTRAST, as well as the corpora available on OPUS[4].

3.2 Baselines

In order to have a reasonable term of comparison for all the language direction, we used the large multilingual pre-trained M2M-100 model (Fan et al., 2021) with 418 million parameters. M2M is a multilingual MT model that supports all languages considered in this shared task. Moreover, since handling the context is one of the important challenges of the task we tried two baselines:

- A *sentence-level* baseline, where each utterance is passed separately to the model.
- A *context-level* baseline, where N consecutive utterances from the same conversation (and from the same direction) are passed and translated jointly by the model. In this paper we report the results of $N = 2$, that based on the automatic metrics performed the best on our validation sets.

While these models are not fine-tuned for *chat* conversation, they achieve good scores with automatic evaluation metrics and show the benefits of using context for this domain, even if they were not originally trained to use context.

We also report results of a larger version of the model (1B parameters) and different context sizes in Appendix A. In addition to these baselines, we also evaluated the results of four publicly available online MT systems on our test sets. In this paper we refer to them as Online-A, B, C, and D.

4 Participants

The participants were asked to submit at most three systems per language pair direction, one primary and a maximum of two contrastive ones. Moreover, the submitting team was required to explicitly indicate their primary and contrastive submissions. We received eighteen submissions from four different teams: BJTU-WeChat (two primaries and four contrastives), IITP-Flipkart (two primaries and four contrastives), HW-TSC (one primary and two contrastives), and Unbabel-IST (one primary and two contrastives). The first three teams participated only for en↔de, while the last team participated in all the language pairs and directions (i.e. en↔de, en↔fr, and en↔pt-br). Table 5 summarizes the participants and their affiliations.

Table 5: The participating teams, their affiliations, and the directions that they participated.

All the participating systems follow a two step training in which a generic model is trained first on a large amount of publicly available data and then fine-tuned on the task data. The systems are different in the following aspects: i) the pre-training step, in which some use the publicly available models like mBART and Facebook-FAIR's WMT 2019, and the others train their own generic models, ii) the model architecture, in which some use deep encoder-decoder transformers, and others use multi-encoder transformers, iii) the fine-tuning stage and the data used in that step, and iv) the translation directions, in which some use bilingual models for each direction and some use a single multilingual model to cover all the language pairs and directions.

4.1 Systems

Here we briefly detail each participant's systems as described by the authors and refer the reader to the participant's submission for further details.

4.1.1 BJTU-WeChat

The joint submission of Beijing Jiaotong University and WeChat is an ensemble of deep Transformer models with 20 layers of encoder and 10 layers of decoder. Their models are firstly trained on the training corpora provided by the general track of WMT 2022. They are then fine-tuned on the training data of the chat translation track of WMT 2020 with several strategies to incorporate the potential context including the multi-encoder framework, speaker tag, and prompt-based fine-tuning.

Inspired by (Zhu et al., 2018) they proposed a Boosted Self-COMET-based Ensemble metric to evaluate the diversity of the generated hypotheses. As they report, it allows them to select some diverse, yet effective models from more than 100 models. Regarding the size of their models, the authors reports numbers that vary from 6.075 Billion to 6.881 Billion parameters.

4.1.2 IITP-Flipkart

IITP-Flipkart uses the Facebook-FAIR's WMT 2019 publicly available pre-trained models for en-de and de-en (Ng et al., 2019).[5] The models are based on the Transformer-big architecture (Vaswani et al., 2017). To fine-tune these models they follow a two-step procedure in which they first fine-tune the models on the training data of the Chat Translation track of WMT 2020 and then fine-tune the resulting models on the parallel validation set provided in the Chat Translation track of WMT 2022. To deal with the data scarcity issue of the task they combine the segments of agent and customer. To do so, for en-de, they use the agent subset of the above mentioned datasets as well as the customer segments by reversing their translation direction. The same applies to other direction.

[5] https://github.com/facebookresearch/fairseq/tree/main/examples/wmt19

For their primary submission they use a dual-encoder version of the WMT 2019 pre-trained FAIR model in which one encoder is used to encode the source context and the other one encodes the source segment. They use the weights of the encoder part of the pre-trained model to initialise the context-encoder weights. For the cross attention they use a weighted average of source-encoder and context-encoder attention. And for context they use the immediate previous source segment. Thus, the context can be either English or German, depending on the speaker of the previous utterance.

To analyze the impact of the context on the translation quality they experiment with a model that is trained with context and during inference it only uses the current sentence without any context. As they report, the results of this contrastive model confirm the observation of Li et al. that the improvement of the results are in some cases due to the fact that context acts as noise generator during training that makes the models more robust. And finally, their second contrastive model is a simple sentence level model that similarly as their primary model uses the Facebook-FAIR's WMT 2019 pre-trained model to initialise the weights. This model does not use any context.

As they reported, their primary submission is a model with 358 Million parameters. Their first contrastive model has the same number of parameters during training since it uses context, while during inference it uses only 312 million parameters since it does not use the context. This is the same number of parameters used by their second contrastive model that does not use any context at all.

4.1.3 HW-TSC

The Huawei Translation Services Center (HW-TSC)) team uses a deep transformer model with 25 layers of encoder and 6 layers of decoder. The model is pre-trained on the training data of the news track of WMT 2021. They used the bilingual validation set of the task to select in-domain data from the bilingual samples of the generic domain data. They reported the usage of self-training (i.e. forward translation), backward translation, model averaging, and context-aware translation.

4.1.4 Team Unbabel-IST

The joint submission of Unbabel and IST (Instituto Superior Técnico) uses the mBART50 model that has 12 layers of encoder and 12 layers of decoder. They fine-tuned the mBART50 model on a combination of the following two datasets: i) the in-domain parallel validation set, and ii) the samples similar to the validation set retrieved from the parallel generics corpus provided by the general track of WMT 2022. To find the similar samples they used LASER (Schwenk and Douze, 2017). At the inference time, their primary submission uses a retrieval-based approach in which for each segment of the test set the top-k nearest neighbors are retrieved from the following two data stores: i) the parallel in-domain validation set and ii) pool of the back-translated in-domain monolingual validation set of the task as well as the samples retrieved from the generic dataset that were used in the first stage of fine-tuning. Their first contrastive submission only uses the parallel validation set. Their second contrastive submission is the vanilla mBART50 model fine-tuned on the in-domain data, without the retrieval component.

Finally, concerning the model size, as they report it has the same number of parameters as mBART50, i.e. 761 million parameters.

5 Evaluation Procedures

Similarly to the previous edition, we evaluated the systems' performance both automatically and manually. This year we used COMET, chrF and SacreBLEU as the automatic metrics and MQM (Lommel et al., 2014) for the human evaluation. Due to time and budget constraints, the manual MQM evaluation was performed on the primary submissions only while all the submissions were evaluated using the automatic metrics. As mentioned earlier, the official rankings of the participating teams were based on the overall MQM score of their translations for the whole conversation, i.e. both *customer* and *agent* sides.

5.1 Automatic Evaluation

For the automatic evaluation of the systems' outputs we used COMET (`wmt20-comet-da`) (Rei et al., 2020), chrF (Popović, 2015), and SacreBLEU[6] (Post, 2018).

5.2 Human Evaluation

The human evaluation was performed by professional linguists and translators using an adaptation of the MQM framework (Lommel et al., 2014)

[6] We used version `2.1.0` with the signature `nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.1.0`

- 31 terminal nodes, including error types that are specific to MT, such as *MT Hallucination*[8] and customer support, such as *Source Issue*[9];
- 2 levels of granularity, composed by the 8 parent categories and the actual 31 terminal nodes (issue types) that annotators can use during the annotation process.

Regarding the severities attribution, we followed the same schema proposed in the MQM framework (Lommel et al., 2014), including a fourth severity, *Neutral*, to account for *Source Issue* errors. The definition of severities used in this evaluation are the following:

- *Neutral*: This severity degree is reserved only for the *Source Issue* category. This is used for linguistic issues that occur in the source text

[8] The *MT Hallucination* issue type is used when the MT generates a completely different translation that has no relation with the source text; the translation can still sound fluent and natural without reading the source, but the meaning is completely different. It is also used when the MT generates a chunk of repetitions in the target text or when the content is translated into gibberish: in other words, the machine generates an output made of non-words or repeated symbols.

[9] The *Source Issue* issue type needs to be used when there is an error in the target text and this is due to an issue in the source text. It can also be used when a part of the source text is written in the target language or in a different language, and the result is a mistranslation in the target.

that may have impact on the target translation and it is a signal of the overall quality of the source text to be translated;

- *Minor*: An error should be rated as minor if it does not lead to a loss of meaning and it does not confuse or mislead the user. It may, however, decrease the stylistic quality or fluency of the text, or make the content less appealing;
- *Major*: The usability or understandability of the content is impacted but it is still not unfit for purpose and the meaning of the content can be perceived as difficult to understand;
- *Critical*: The error severely changes the meaning of the original text. The reader cannot recover the actual meaning of the original text and the error carries health, safety, legal or financial implications to the end user/reader. In addition to this, a critical error also violates geopolitical usage guidelines, causes the application to crash or negatively modifies/misrepresents the functionality of the product or service. Finally, it can be offensive towards an individual or a group (a religion, race, gender, etc.).

To calculate the final MQM score per conversation the formula below is used:

$$\text{MQM} = 100 - \frac{I_{\text{Minor}} + 5 \times I_{\text{Major}} + 10 \times I_{\text{Crit.}}}{\text{Sentence Length} \times 100} \tag{1}$$

where I_{Minor} denotes the number of minor errors, I_{Major} the number of major errors and $I_{\text{Crit.}}$ the number of critical errors.

Figure 1 shows an excerpt of a pt-br customer conversation annotation, performed on a proprietary translation errors annotation tool from Unbabel. In this example, two *Source Issue* annotations are showcased, *proprio* and *and* that caused one Critical *Untranslated* error and one Critical *Grammar* error in the target text. In both cases, these examples outline some of the specificities of chat language and user-generated content, such as the lack of diacritics (Gonçalves et al., 2022) that can be observed in *proprio* and *e* on the source side (left pane) of the conversation. In the first case, *proprio*, a non-existent word in Portuguese, should have been written as *próprio*. As for the second case, *e* is a Portuguese conjunction that was translated literally into English, *and*, while the correct form should have been the verb *ser* (*to be* in English), conjugated in the 3rd person singular, *é*. The third error shown in Figure 1 shows yet another example of chat-specific language, such as the usage of a more idiomatic style (Gonçalves et al., 2022). The expression *como baixo?* refers to how *something can be downloaded from somewhere* and, besides its well-formedness in Portuguese, the style is idiomatic and conversational. The result is a *Mistranslation* error that refers to a literal translation into English. In this case, the meaning of the source text is completely lost and cannot be inferred by the reader.

Finally, as in the previous edition, we evaluated only a subsample of the full test set. For this, we randomly sampled conversations until the number of segments per direction was, at least, 500. We performed the annotations on both sides and calculated the overall conversation MQM score of each submission as the final score to use for the official ranking of the teams.

5.2.1 Customer Utility Analysis (CUA)

Besides reporting the overall MQM scores—the average MQM scores across conversations—, we decided to report, as a complement, a utility framework called Customer Utility Analysis (CUA) (Stewart et al., 2022). We decided to add this complementary analysis for two main reasons: 1) it gives us an idea of the quality across individual conversations; and 2) since MQM scores can be hardly understood without the context of a scale of reference or any direct connection the task-specific utility or value, CUA plots allow a better quality interpretation. This is possible because, as mentioned in §5.2, MQM is calculated by taking into account several factors, such as the total number of words of a conversation, the number of minor, major and critical errors and a severity multiplier. After the computation of the MQM scores at the conversation level, these are mapped into four different MQM buckets. In order to render this analysis more understandable from a visual point of view, we used a four color schema with the following MQM ranges:

- *Weak*: Dark Red (negative - 39 MQM)
- *Moderate*: Light Red (40 - 59 MQM)
- *Good*: Light Green (60 - 79 MQM)
- *Excellent*: Dark Green (80 - 100 MQM)

Ideally, we want the MT systems to have larger green and smaller red buckets, indicating less errors in the MT outputs and higher MQM scores.

6 Discussion

In this section we analyze the results of the automatic and human evaluation of the systems from different aspects.

6.1 Official ranking of the systems

The MQM scores of all the primary submissions as well the baselines (with context size 2) are presented in Table 9. As can be observed, in addition to the MQM score of each direction, the overall conversation-level MQM scores are also reported for each system.

Based on the overall MQM scores, the BJTU-WeChat team ranks first for the en↔de language pair, achieving higher MQM scores for both directions. This is consistent with the automatic scores of the systems reported in Table 6. BJTU-WeChat is followed by Huawei, Unbabel-IST, and IITP-Flipkart. As we can see in the distribution of the error severities in Figure 2, BJTU-WeChat produces significantly less critical and major errors in both directions. In the Neutral category we can see that all the systems perform almost the same, including the baselines. Based on this observation and the definition of this severity category (§5.2) we can infer that all the systems handle source-related issues more or less similarly. This calls for methods that are more reliable to source sentence issues, in particular for the *customer* side in which we have a significantly larger amount of issues when compared to the *agent* side.

By looking at the distribution of the error types presented in Table 15 we can see that "Mistranslation" is the most frequent error for all the systems. Given the definition of this error[10] and the fact that there was no in-domain training data for the given domain it was expected to see a large number of these errors in the outputs of all the MT systems.

For the en↔de language pair we received submissions from four teams, however, for en↔fr and en↔pt-br we received the outputs of one participating team only, making it more difficult to do an in-depth analysis on the results. The MQM scores of the baselines and the participating team are reported in Table 9, and their automatic scores can be found in Tables 7 and 8, respectively. As we can see, the Unbabel-IST systems outperform the baselines significantly both in terms of the manual MQM scores as well as the automatic metrics.

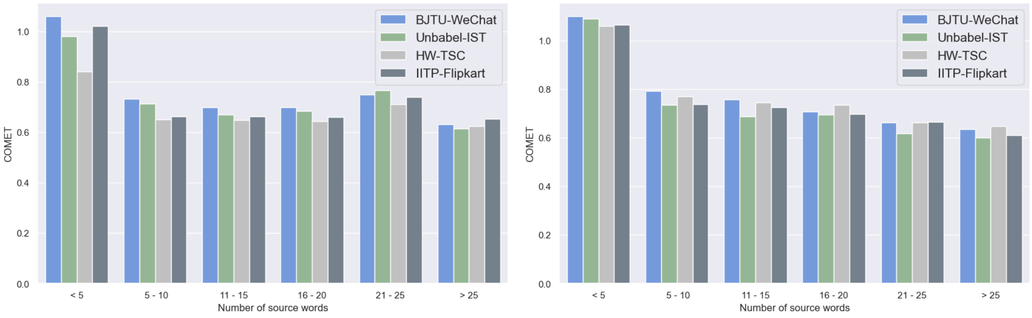
6.2 Computational efficiency of the approaches

The results of the primary submissions and the online systems (Table 6) shows that there is a big difference between the BJTU-WeChat submission and the other systems. As reported by the participants, this system is the only submission that uses an ensemble of a large number of models that makes it the least computationally efficient solution for the problem. The other submissions obtain results similar or better than the online systems and do not resort to model ensembling, making them more computationally efficient than the winning submission. The applicability and the computational efficiency of the models is one of the factors that we plan to pay more attention to in the future editions of the shared task.

6.3 Noisy source and its impact on MT quality

By comparing the MQM scores of the two directions (i.e. *agent* and *customer*) we can see that independently of the language pair, the scores of the *customer* side are significantly lower than the

[10] The word or phrase being translated wrongly according to the domain of interest.



(a) en→de

(b) de→en

Figure 3: COMET scores of the segments in different buckets based on the number of words in the source for (a) *agent* direction (en→de) and (b) *customer* direction (de→en).

scores of the *agent* side. This is in contrast to the previous observations that translating into English is usually easier than translating from English (Akhbardeh et al., 2021). We assume this is partially due to the different amounts of noise in the source segments of each direction and their impact on the final quality of the MT systems. To support our claim, we analyzed the source side of all the text conversations with a proprietary rule-based tool developed at Unbabel to detect spelling and grammatical errors, perform writing style checks (related to the formality of the text), among the detection of other types of issues that are specific to the content type of customer service conversations. As we can see in Table 10 the *customer* segments contain a larger degree of noise, up to 4 times, with respect to the *agent* side. We then proceeded by splitting the source segments of each direction into two sets of *noisy* and *non-noisy* categories and analyzed the quality of the models on each set separately. As we can see in Figure 5 the quality of the models on the noisy samples is significantly lower compared to the non-noisy samples. This is in line with the findings of Gonçalves et al., in which customers requiring customer support help usually exhibit high levels of impatience and frustration, that might be translated into agrammatical and unstructured text with lexical choices that often result in a degradation of the machine translation output.

6.4 Sentence length and MT quality

Looking at the test sets we can see varying lengths of source sentences, with the majority of them being very short segments (see Figure 6). To understand the impact of the sentence lengths on the final quality of the MT systems we grouped the input sentences into six buckets and measured the COMET score of each bucket (see Figure 3 for the COMET scores of the primary submissions of en→de and de→en). Independently of the direction, we can see that: 1) systems perform fairly similarly within each bucket; and 2) systems' performances tend to decrease as the number of source words increases. The pattern is very similar for the other language pairs and directions.

	agent	customer
en↔de	55	105
en↔fr	40	116
en↔pt-br	24	95

Table 10: The number of noisy source segments in each side of the test conversations.

6.5 MT systems and CUA analysis

As mentioned in §5.2.1, CUA analysis provides complementary information to have a more clear understanding on the distribution of MQM scores. The bucketing approach used in CUA helps to easily interpret the quality of the MT systems. By looking into the de→en primary submissions, we can see that the BJTU-WeChat system not only outperforms the other systems significantly, but also produces the highest number of *excellent* translations. We can also see that, in general, the *agent* directions are easier to translate. In fact, no system produces any *Weak* or *Moderate* translations for this direction, while we can see a large number of *Weak* or *Moderate* ones in the outputs of all the systems for the *customer* direction.

6.6 Usage of context

All the four participating teams reported the incorporation of context in their experiments. But, depending on the approach, and the data they used as the context, they obtained different results and draw different conclusions. BJTU-WeChat used a simple prompt learning approach in which they add two preceding bilingual contexts at the tail of each utterance with a special token to indicate the boundary of the context. Their results show slight performance gains over the models that do not use the context. HW-TSC explores a similar approach but no promising results can be observed. This can be due to different factors like implementation details, the size and the combination of the data used as context, among other factors. For more details about the approaches and their difference please refer to their system description papers.

Differently than the BJTU-WeChat and the HW-TSC teams that use variations of the concatenation approach, IITP-Flipkart reports using an additional context encoder for incorporating context information. However, based on the test sets results we cannot observe any meaningful improvement over the system that does not incorporate the context, at least with automatic evaluation metrics.

Finally, Unbabel-IST report that in the few experiments they performed using context they did not observe any meaningful improvement on the performance of their models.

7 Conclusions

We presented the results of the WMT 2022 Chat Translation Shared Task. This year, we provided the participants with anonymized genuine bilingual Customer Support conversations for development and test sets. The conversations are part of the MAIA corpus, a corpus that we introduced here for the first time that aim to provide the best possible research ground for this very particular domain.

Four different teams participated in en↔de and one team participated also for en↔fr, and en↔pt-br. All participants covered both directions (i.e. *customer* and *agent*). We evaluated submissions with automatic metrics (i.e. COMET, chrF, and SacreBLEU) and primary submissions with MQM human evaluation. The MQM evaluations were conducted under an adaptation of the

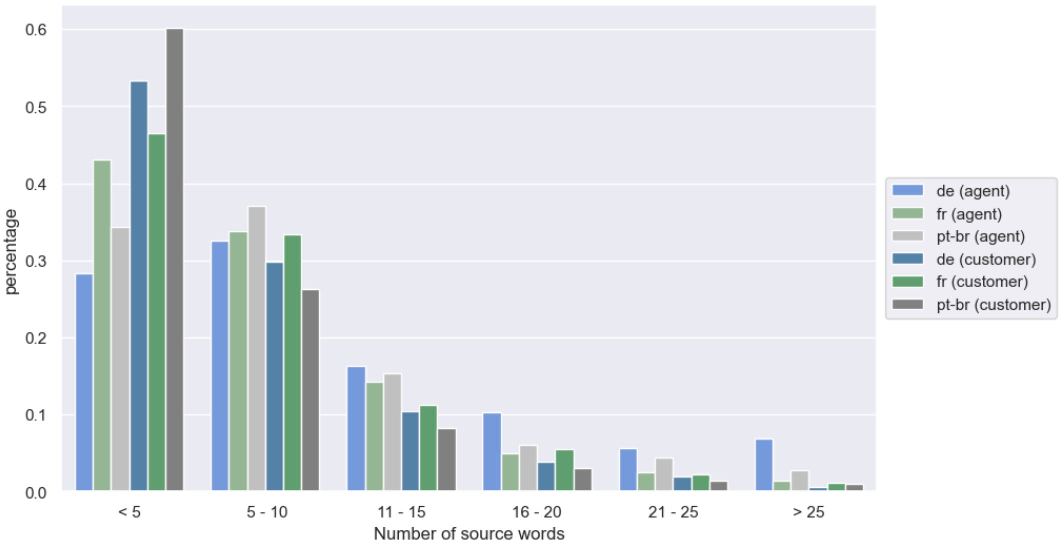

Figure 6: Percentage of segments when bucked according to the number of source words per lp and direction.

MQM framework (Lommel et al., 2014), that is tailored to assess Customer Support translated content (Gonçalves et al., 2022), providing a rich analysis of the type of errors that, we hope, will foster future MT research in this domain.

Acknowledgements

We would like to thank Vera Cabarrão and Miguel Menezes for their work in the anonymization of the data; Tânia Vaz, Madalena Gonçalves, and Maximilian Kohl for their help conducting the MQM annotations; Ricardo Rei and João Alves for useful discussions regarding the methodology used; and Pedro Gonçalves for the legal advise that made the release of the data possible. Abstract

This paper presents the results of the First WMT Shared Task on Sign Language Translation (WMT-SLT22)[1]. This shared task is concerned with automatic translation between signed and spoken[2] languages. The task is novel in the sense that it requires processing visual information (such as video frames or human pose estimation) beyond the well-known paradigm of text-to-text machine translation (MT). The task featured two tracks, translating from Swiss German Sign Language (DSGS) to German and vice versa. Seven teams participated in this first edition of the task, all submitting to the DSGS-to-German track. Besides a system ranking and system papers describing state-of-the-art techniques, this shared task makes the following scientific contributions: novel corpora, reproducible baseline systems and new protocols and software for human evaluation. Finally, the task also resulted in the first publicly available set of system outputs and human evaluation scores for sign language translation.

1 Introduction

This paper presents the outcome of the First WMT Shared Task on Sign Language Translation (WMT-SLT22). The focus of this shared task is automatic translation between signed and spoken languages. Recently, Yin et al. (2021) called for including signed languages in NLP research. We regard our shared task as a direct answer to this call. While WMT has a long history of shared tasks for spoken languages (Akhbardeh et al., 2021), this is the first time that signed languages are included in a WMT shared task.

Sign language translation requires processing visual information (such as video frames or human pose estimation) beyond the well-known paradigm of text-to-text machine translation (MT). As a consequence, solutions need to consider a combination of Natural Language Processing (NLP) and computer vision (CV) techniques.

In the field of sign language MT there is a general lack of suitable and freely available datasets and code. For this reason it was necessary for us to build and distribute novel training corpora and we also published reproducible baseline code. Likewise, existing protocols and toolkits for human evaluation had to be adapted to support sign languages.

In this first edition of the shared task we considered one language pair: Swiss German Sign Language (DSGS) and German. We offered two tracks: DSGS-to-German translation and German-to-DSGS translation.

Seven teams participated in the task, which we consider a success. All teams submitted to the DSGS-to-German track, while there were no submissions to the German-to-DSGS track.

The remainder of this paper is organized as follows:

[1] https://www.wmt-slt.com/

[2] In this paper we use the word "spoken" to refer to any language that is not signed, no matter whether it is represented as text or audio, and no matter whether the discourse is formal (e.g. writing) or informal (e.g. dialogue).

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 744 - 772
December 7-8, 2022 ©2022 Association for Computational Linguistics

- We give some background on sign languages and sign language processing in §2.
- We describe the shared task tracks and submission procedure in §3.
- We report on the corpora we built and distributed specifically for this task in §4 and §5.
- We describe all submitted systems, including our baseline in §6.
- We ran both an automatic and a human evaluation. We explain our evaluation in §7.
- We share the main outcomes in §8 and discuss in §9.

2 Background

We consider sign language processing (SLP) a sub-area of Natural Language Processing (NLP), and automatic sign language translation (SLT), a more narrowly focused discipline within SLP.

We first give an introduction to sign languages (§2.1) and describe the societal and academic relevance of SLP (§2.2). Then we give an overview of SLP in general (§2.3), of SLT in particular (§2.4) and finally motivate this shared task (§2.5).

2.1 Sign languages

Sign languages (SLs) are the natural languages used in deaf communities. Contrary to the popular belief that sign language is universal, hundreds of different SLs have been documented so far. They are still scarcely described and under-resourced. For example, few reference grammars exist, lexicons only have partial coverage and existing corpora are small.

Nature of sign languages Sign languages are visuo-gestural languages. A person expresses themselves using many parts of the body (hands and arms, but also face, mouthing, gaze, shoulders, torso, etc.) while the interlocutor perceives the message through the visual channel. The linguistic system of SLs makes use of these specific linguistic cues. Information is expressed simultaneously (as opposed to the sequential nature of spoken language), organized in three-dimensional space, and iconicity plays a central role (Woll, 2013; Perniss et al., 2015; Slonimska et al., 2021).

Writing systems To date, SLs do not have a written form or graphical system for transcription that is universally accepted (Pizzuto and Pietrandrea, 2001; Filhol, 2020). Several notation systems, such as HamNoSys (Hanke, 2004) or SignWriting (Sutton, 1990; Bianchini and Borgia, 2012), are used in research or teaching but are rarely adopted as a writing system in everyday life.

A common misconception among MT researchers is that transcribed glosses are a full-flegded writing system for sign languages. In reality, glossing is a linguistic tool, useful for annotating corpora for linguistic studies (Johnston, 2010). Glosses are not a means of writing SL, and they do not adequately represent the meaning of an SL utterance. Importantly, “deaf people do not read or write glosses” in everyday life (Anonymous, 2022). Moreover, glosses mostly consist of words taken from the surrounding spoken language, which is generally only a second language to deaf signers (§2.2, societal relevance).

2.2 Relevance of sign language processing

SLP is a research area with high potential impact, as it is relevant in a societal and academic sense.

Societal relevance The overall aim of SLP is to provide language technology for sign languages, which currently are somewhat overlooked. The vast majority of NLP systems are designed for spoken languages, not for signed languages. This means that more research in SLP could result in more equal access to language technology.

The more specific goal of SLT is to facilitate communication between deaf and hearing communities. There is a need for this because speakers of spoken languages and signers of sign languages experience communication difficulties (the same kind of difficulties encountered by speakers of different spoken languages). We emphasize that deaf and hearing people could benefit from such technologies in equal measure.[3]

Besides aiding direct communication, SLT would improve accessibility to spoken language content, given that spoken languages are often a second language for deaf people, where they exhibit varying proficiency. The reverse direction can also be useful, for example to automatically

[3] We distance ourselves from the harmful view that only deaf people are in need (of access to spoken language discourse). Language barriers are inherently two-way, and addressing them involves both parties.

subtitle signed content to make it accessible to people who do not know SLs (Bragg et al., 2019).

Academic relevance In the field of Natural Language Processing (NLP), working on SLs is highly innovative and timely. Recently, a call for more inclusion of signed languages in NLP (Yin et al., 2021) was widely publicized, and an ACL initiative for Diversity and Inclusion[4] targets SL processing as well.

2.3 Sign language processing

Sign language processing is an interdisciplinary field, bringing together research on NLP and computer vision, among other disciplines (Bragg et al., 2019). For a general overview in the context of NLP see Yin et al. (2021); Moryossef and Goldberg (2021).

Tasks SLP involves a variety of (sub)tasks with individual challenges. Widely known tasks are sign language recognition, sign language translation and sign language production (or *synthesis*). Sign language recognition usually refers to identifying individual signs from videos, see Koller (2020) for an overview. Sign language translation refers to systems that transform sign language data to a second language, no matter whether signed or spoken, see De Coster et al. (2022) for a comprehensive survey. Finally, sign language production refers to rendering sign language as a video, using methods such as avatar animation (Wolfe et al., 2022) or video generation.

SLP research is challenging for a number of different reasons. The ones we chose to highlight here are linguistic properties, availability of data and availability of basic NLP tools.

Linguistic challenges SLP is challenging because of the characteristics of sign languages (§2.1), for instance multilinearity, use of the signing space and iconicity. As explained earlier, SLP needs to take into account manual and non-manual cues in order to capture a complete linguistic picture of an SL utterance (Crasborn, 2006). Information is presented simultaneously, rather than sequentially. Signing makes frequent use of indexing strategies for example to identify referents introduced earlier in the discourse or timelines (Engberg-Pedersen, 1993).

Sign languages have an established vocabulary but are also lexically productive to allow for definition of new signs or constructions to be used to depict entities or situations (Johnston, 2011).

Availability of data Given the current research landscape in NLP, sign languages are under-resourced. An analysis by Joshi et al. (2020) places all sign languages considered in this study in the category "left behind" (together with many spoken languages). Existing resources are small and also heterogeneous. They are created under a variety of circumstances and vary in quality (e.g. video resolution), signer demographics (e.g. deaf vs. hearing signers), richness of annotation (e.g. glosses, sentence segmentation, translation to a spoken language) and linguistic domain (e.g. only weather reports).

Also, not all corpora are easily accessible online and some have restrictive licenses that disallow NLP research. A survey of SL corpora available in Europe can be found in Kopf et al. (2021).

Lack of basic linguistic tools SLP currently lacks fundamental NLP tools that are readily available for spoken languages. Such tools include automatic language identification (Monteiro et al., 2016), sign segmentation (De Sisto et al., 2021), sentence segmentation (Ormel and Crasborn, 2012; Bull et al., 2020) and sentence alignment (Varol et al., 2021). Although there are experimental solutions, they are not yet viable in practice.

Tools like these would be crucial to create better corpora by constructing them automatically, as is routinely done for spoken languages (Bañón et al., 2020), and develop better high-level NLP solutions.

2.4 Sign language translation

In recent years, different methods to tackle SLT have been proposed, most of them suggesting a cascaded system where a signed video is first converted to an intermediate representation and then to spoken text (similarly for text-to-video translation). Intermediate representations (with individual strengths and weaknesses) include pose estimation (§5.3), glosses or writing systems such as HamNoSys (§2.1, writing systems).

There is existing work on gloss-to-text translation and vice versa (e.g. Camgöz et al. 2018; Yin and Read 2020), pose-to-text translation and

[4] https://www.2022.aclweb.org/dispecialinitiative

vice versa (e.g. Ko et al. 2019; Saunders et al. 2020a,b,c) and systems involving HamNoSys (e.g. Morrissey 2011; Walsh et al. 2022). Recently, direct video-to-text translation was also proposed by Camgöz et al. (2020a,b). For rendering sign language output, avatars are commonly used (Wolfe et al., 2022), as well as methods to generate videos of realistic signers (e.g. Saunders et al. 2022).

Parallel datasets In terms of datasets, past work in SLT can be characterized as focusing very much on a narrow linguistic domain, most of the work was done on one single data set called `RWTH-PHOENIX Weather 2014T` (Forster et al., 2014). PHOENIX has a size of 8k sentence pairs and contains only weather reports. The biggest parallel sign language corpus to date, the Public DGS Corpus (Hanke et al., 2020), contains roughly 70k sentence pairs.

Thus, there is a clear shortage of usable parallel corpora and existing ones are orders of magnitude smaller than what is considered an acceptable size for spoken language MT (as a rule of thumb, at least hundreds of thousands of sentence pairs). Nevertheless, there are plenty of spoken languages that also have little parallel data and MT methods have been developed specifically for low-resource MT (Sennrich and Zhang, 2019).

Evaluation For spoken language MT a variety of automatic metrics exist. These include more conventional, string-based metrics such as BLEU (Papineni et al., 2002) or chrF (Popović, 2015), as well as recent, learned metrics based on embeddings like COMET (Rei et al., 2020). In the context of SLT, no automatic metrics are validated empirically, but if the target language is spoken, many existing metrics are reasonable to use. However, if sign language is the target language, no automatic metric is known at the time of writing and the only viable evaluation method is human evaluation. A human evaluation of SLT systems has never been conducted on a large scale before, and there are open questions regarding the exact evaluation methodology and what the ideal profile (e.g. hearing status, language proficiency) for evaluators should be.

2.5 Motivation for this shared task

Our main motivation is that sign languages are natural languages (§2.1) that are currently overlooked in NLP and SLT research (§2.3, §2.4). The shared task brings this topic to the attention of MT researchers. We decided to create a new shared task as opposed to other activities since we believe this format has a unique potential to foster progress in MT and to also make progress measurable over time.

Concrete ways in which the shared task might boost research is by creating public benchmark data, translations by many state-of-the-art systems and judgements of translation quality by humans (see also §9.4 on ways we are adding value).

3 Tracks and submission procedure

We offered two translation directions ("tracks"): translation from Swiss German Sign Language (DSGS) to German and vice versa.

Translation from DSGS to German was our primary translation direction in the sense that submitted systems were ranked on a leaderboard and we provided baseline systems. Systems translating from German to DSGS were not ranked on the leaderboard while the task was running, but we still encouraged participants to submit such systems. We were prepared to provide human evaluation for all submitted systems, regardless of the translation direction.

We deliberately did not limit the shared task to any particular kind of SL representation as input or output of an MT system. For DSGS-to-German translation participants were free to use video frames, pose estimation or something else. For German-to-DSGS participants were free to submit a video showing pose estimation output, an avatar or a photo-realistic signer.

Participants submitted translations on the OCELoT platform[5] which has a public leaderboard. We modified OCELoT slightly in order to disable automatic metrics on the leaderboard for German-to-DSGS, since currently no automatic metrics exist for SL output. Participants were allowed to make up to seven submissions, one of them the primary submission.

Main outcome Seven teams (including one from the University of Zurich whose submission we consider a baseline) participated in our task. All of them submitted to the DSGS-to-German track, while there were no submissions for the second translation direction.

	German-to-DSGS	1	183	5	228	411

Table 1: Overview of training, development and test data. SRF and FocusNews are two different training corpora (§4.2). Segment count for the training corpora is after automatic sentence segmentation. The development data for both translation directions is identical, while the test data is different for DSGS-DE and DE-DSGS.

4 Data

For this task we provided separate training, development and test data, where the training data was available from the beginning while the development and test data were released in several stages.

Table 1 gives a high-level overview of our training, development and test data.

Necessity of creating training data The data we provided are new corpora that we built and published. This was necessary because existing datasets for SL machine translation did not meet our requirements. Existing datasets either have a license that is too restrictive, are not parallel enough in the sense of being only "comparable corpora", are too small or have a very limited linguistic domain. For example, the most widely used dataset in SL machine translation research, PHOENIX (introduced in §2.4), has a size of 8k sentence pairs and contains only weather reports.

Following the long history of WMT shared tasks for spoken language machine translation (Akhbardeh et al., 2021), we opted for data that contains general news, hence a more open domain.

4.1 Licensing and attribution

Our training corpora have different licenses that are summarized here. This overview paper must be cited if the corpora are used.

FocusNews corpus This dataset can be used only for this shared task or its future iterations. Other uses of the data require express permission by the data owners. Interested parties should contact the organizers for further information.

SRF corpus This dataset can be used for non-commercial research under an Attribution-NonCommercial-ShareAlike 4.0 International license (CC BY-NC-SA 4.0)[6].

4.2 Training Data

The training data comprises two corpora, called FocusNews and SRF. The linguistic domain of both corpora is general news, and both contain parallel data between DSGS and German. The corpora are distributed through Zenodo[7].

The statistics of the two corpora are summarised in Table 2.

Training corpus 1: FocusNews [8] The FocusNews data originates from a former deaf online TV channel, FocusFive[9]. We provide the news episodes (FocusNews), as opposed to other programs. The data consists of 197 videos with associated subtitles of approximately 5 minutes each. The videos feature deaf signers of DSGS and represent the source for translation. The German subtitles were created in post-production by hearing SL interpreters.

We provide episodes within the time range of 2008 (starting with episode 43) to 2014 (up to episode 278). The videos were recorded with different framerates, either 25, 30 or 50 fps. The video resolution is 1280 x 720.

While this data set is small (by today's standards in spoken language machine translation), we emphasize the importance of using deaf signer data for shared tasks like ours. There are crucial differences between the signing of hearing interpreters and deaf signers, and interpreted signing

may bear more resemblance to spoken language structures (Janzen, 2005).

Training corpus 2: SRF [10] The dataset contains daily national news and weather forecast episodes broadcast by the Swiss National TV (*Schweizerisches Radio und Fernsehen*, SRF)[11]. The episodes are narrated in Standard German of Switzerland (different from Standard German of Germany, and different from Swiss German dialects) and interpreted into DSGS. The interpreters are hearing individuals, some of them children of deaf adults (CODAs).

The subtitles are partly preproduced, partly created live via respeaking based on automatic speech recognition.

While both the subtitles and the signing are based on the original speech (audio), due to the live subtitling and live interpreting scenario, a temporal offset between audio and subtitles as well as audio and signing is inevitable. This offset or "alignment shift" is visualized in Figure 1.

Manual alignment In our training corpus, the offset between the signing and the subtitles was manually corrected by deaf signers with a good command of German. The live interview and weather forecast parts of each episode were ignored, as the quality of the subtitles tends to be noticeably lower for these parts.

The parallel data comprises 29 episodes of approximately 30 minutes each with the SL videos (without audio track) and the corresponding subtitles. We selected episodes from two time spans: 13/03/2020 to 19/06/2020 and 04/01/2021 to 26/02/2021, featuring three different SL interpreters. (Three interpreters consented to having their likeness used for this shared task.) The videos have a framerate of 25 fps and a resolution of 1280 x 720.

In addition to the parallel data we provided all available German subtitles from 2014 to 2021 as monolingual data. In total, there are 1949 subtitle files with a total of 570k sentences (count after automatic segmentation).

4.3 Development data

The development data consists of segments extracted from undisclosed SRF and FocusNews episodes (see §4.2 for a general description). This data was also manually aligned and the signer is a "known" person that appeared in the training set. The framerate of development videos is 25 fps for SRF and 50 fps for FocusNews.

4.4 Test data

We distribute separate test data for our two translation directions.

[10] Here we describe Zenodo release version 1.2 of the corpus. The data provided here is an extended version of the dataset published as part of the Content4All project (EU Horizon 2020, grant agreement no. 762021).

[11] https://www.srf.ch/play/tv/sendung/tagesschau-in-gebaerdensprache?id=c40bed81-b150-0001-2b5a-1e90e100c1c0

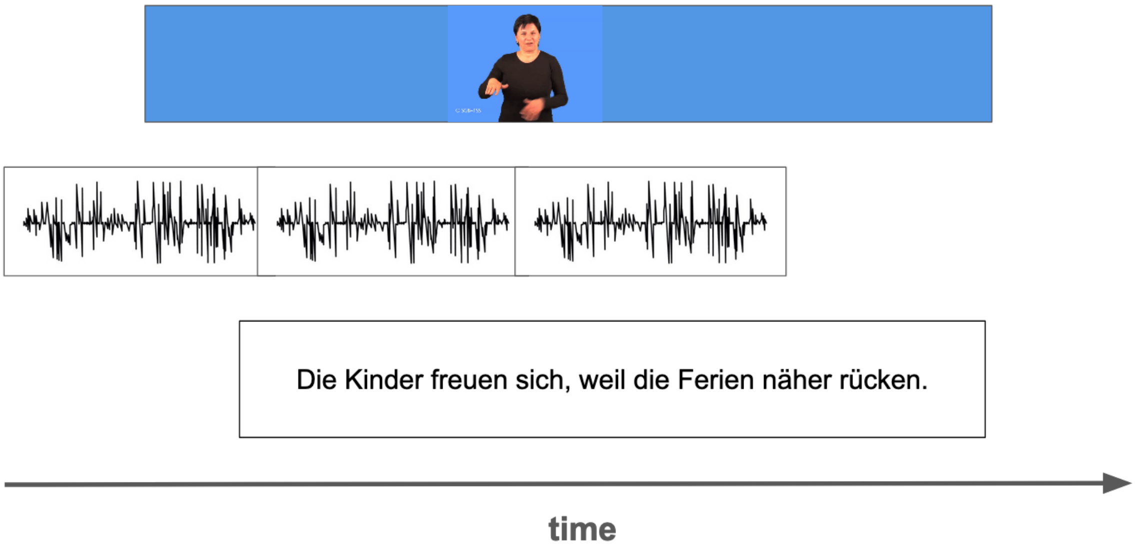

Figure 1: Illustration of alignment shift in sign language corpora. From top to bottom: a sign language video, an audio track with speech, a spoken language subtitle in German. Information in these three modalities do not start and end at the same time, adjusting their start and end times is referred to as *alignment*.

DSGS-to-German Additional, undisclosed SRF and FocusNews episodes that are manually aligned. As for the development data, the signers are "known" persons and the framerate of videos is 25 fps for SRF and 50 fps otherwise.

German-to-DSGS This subset of the test data has two distinct parts:

1. Additional, undisclosed FocusNews episodes that are manually aligned. As for the development data, the signers are "known" persons and the framerate of videos is 50 fps.

2. New translations created specifically for this shared task. The domain is identical to the training data (general news). In this case German subtitles are the source for human translation, DSGS videos are the target. The human translator is deaf (in contrast to all of the SRF data, where signers are hearing interpreters). The framerate of these videos is 50 fps and they are recorded with a green screen.

For German-to-DSGS translation we consider it important that the reference translations are created by deaf signers instead of hearing interpreters.

4.5 Automated access to training data

Our baseline system described in §6.1 automatically downloads all subsets of the data.

In addition, we added our training corpora to the Sign Language Datasets library (Moryossef and Müller, 2021b). The datasets can now be loaded automatically as a Tensorflow data set, provided that the user has previously obtained Zenodo access tokens.

5 Data preprocessing

For each data set described in §4 we provided videos and corresponding subtitles. In addition, we included pose estimates (location of body keypoints in each frame) as a convenience.

5.1 Video processing

Videos are re-encoded with lossless H264 and use an mp4 container. The framerate of videos is unchanged, meaning either 25, 30 or 50. We are not distributing the original videos but ones that are preprocessed in a particular way so that they only show the part of each frame where the signer is located (cropping) and the background is replaced with a monochrome color (signer masking), see Figure 2 for examples.

Cropping We manually annotate a rectangle (bounding box) around where the signer is located for each video. We then crop the video to only keep this region using the FFMPEG library.

Signer segmentation and masking To the cropped video we apply an instance segmentation

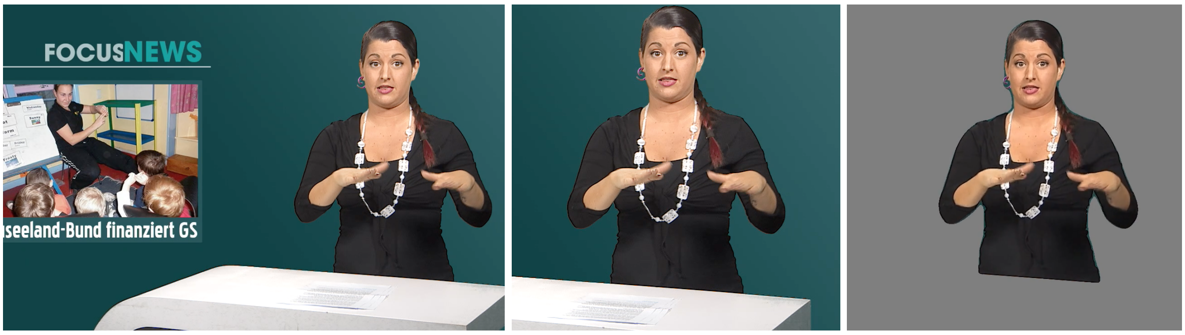

Figure 2: Illustration of video preprocessing steps (cropping, instance segmentation and masking). From left to right: original frame, cropped frame, masked frame.

model, Solo V2 (Wang et al., 2020), to separate the background from the signer. This produces a mask that can be superimposed on the cropped video to replace each background pixel in a frame with a grey color (`[127,127,127]` in RGB).

5.2 Subtitle processing

For subtitles that are not manually aligned (all of FocusNews and monolingual SRF data), automatic sentence segmentation is used to redistribute text across subtitle segments, see Figure 3 for examples.

This process also adjusts timecodes in a heuristic manner if needed. For instance, if automatic sentence segmentation detects that a well-formed sentence stops in the middle of a subtitle, a new end time will be computed. The end time is proportional to the location of the last character of the sentence, relative to the entire length of the subtitle. See Example 2 in Table 3 for an illustration of this case.

5.3 Pose processing

"Poses" are an estimate of the location of body keypoints in video frames. The exact set of keypoints depends on the pose estimation system, well known ones are OpenPose (Cao et al., 2019)[12] and MediaPipe Holistic (Lugaresi et al., 2019)[13]. Usually such a system provides 2D or 3D coordinates of keypoints in each frame, plus a confidence value for each keypoint.

The input for pose processing are cropped and masked videos (§5.1). See Figure 3 for examples of pose estimation on our data.

OpenPose We are using the OpenPose Body135 model. OpenPose often detects several people in our videos, even though there is only one single person present. We distribute the original predictions which contain all people that OpenPose detected.

MediaPipe Holistic As an alternative, we also estimate signers' poses with the MediaPipe Holistic system developed by Google. Unlike our OpenPose model, which only provides 2D joint locations, MediaPipe produces both 2D and 3D joint location coordinates. Values from Holistic are normalized between 0 and 1, instead of referring to actual video coordinates.

6 Baseline and submitted systems

In this section we describe all submissions to our shared task. In case there are substantial differences between the primary and secondary submissions of a team we opted to describe the primary submission here. At the time of writing this overview paper six out of seven teams have given us detailed information about their submissions. The submissions are summarized in Table 4.

Overall, the participating teams have diverse academic backgrounds, most of them combine computer vision and NLP expertise. All submitted systems are sequence-to-sequence models based on Transformers (Vaswani et al., 2017). Participants chose to represent sign language data as either video frames (using a visual feature extractor on the encoder side) or pose features, with no clear majority in this regard.

Two systems, by LATTIC and MSMUNICH, are unconstrained because their visual encoder component is pretrained on WSASL (Li et al., 2020) or is an existing model taken from Varol

et al. (2021). Only one team (DFKI-SLT) used synthetic parallel data and no submission used the monolingual subtitles we distributed.

Three teams have published their code, with two other teams planning to do so in the future.

6.1 Submission by UZH (baseline system)

We provided code to train baseline systems for DSGS to German in a public Github repository (Müller et al., 2022)[14]. The codebase contains scripts to preprocess data, train, translate and evaluate models and should allow to reproduce our results exactly.

The underlying sequence-to-sequence toolkit is Sockeye (Hieber et al., 2022) which is based on Pytorch (Paszke et al., 2019). We adapted Sockeye so that it supports encoding or decoding continuous vectors instead of discrete sequences of tokens. Our system is a pose-to-text translation model that reads a sequence of pose frames and converts them to the model size with a simple learned projection. The baseline does not involve pretraining or additional data and is therefore a constrained submission.

Preprocessing We used OpenPose (Cao et al., 2019) predictions (as opposed to MediaPipe Holistic or a third option). If OpenPose predicted several people in a frame, we simply chose the first one and ignored all other values. Poses are normalized by shoulder width. We convert all pose sequences to a framerate of 25 fps. On the spoken language side we do not apply any preprocessing except learning and applying a Sentencepiece segmentation model (Kudo, 2018) with a vocabulary size of 1000.

For training and translation we used one Tesla V100-32GB GPU and the training took between two and four hours.

6.2 Submission by LATTIC (Shi et al., 2022)

The system submitted by LATTIC is a Transformer-based sequence-to-sequence model which uses as input visual representations derived from an Inflated 3D ConvNet (I3D) (Carreira and Zisserman, 2017) and text as the target. The I3D models is pretrained on the WLASL[15] dataset (an isolated sign dataset). The input representation is resized video frames, the frames were resized to 224x224. For the spoken language side Sentencepiece (Kudo and Richardson, 2018) was used to generate a vocabulary of 18k tokens. The system is developed from scratch, without the use of existing MT software, and has a Transformer architecture (Vaswani et al., 2017). The I3D model is first trained on Kinetics, an action recognition dataset (Carreira and Zisserman, 2017), then it is trained for isolated sign language recognition. Before feeding input to the model, each isolated sign video is truncated, resized, randomly cropped to 224x224 and horizontally flipped with probability 0.5. Models were trained on several GPU types (A4000, A6000 and Titan RTX) and the training took roughly four hours per model.

6.3 Submission by MSMUNICH (Dey et al., 2022)

Microsoft's submission to WMT-SLT is a sequence-to-sequence Transformer model. It is based on an existing model pretrained on the

[14] https://github.com/bricksdont/sign-sockeye-baselines

[15] https://github.com/dxli94/WLASL

BSL1K dataset (Varol et al., 2021)[16]. Similar to the submission of LATTIC, this system also uses a pretrained I3D model. The system takes as input consecutive video frames and predicts over 1000 signs. For the text side, text normalisation such as lowercasing, conversion of numerals and data cleaning were applied. The authors emphasize that such careful data preprocessing and postprocessing was crucial. The underlying MT framework is Fairseq (Ott et al., 2019).

6.4 Submission by SLT-UPC (Tarrés et al., 2022)

The submission of UPC[17] is also a Transformer-based sequence-to-sequence model, based on a smaller Transformer architecture. To pretrain the model, PHOENIX (Forster et al., 2014) data was used. However, the results achieved with pretraining were no better than the primary submission (without pretraining). The authors built independent vocabularies for each training corpus. The best results were obtained by only training on the FocusNews dataset.

As a representation for the SL side, MediaPipe Holistic was used, re-extracting the features using the pose library by Moryossef and Müller (2021a). The authors interpolated the pose sequences to unify the framerate to 25fps and used data augmentation on the poses (using pose libary augmentation functions such as rotation, scaling and shear). For the text side Sentencepiece was used to generate vocabularies of 1000, 2000 and 4000. Their main submission had a vocabulary of 1000. The code is based on Fairseq and is available on GitHub[18]. To train their models, one Nvidia GeForce RTX 3090 was used and training for the main submission took roughly 3.5 hours.

6.5 Submission by DFKI-SLT (Hufe and Avramidis, 2022)

The submission of DFKI-SLT is a sequence-to-sequence model trained with JoeyNMT (Kreutzer et al., 2019), using chrF as the validation metric. The authors describe their system as having three main modules. In the first, SL images are converted into intermediate pose keypoint representations; the second module employs data augmentation (geometrical transformations) to increase sample efficiency and decrease the effect of spurious feature correlations; and the third employs a Transformer network to perform translation.

The system is trained only on FocusNews. The representation of the SL side was based on MediaPipe Holistic. The text side was only lowercased and the maximum sentence length was set to 400. The models were trained on an Nvidia RTXA6000.

6.6 Submission by DFKI-MLT (Hamidullah et al., 2022)

The main idea behind the DFKI-MLT approach is to learn feature representation and translation in a single model, and to train them together. The system architecture consists of two connected blocks: the first block, implemented using CNNs, is intended to capture visual representations and the second one, implemented with Transformers, aims to capture language. The visual component is based on a ResNet (Hara et al., 2017). In particular, the visual encoding in the submitted system consists of the original 3D ResNet10 with output conversion. The conversion creates a sequence of vectors from the single output vector to adapt to the Transformer encoder input. The visual vector is projected through a linear layer which is connected directly to the language block. The language block is a simple Transformer. The training is end-to-end, aiming to force the visual block to take into account the language representation when building the visual embedding.

6.7 Submission by NJUPT-MTT

Finally, we received submissions from the machine translation lab at Nanjing University of Posts and Telecommunications (NJUPT-MTT). No system paper was submitted and the authors did not provide further information.

7 Evaluation Protocols

We performed both a human (§7.1) and an automatic (§7.2) evaluation of translation quality. Our final system ranking is based on the human evaluation only.

7.1 Human evaluation

In our human evaluation, we followed the setting established by the recent WMT21 conference (Akhbardeh et al., 2021) and adapted it to the requirements of SLT evaluation.

[16] https://www.robots.ox.ac.uk/~vgg/research/bslattend/

[17] https://www.upc.edu/ca

[18] https://github.com/mt-upc/fairseq/tree/wmt-slt22

We employed the source-based direct assessment (DA; Graham et al., 2013; Cettolo et al., 2017) methodology with document context, extended with Scalar Quality Metric (SQM; Freitag et al., 2021), which was piloted at the IWSLT 2022 evaluation campaign (Anastasopoulos et al., 2022). Assessments were performed on a continuous scale between 0 and 100 as in traditional DA but with 0-6 markings on the analogue slider and custom annotator guidelines specifically designed for our task.

Human evaluation settings We used the Appraise evaluation framework[19] (Federmann, 2018) for collecting segment-level judgements within document context. As there were submissions in the DSGS-to-German direction only (§3), we only set up a sign-to-text human evaluation campaign. Annotators were presented with video fragments as source context and translation outputs of a random document from an MT system. The reference translation and the official baseline were included as additional system outputs. Documents longer than ten segments were split into document snippets with ten or fewer consecutive segments. A screenshot of an example annotation in Appraise is presented in Figure 4.

We hired four evaluators who were native German speakers and trained DSGS interpreters. They did not have prior experience with evaluation of MT output. Each evaluator was assigned an identical set of annotation tasks comprising documents from the entire test set and all participating systems, including the baseline system and the reference translation. 196 segments were given to each annotator more than once to conform to Appraise's requirement of 100 segments per task and in order to measure intra-annotator agreement.

We did not include any quality control items in the annotation tasks as we had multiple independent annotations of the entire test set and because of the very low quality of translations, which would make them indistinguishable from segments with randomly replaced words or phrases used as quality control items.

Justification for custom guidelines We designed custom guidelines to account for different modalities (e.g. avoid confusing mentions of "text" in the instructions when the source or target is in fact a video) and to tailor them towards SL content. For example, we added *naturalness of motion* as an evaluation criterion for evaluations with SL output. Following IWSLT 2022, we also removed any mention of "grammar" to shift emphasis away from grammatical issues towards translation-breaking differences in meaning. The full instructions to evaluators in English and German are listed in Appendix A.

Data and scripts used for generating tasks and computing the final system rankings are publicly available in a Github repository.[20]

7.2 Automatic evaluation

To complement our human evaluation (which provides the main ranking) we also provide an automatic evaluation. We evaluate the submissions and the baseline system from DSGS into German using three automatic metrics: BLEU (Papineni et al., 2002), chrF (Popović, 2015) and BLEURT (Sellam et al., 2020). We note that learned, semantic metrics correlate better with human judgement (Kocmi et al., 2021), but if they consider the source text as an input (e.g. COMET; Rei et al., 2020), they cannot be used in our context because our source is video and not text. We use sacreBLEU (Post, 2018) for BLEU[21] and chrF[22] and the python library for BLEURT.[23] In all cases, we estimate 95% confidence intervals via bootstrap resampling (Koehn, 2004) with 1000 samples.

8 Results

8.1 Human evaluation

Assessment scores Three out of the four evaluators completed all tasks, which gave us at least three independent judgements for each segment from the official test set. In total, for the output of eight systems, we collected 133,000 segment-level and 1,191 document-level assessment scores, which averages to 1,811.4 scores per system.

System ranking The system ranking is based on the average DA segment-level scores computed from the human assessment scores. We did not

Swiss-German Sign Language (Deutschschweizer Gebärdensprache (DSGS)) → German (Deutsch)

Unten sehen Sie ein Dokument mit 12 Sätzen in Deutschschweizer Gebärdensprache (DSGS) (linke Spalten) und die entsprechenden möglichen Übersetzungen auf Deutsch (rechte Spalten). Bewerten Sie jede mögliche Übersetzung des Satzes im Kontext des Dokuments. Sie können bereits bewertete Sätze jederzeit durch Anklicken eines Eingabevideos erneut aufrufen und die Bewertung aktualisieren.

Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Eingabevideo sind verloren gegangen. Die Grammatik ist irrelevant.
2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Die Grammatik kann mangelhaft sein.
4: Der grösste Teil der Bedeutung ist erhalten und es gibt nur wenige Grammatikfehler: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann einige Grammatikfehler oder kleinere kontextuelle Unstimmigkeiten aufweisen.
6: Perfekte Bedeutung und Grammatik: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Auch die Grammatik ist korrekt.

Figure 4: A screenshot of an example sign-to-text annotation task in Appraise featuring document-level source-based direct assessment (DA) with scalar quality metrics (SQM) and custom annotator guidelines in German.

make any distinction between segment-level and document-level scores, simply including the latter as additional data for computing the average scores.

The official system ranking is presented in Table 5. Systems which significantly outperform all others, according to Wilcoxon rank-sum test $p < 0.05$, are grouped into clusters, which is indicated by horizontal lines. Rank ranges giving an indication of the respective system's translation quality within a cluster are based on the same head-to-head statistical significance tests. Contrary to previous evaluation campaigns (Akhbardeh et al., 2021) which calculate the rankings based on standardized scores (z-scores), we decided to not do so, because the large number of zero-scored items led to a rather skewed standardization scale which affected the calculation of the clusters.

According to our human evaluation (Table 5), MSMUNICH and LATTIC have the highest quality score among all MT systems. All other systems ended up in the same cluster with overall lower translation quality. Both winning systems are unconstrained, having been pretrained on other SL datasets, and achieve an average score of 2 in the continuous range of [0, 100], as compared to a a score of 87 for human translations and 0.52 for the baseline system. By looking at the domain-specific results, however, one can see that the performance of these two systems is around 3.5 for the FocusNews part of the test set and only 0.28-0.38 for the SRF part.

We show an additional analysis of the score distribution for each system in Appendix D.

Annotator agreement In Table 6 we are reporting intra-annotator agreement, measured with Fleiss κ (Fleiss, 1971) only as an approximation, noting the concerns of Ma et al. (2017) that kappa coefficients are not suitable for continuous scales. In order to calculate the coefficient, the values have been discretized in seven bins in the scale 0-6, since those were the scores marked on the continuous evaluation bar that was given to the annotators. One can observe that the intra-annotator agreement for raters 1 and 2 is *good* whereas for raters 3 and 4 is *very good* (Landis and Koch, 1977; Agresti, 1996).

In order to ensure the agreement between the annotators, we computed the ranks with different combinations of annotators and we did not observe changes in the ranks.

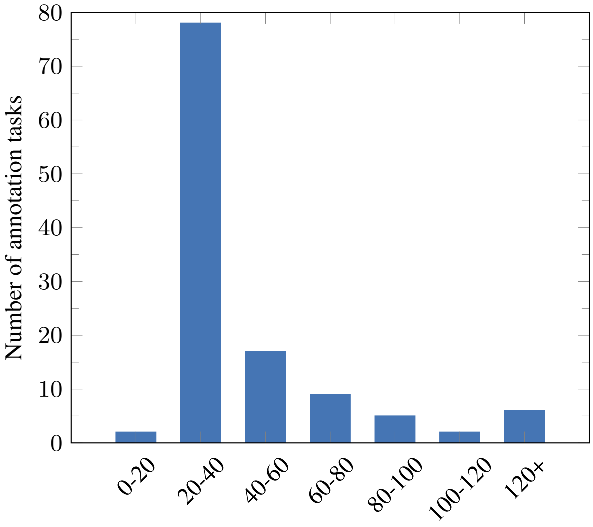

Figure 5: Number of task completion times (a task consists of 100 segments) grouped into 20-minute buckets, after removing top and bottom 5-percentiles.

Evaluation speed Three evaluators have completed the entire evaluation. A single task requiring 100 segment-level and about 12 document-level annotations took on average 45 minutes to complete, after excluding 5% of slowest and fastest task annotations. The majority of tasks were finished in between 20 and 40 minutes as shown in Figure 5.

On average, evaluators judged with a speed of 200 to 250 sentence pairs per hour. This is in line with previous evaluations for spoken language MT. We believe having such an estimate of evaluation speed is useful for future evaluations.

Feedback from evaluators After completing the evaluation two out of four evaluators filled in a form meant for feedback regarding the evaluation procedure and the Appraise platform. All evaluators gave us additional informal feedback.

In general, evaluators reported that their experience with Appraise was positive, and that our instructions were clear. At least two people would be willing to do similar work in the future. Concerning Appraise development, at least two people experienced technical problems[24] and evaluators suggested that the user interface could be improved in some places. For instance, automatically playing videos could make evaluations more efficient.

[24] During the evaluation period there were major outages on Azure and the technical issues reported by our evaluators may be unrelated to the user interface or evaluation task.

Table 5: Official results of the WMT22 Sign Language Translation task for translation from Swiss German Sign Language to German. Systems are ordered by averaged (non-standardized) human score in the percentage scale. Lines indicate clusters according to a Wilcoxon rank-sum test $p < 0.05$. Gray rows indicate unconstrained systems.

annotator	κ	**items**
1	0.77±0.07	235
2	0.76±0.13	62
3	0.90±0.06	235
4	0.88±0.06	235

Table 6: Intra-annotator agreement based on the Fleiss κ coefficient for reliability of agreement (with scores discretized in the scale 0-6).

Informally, evaluators have told us that some videos do not have ideal cuts, in the sense that the beginning or end are slightly cut off. This is perhaps inevitable in continuous signing, or a problem in our manual alignment process. They have also pointed out that showing machine-translated target context can be confusing because for our use case quality is so low.

More detailed feedback forms submitted by evaluators are listed in Appendix C.

8.2 Automatic Evaluation

Table 7 summarises the results of the automatic evaluation. We report the scores for the full test set and also for the SRF and FocusNews subsets and boldface the primary submissions that have been evaluated manually. The low scores for all systems and metrics demonstrate the difficulty of the task. For most systems but SLATTIC with BLEU, translation quality is higher for FocusNews than for SRF. This might be an effect of the length of the source videos: SRF videos are six times longer than FocusNews, which might make the alignment with the textual part more difficult at sentence level.

The best system in the automatic evaluation depends on the evaluation metric. MSMUNICH.2 is the best system according to BLEU, SLATTIC.4 according to chrF and MSMUNICH.1 according to BLEURT. Notice that only the best system according to BLEU among these three was submitted as primary system and therefore manually evaluated. This shows that participants probably used mainly BLEU as the metric for development, except DFKI-SLT who reported that they used chrF because BLEU was always zero.

The correlation between human rankings and automatic metrics is delicate because we only have seven data points. The metric that correlates best with human scores at system level is BLEU ($r = 0.510$, $\rho = 0.571$) followed by chrF ($r = 0.508$, $\rho = 0.214$). BLEURT shows only a weak correlation with $r = 0.314$ and $\rho = 0.286$. In our scenario, translation quality is really low, and the sentences that have been properly translated are very short (e.g. *Bis nächste Woche.*). In this case, n-gram matching metrics perform better than semantic metrics.

See Appendix B for an extended discussion of the correlation between all automatic metrics (BLEU, chrF, BLEURT).

9 Discussion

9.1 General translation quality

Overall, all systems perform poorly in our shared task, as there is an extreme difference in average score between all systems and the human reference translation. The systems exhibit well-known problems of natural language generation such as overfitting to few high-probability hypotheses and hallucination (Lee et al., 2018; Raunak et al., 2021).

The best submitted system in the best case achieves an average score of about 4 out of 100, which indicates that current automatic translations are not usable in practice, unlike spoken language MT where in specific scenarios experiments have

Table 7: Automatic evaluation of all the submission for the full WMT-SLT test set (all), the SRF subset and the FocusNews (FN) subset. Mean and 95% confidence intervals obtained via bootstrap resampling are shown. Primary submissions manually evaluated are boldfaced. Note that the official ranking is given by the human evaluation (Table 5).

shown systems to be on par with human translation (Hassan et al., 2018; Popel et al., 2020). In the following paragraphs we discuss potential reasons for this outcome.

Size of training data The corpora we have built for this shared task (§4) are superior to existing datasets (in terms of size, license, linguistic domain and alignment quality), but are still small. Taken together our corpora contain 20k parallel sentence pairs only, and 600k monolingual German sentences. This limits the optimal translation quality that could in theory be obtained in a constrained setup. This is corroborated by the fact that the two unconstrained systems have won the shared task (§8).

Building larger parallel SL corpora in itself is challenging. Even though recently steps were taken to collect larger amounts of data (e.g. in the projects EASIER and SignON), such resources are not immediately useful because basic linguistic tools used to prepare parallel corpora are not available (§2.3, lack of basic linguistic tools). For spoken language NLP, such tools are commonplace, work well and are used to automatically compile large corpora. For example, Bitextor[25], a tool developed in the Paracrawl project (Bañón et al., 2020), relies on the automatic alignment tool BleuAlign (Sennrich and Volk, 2011).

Modality gap But even if much more training data was available, it is likely that current MT methods are not adapted well enough to SL data. NLP methods in general are tailored towards text and may perform worse or not be applicable at all to other modalities. For example, there are currently no efficient tools for automatic SL segmentation (Yin et al., 2021), while for text-based MT, subword segmentation (Sennrich et al., 2016; Kudo, 2018) has become a staple in research.

While all systems submitted this year are signed-to-spoken systems, the modality gap is more apparent for automatic spoken-to-sign translation because generating continuous outputs requires more fundamental changes to existing MT toolkits (as opposed to the changes necessary for continuous inputs).

[25] https://github.com/bitextor/bitextor

The proclivity of existing MT research for text data is confirmed by the number of recent works that chose to represent SL content as (textual) gloss sequences, despite the fact that glosses are not an adequate representation of meaning (Anonymous, 2022).

9.2 Reliability of evaluation procedure

Our evaluation is reliable since we conduct a human evaluation (compared to other shared tasks which produce official rankings based on automatic metrics). But even compared to shared tasks that do offer human evaluation (such as the General task this year), we believe that our evaluation is strong, since we have three to four (at least three) independent judgements for each system output across the entire test set.

9.3 Limitations of shared task setup

We note several limitations of the specific experimental setup in this year's shared task.

Generalization As explained in §4 all signers that appear in the development and test sets are known, in the sense of also being present in the training data. It is therefore important to emphasize that our shared task evaluates the performance of systems on familiar signers, and does not test generalization to unseen individuals.

Recording conditions Since our training data is derived from news broadcasts, the recording conditions and video quality are favourable. For example, the signer is always recorded against a monochrome and static background. The recording angle is very consistent, as cameras are mounted on a fixed rig. Signers always directly face the camera. The recording conditions therefore resemble laboratory conditions.

This means that our shared task does not evaluate "signing in the wild" (examples: mobile recordings of varying quality, varying angles, moving background including other people) and it is likely that the outcome would be different in that case.

Interpretation vs. translation Some of our training material is interpreted live (§4). Interpretation has constraints that are very different from offline translation, most notably, interpreters are under severe time pressure. This has consequences for the resulting signed material, which may sometimes omit phrases to keep up with the narrative, or interpreters would sign an utterance differently if they could give it a second thought.

A general property of SL interpretation (and hearing signers in general, as opposed to deaf signers) is that its linguistic structure tends to follow the structure imposed by the spoken language being translated (Janzen, 2005). This means that systems trained on such material may resemble hearing interpreters more than deaf translators.

9.4 Value created by this shared task

This shared task provides new insights and resources that previously did not exist for SLT, and that are valuable for the community.

We provided new training corpora and an official development and test set. We open-sourced a baseline system and code that is fully reproducible. We design protocols for human evaluation and adapt existing evaluation software accordingly. Lastly, the shared task resulted in the first openly available set of human judgements of automatic SL translations. Future work could use these scores for metric development, for instance.

10 Conclusion and future directions

In this paper we present the first WMT Shared Task on Sign Language Translation (WMT-SLT22). We consider automatic sign language translation, and sign language processing in general, to be of wide public interest and to have a high potential impact (§2).

Seven teams participated in this first edition of the shared task. Overall, we observed low system performance with an average human evaluation score of about 4 out of 100 (for the best-performing system), which is not usable in practice. The main reasons for this outcome are a lack of usable training data, a modality gap (considering that most existing work in MT is based on text) and a lack of basic NLP tools specifically for sign languages.

Future of the shared task Future iterations of the shared task could introduce more language pairs and larger training data. Since this year all submissions are signed-to-spoken systems, the shared task could also focus more on sign language generation going forward.

Furthermore, we will consider introducing additional MT-related tasks such as a sign language version of the metrics task. This perhaps requires a better distribution of human evaluation scores, as our current set of scores very much focuses on both ends of the score spectrum (we do not have many mid-range scores).

Finally, future human evaluation experiments for spoken-to-signed translation could be run differently than explained in this paper. Namely, for campaigns where a sign language is the target language the evaluation could be reference-based instead of source-based. The advantage of this change would be that deaf evaluators can perform this evaluation, instead of hearing interpreters for whom in this case the target language is not their first language.

11 Ethical statement

Within this shared task, two main ethical considerations emerge: the potential impact of SL technology on target users and privacy considerations.

Research in sign language processing, if not executed carefully, may inadvertently cause harm to end users, especially members of deaf communities. Hearing scientists should refrain from prescribing what sort of language technology should be accepted by deaf individuals and should avoid claiming that their approach "solves" any particular problem. Ideally, research of this nature should include deaf people, not only at evaluation time, but in the entire development cycle.

Secondly, there is a concern for the privacy of individuals depicted in SLP datasets. For the specific use case of sign language data, proper anonymisation is impossible since identifying details such as facial expressions are crucial for sign language communication. We have obtained written permission of all individuals shown in our datasets. Storing and processing pose estimation features instead of raw videos may be an alternative that provides anonymity (and has other generalization effects such as ignoring differences in race, gender, clothing, background etc.). However, in our shared task and related literature (Moryossef et al., 2021) video features outperform pose features.

Acknowledgments

This shared task was funded by the European Association for Machine Translation (EAMT) and by Microsoft AI for Accessibility. We are grateful for their support which enabled us to provide test data, human evaluation and interpretation in International Sign during the WMT conference.

The organizing committee further acknowledge funding from the following projects: the EU Horizon 2020 projects EASIER (grant agreement number 101016982) and SignON (101017255), the Swiss Innovation Agency (Innosuisse) flagship IICT (PFFS-21-47) and the German Ministry of Education and Research through the project SocialWear (01IW20002).

Thanks to Stanko Pavlica from FocusFilm and Robin Ribback from SWISSTXT for their help with data and licensing. Thanks to Tom Kocmi and Christian Federmann from Microsoft Munich for their help with the submission and evaluation platform. Thanks to Yvette Graham, Nitika Mathur and Tom Kocmi for providing expertise on statistical analysis.

Finally we would like to extend heartfelt thanks to the DSGS interpreters who performed our human evaluation: Michèle Berger, Sarah Caminada, Janine Criblez and Tanja Joseph.

A Appraise instructions to human evaluators

A.1 Sign-to-text direction

A.1.1 English

Below you see a document with 10 sentences in Swiss-German Sign Language (Deutschschweizer Gebärdensprache (DSGS)) (left columns) and their corresponding candidate translations in German (Deutsch) (right columns). Score each candidate sentence translation in the document context. You may revisit already scored sentences and update their scores at any time by clicking on a source video.

Assess the translation quality on a continuous scale using the quality levels described as follows:

- 0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Grammar is irrelevant.
- 2: Some Meaning Preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Grammar may be poor.
- 4: Most Meaning Preserved and Few Grammar Mistakes: The translation retains most of the meaning of the source. It may have some grammar mistakes or minor contextual inconsistencies.
- 6: Perfect Meaning and Grammar: The meaning of the translation is completely consistent with the source and the surrounding context. The grammar is also correct.

Please score the overall document translation quality (you can score the whole document only after scoring all individual sentences first). Assess the translation quality on a continuous scale using the quality levels described as follows:

- 0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Grammar is irrelevant.
- 2: Some Meaning Preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Grammar may be poor.
- 4: Most Meaning Preserved and Few Grammar Mistakes: The translation retains most of the meaning of the source. It may have some grammar mistakes or minor contextual inconsistencies.
- 6: Perfect Meaning and Grammar: The meaning of the translation is completely consistent with the source and the surrounding context. The grammar is also correct.

A.1.2 German

Unten sehen Sie ein Dokument mit 10 Sätzen in Deutschschweizer Gebärdensprache (DSGS) (linke Spalten) und die entsprechenden möglichen Übersetzungen auf Deutsch (rechte Spalten). Bewerten Sie jede mögliche Übersetzung des Satzes im Kontext des Dokuments. Sie können bereits bewertete Sätze jederzeit durch Anklicken eines Eingabevideos erneut aufrufen und die Bewertung aktualisieren.

Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

- 0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Eingabevideo sind verloren gegangen. Die Grammatik ist irrelevant.
- 2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Die Grammatik kann mangelhaft sein.

- 4: Der grösste Teil der Bedeutung ist erhalten und es gibt nur wenige Grammatikfehler: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann einige Grammatikfehler oder kleinere kontextuelle Unstimmigkeiten aufweisen.
- 6: Perfekte Bedeutung und Grammatik: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Auch die Grammatik ist korrekt.

Bitte bewerten Sie die Übersetzungsqualität des gesamten Dokuments. (Sie können das Dokument erst bewerten, nachdem Sie zuvor alle Sätze einzeln bewertet haben.) Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

- 0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Eingabevideo sind verloren gegangen. Die Grammatik ist irrelevant.
- 2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Die Grammatik kann mangelhaft sein.
- 4: Der grösste Teil der Bedeutung ist erhalten und es gibt nur wenige Grammatikfehler: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann einige Grammatikfehler oder kleinere kontextuelle Unstimmigkeiten aufweisen.
- 6: Perfekte Bedeutung und Grammatik: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Auch die Grammatik ist korrekt.

A.2 Text-to-sign direction

A.2.1 English

Below you see a document with 10 sentences in German (Deutsch) (left columns) and their corresponding candidate translations in Swiss-German Sign Language (Deutschschweizer Gebärdensprache (DSGS)) (right columns). Score each candidate sentence translation in the document context. You may revisit already scored sentences and update their scores at any time by clicking at a source text.

Assess the translation quality on a continuous scale using the quality levels described as follows:

- 0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Naturalness of motion is irrelevant.
- 2: Some Meaning Preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Naturalness of motion may be poor.
- 4: Most Meaning Preserved and Acceptable Natural Motion: The translation retains most of the meaning of the source. It may have some minor mistakes or contextual inconsistencies. Motion may appear unnatural.
- 6: Perfect Meaning and Naturalness: The meaning of the translation is completely consistent with the source and the surrounding context. Motion is natural.

Please score the overall document translation quality (you can score the whole document only after scoring all individual sentences first). Assess the translation quality on a continuous scale using the quality levels described as follows:

- 0: Nonsense/No meaning preserved: Nearly all information is lost between the translation and source. Naturalness of motion is irrelevant.
- 2: Some Meaning Preserved: The translation preserves some of the meaning of the source but misses significant parts. The narrative is hard to follow due to fundamental errors. Naturalness of motion may be poor.

- 4: Most Meaning Preserved and Acceptable Natural Motion: The translation retains most of the meaning of the source. It may have some minor mistakes or contextual inconsistencies. Motion may appear unnatural.
- 6: Perfect Meaning and Naturalness: The meaning of the translation is completely consistent with the source. Motion is natural.

A.2.2 German

Unten sehen Sie ein Dokument mit 10 Sätzen auf Deutsch (linke Spalten) und die entsprechenden möglichen Übersetzungen in Deutschschweizer Gebärdensprache (DSGS) (rechte Spalten). Bewerten Sie jede mögliche Übersetzung des Satzes im Kontext des Dokuments. Sie können bereits bewertete Sätze jederzeit durch Anklicken eines Quelltextes erneut aufrufen und die Bewertung aktualisieren.

Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

- 0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Ausgangstext sind verloren gegangen. Es ist irrelevant, ob die Bewegungen natürlich sind.
- 2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Bewegungen können mangelhaft sein.
- 4: Der grösste Teil der Bedeutung ist erhalten und die Bewegungen sind akzeptabel: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann kleine Fehler oder kleinere kontextuelle Unstimmigkeiten aufweisen. Bewegungen sehen teilweise nicht natürlich aus.
- 6: Perfekte Bedeutung und Natürlichkeit: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Bewegungen wirken natürlich.

Bitte bewerten Sie die Übersetzungsqualität des gesamten Dokuments. (Sie können das Dokument erst bewerten, nachdem Sie zuvor alle Sätze einzeln bewertet haben.) Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

- 0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Ausgangstext sind verloren gegangen. Es ist irrelevant, ob die Bewegungen natürlich sind.
- 2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Bewegungen können mangelhaft sein.
- 4: Der grösste Teil der Bedeutung ist erhalten und die Bewegungen sind akzeptabel: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann kleine Fehler oder kleinere kontextuelle Unstimmigkeiten aufweisen. Bewegungen sehen teilweise nicht natürlich aus.
- 6: Perfekte Bedeutung und Natürlichkeit: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Bewegungen wirken natürlich.

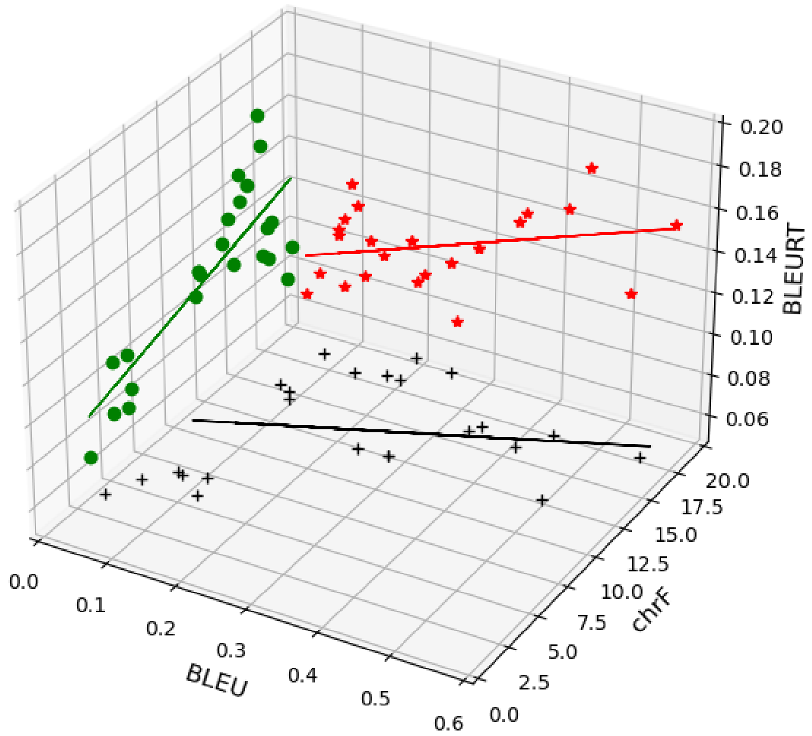

Figure 6: Correlation between the metrics used in the automatic evaluation. Automatic evaluation scores projected into the 2D spaces for BLEU–chrF (black crosses, $r = 0.447$), BLEU–BLEURT (red stars, $r = 0.703$) and chrF–BLEURT (green dots, $r = 0.443$).

B Correlation between automatic metrics

Metrics do not correlate well with each other, especially if chrF is compared to a second metric. Figure 6 plots the projection for the scores on the full test set by metric pair for the 23 submissions and the baseline. The Pearson correlation shows that metrics are far from a linear relation: BLEU–chrF has $r = 0.447$, BLEU–BLEURT $r = 0.703$ and chrF–BLEURT $r = 0.443$. Spearman correlation, accounting only for monotonicity, is lower in the three cases specially for chrF–BLEURT ($\rho = 0.259$), with $\rho = 0.421$ for BLEU–chrF and $\rho = 0.633$ for BLEU–BLEURT.

C Feedback from evaluators

Table 8 lists detailed by evaluators regarding the human evaluation procedure and the Appraise system. Two out of four evaluators submitted a response.

	Answer 1	Answer 2
What is your experience in assessing machine translation outputs?		
	None: this was my first time	Low: I have done it once or a long time ago
Please specify how much you agree or disagree with the following statements.		
Generally, my experience with the tool was positive	Agree	Strongly agree
Instructions were clear	Agree	Strongly agree
Quality levels 0-6 were helpful to me	Agree	Strongly Agree
Source videos/texts were understandable	Neutral	Strongly Agree
There was too much repetitiveness	Disagree	Agree
Documents were too long	Disagree	Strongly Disagree
Segments were too short	Neutral	Disagree
In some cases, the context was insufficient	Strongly Agree	Disagree
I experienced technical issues	Agree	Agree
I would be willing to do similar work in future	Strongly agree	Agree
Please provide more details related to the statements above that you think can be useful to us. What was most troublesome? What could we improve?		
	it would be very helpful, if the video started automatically when moving to the next segment. (some did, but many more did not) It would save a click. Also, the submit button could be on the left side under the 0 score (at the moment, as most translation are not yet good quality)	-
What were the main or most common issues with the automatic translations?		
	This question is not clear to me. You mean on a technical level or something else? meaning was garbage, some did not know the German Umlaute äüö	-
This evaluation campaign featured the Direct Assessment with Scalar Quality Metrics method. What do you think about this method? On a scale between -3 (negative) and 3 (positive) it was...		
difficult/easy	2	2
stressful/relaxed	2	-2
laborious/effortless	1	2
slow/fast	0	0
inefficient/efficient	2	2
boring/exciting	-2	3
complicated/simple	2	2
annoying/enjoyable	0	1
limiting/creative	-2	0
impractical/practical	2	0

Table 8: Feedback from evaluators about the human evaluation setup and the Appraise platform.

D Human evaluation score distribution

To complement our analysis we show the distribution of scores for each system in Figure 7. The set of scores (excluding zero scores, which are not shown in the figure) resembles a bimodal distribution, with most of the scores residing at both ends of the spectrum. MSMUNICH is the system with the most scores in the highest-quality bucket.

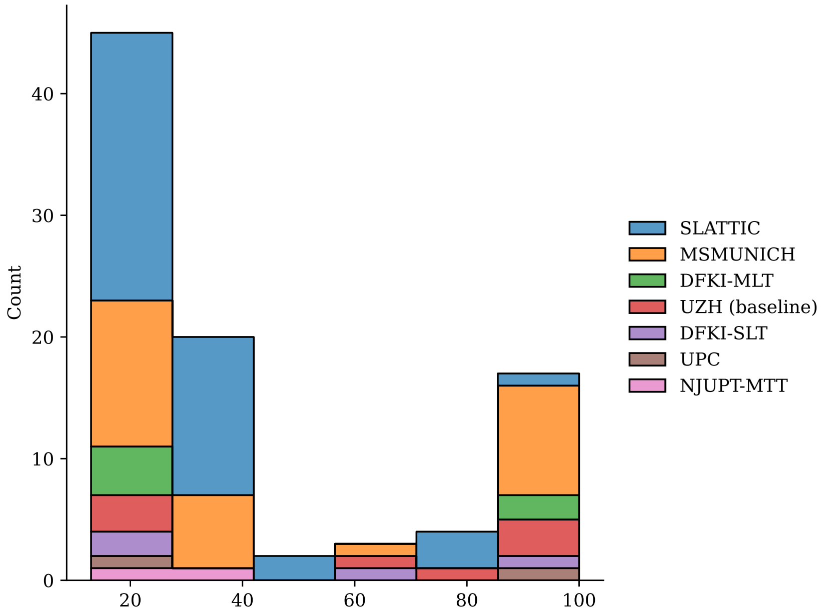

Figure 7: Distribution of human evaluation scores for all submitted systems discretized in seven bins, excluding scores of bin 0 (lowest quality).

Findings of the WMT’22 Shared Task on Large-Scale Machine Translation Evaluation for African Languages

Abstract

We present the results of the WMT’22 Shared Task on Large-Scale Machine Translation Evaluation for African Languages. The shared task included both a data and a systems track, along with additional innovations, such as a focus on African languages and extensive human evaluation of submitted systems. We received 14 system submissions from 8 teams, as well as 6 data track contributions. We report a large progress in the quality of translation for African languages since the last iteration of this shared task: there is an increase of about 7.5 BLEU points across 72 language pairs, and the average BLEU scores went from 15.09 to 22.60.

1 Introduction

A large portion of the world’s population speak *low-resource languages*, and would benefit from improvements in translation quality on their native languages. Recent advances in translation quality, particularly from massively multilingual models (Fan et al.; Ma et al., 2021), have enabled progress in the translation quality of low-resource languages. However, many languages have seen little to no progress. This is particularly true for African languages. For example, in the 2021 Large Scale Multilingual Evaluation shared task (Wenzek et al., 2021), there was a progress[2] of +19.3 avg. BLEU when translating into languages like Irish and Welsh (included in the Other Indo-European grouping), but only a progress of +3.5 avg. BLEU when translating into languages like Fula and Igbo (included in the Nilotic/Atlantic Congo grouping).

The African continent is home to a rich diversity of languages. Around a third of the world’s living languages are from Africa and only a small fraction of the resources in NLP and Machine translation are dedicated to them (Orife et al., 2020). As a result, African language speakers do not benefit from language technologies similarly to other Global North language speakers (Blasi et al., 2022). A major (but not the sole) hurdle to building language technologies for African languages is data availability (Joshi et al., 2021), with significant efforts underway stemming –importantly– from Africa itself (Nekoto et al., 2020).

To bring attention of the research community to the challenges of translating African Languages, this year we focus on the multilingual evaluation of 24 African Languages together with French and English. We base our evaluation on the benchmark provided by FLORES (Goyal et al., 2022), and its recent expansion to more African languages (NLLB Team et al., 2022).

In this second multilingual large-scale shared task, we evaluate the progress on massively multilingual translation for African Languages in a non-English-centric way. We propose 100 evaluation language pairs, based on regional clusters (South/South-East Africa, Horn of Africa and Central/East Africa, Nigeria and Gulf of Guinea, and Central Africa; and pivot languages (English, French). This year is characterized by two further innovations: first, a data track is included, in which participants share corpora to be used during the shared task; second, we perform human evaluation for a subset of the language pairs.

In the remainder of this paper, we describe the task setup, the participants, and the official results for the task. We also analyze the results to understand better the languages for which progress has been attained, and those where a gap in quality is still observed. Finally, we propose future directions for other tasks in the future.

Author names are sorted in alphabetical order.

[2] Progress was determined by comparing the average BLEU score between the best system in the task vs. the baseline.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 773 - 800
December 7-8, 2022 ©2022 Association for Computational Linguistics

2 Shared Task and Tracks

This year's task focuses on the 24 African languages listed in Table 1, along with French and English which are included as colonial linguae francae for evaluation purposes. These languages are all supported by the FLORES benchmark in its most recent expansion (NLLB Team et al., 2022).

Afrikaans	afr	Oromo	orm
Amharic	amh	Shona	sna
Chichewa	nya	Somali	som
Nigerian Fulfulde	fuv	Swahili	swh
Hausa	hau	Swati	ssw
Igbo	ibo	Tswana	tsn
Kamba	kam	Umbundu	umb
Kinyarwanda	kin	Wolof	wol
Lingala	lin	Xhosa	xho
Luganda	lug	Xitsonga	tso
Luo	luo	Yorùbá	yor
Northern Sotho	nso	Zulu	zul

Table 1: Focus African languages for this shared task. In addition to these, we also include French and English.

The human and automatic evaluation is based around 100 language directions, selected based on translator and annotator availability:

- **Languages of South and Southeast Africa**: xho-zul, zul-sna, sna-afr, afr-ssw, ssw-tsn, tsn-tso, tso-nso, nso-xho (8 directions).
- **Languages of the Horn of Africa**: swh-amh, amh-swh, luo-orm, som-amh, orm-som, swh-luo, amh-luo, luo-som (8 directions).
- **Languages of West Africa**: hau-ibo, ibo-yor, yor-fuv, fuv-hau, ibo-hau, yor-ibo, fuv-yor, hau-fuv, wol-hau, hau-wol, fuv-wol, wol-fuv (12 directions).
- **Languages of Central Africa**: kin-swh, lug-lin, nya-kin, swh-lug, lin-nya, lin-kin, kin-lug, nya-swh (8 directions).
- **Cross-regional pairs**: amh-zul, yor-swh, swh-yor, zul-amh, kin-hau, hau-kin, nya-som, som-nya, xho-lug, lug-xho, wol-swh, swh-wol (12 directions)
- **English pivots:** 22 languages translated into and from eng: afr, amh, nya, fuv, hau, ibo, kam, kin, lug, luo, nso, orm, sna, som, swh, ssw, tsn, umb, xho, tso, yor, zul (44 directions).
- **French pivots:** 4 languages translated into and from fra: kin, lin, swh, wol (8 directions).

3 Data Track

The data track focused on the contribution of novel corpora. Participants were welcomed to open-source and share monolingual, bilingual or multilingual datasets relevant to the training of MT models for this year's set of languages. There were seven submissions in this track:

LAVA[3] LAVA Corpus contains millions of parallel bilingual sentences, which are mined from Common Crawl. It covers five African languages.

MAFAND-MT (Adelani et al., 2022)[4] contains a few thousand high-quality and human translated parallel sentences for 21 African languages in the **news** domain. Each language has between 1,400 - 34,500 parallel sentences for training and/or evaluation. The languages covered are Amharic, Bambara, Ghomala, Ewe, Fon, Hausa, Igbo, Kinyarwanda, Luganda, Dholuo, Mossi, Chichewa, Nigerian-Pidgin, chiShona, Swahili, Setswana, Twi, Wolof, Yorùbá, isiXhosa, and isiZulu. These languages include 7 languages which were not present in the Shared task (and which are not reported therefore in Table 2).

KenTrans[5] This project produced a parallel corpus between Swahili and 2 other Kenya Languages: Dholuo and Luhya. The Luhya Language has several dialects. In the project 3 dialects were chosen as a start: Lumarachi, Logooli and Lubukusi. A total of 12,400 sentences were translated to Kiswahili from a sample of Dholuo and Luhya (1500 Dholuo-Kiswahili sentence pairs and 10,900 Luhya-Kiswahili sentence pairs). This corpus has an extension to speech in the version of Kencorpus (Wanjawa et al., 2022)[6].

Monolingual African languages from ParaCrawl[7] This release contains derived corpora built from language classified extracts of the ParaCrawl project. Monolingual data in this release comes from the Internet Archives and targeted crawls performed in the paracrawl project with document level language classification.

Table 2: Dataset submissions: covered Shared task languages, dataset sizes (i.e. number of parallel sentences in all translation directions), and participating teams that made use of the dataset in their submission.

SA Languages[8] The dataset was constructed using public available data mostly from South African Government websites.

WebCrawlAfrican (Vegi et al., 2022b) [9] Web Crawl African is a collection of African Multilingual parallel corpora comprising of 695,000 (approx) sentence pairs, covering 15 African languages plus English and 73 language pairs. African languages covered include Afrikaans, Lingala, Swati, Amharic, Luganda, Tswana, Chichewa, Hausa, Oroma, Xhosa, Igbo, Xitsonga, Yoruba, Swahili, Zulu. It covers variety of domains political, stories, religious and songs. Corpora have sentences covering both formal and informal writing styles.

This participation is summarised in Table 2 which includes language covered, dataset size and participating teams that currently used the dataset for their submission. All datasets where at least used by 3 teams in the evaluation. Note that the most used corpus was MAFAND-MT which was used by 6 different teams.

4 System Track

We provided a selection of training corpora, i.e. parallel sentences, to enable training of the MT systems. Submissions in the constrained translation track were only allowed to use data from the following sources:

- all corpora from the data track (see section 3);
- parallel corpora from OPUS (Tiedemann, 2012);[10]
- parallel corpora mined from Common Crawl using the LASER3 multilingual sentence encoder.

Participants who used other resources, had to submit to the unconstrained translation track.

Publicly available resources for African languages are very limited, for some of them less than fifty thousand sentences of bitexts are available. In addition to human translated sentences, several approaches were proposed to automatically mine parallel sentence from large collections of monolingual data. Unfortunately, recent approaches like ParaCrawl or CCMatrix (Schwenk et al., 2021) cover only few African languages. We extended the basic idea of mining based on a similarity measure in an multilingual embedding space (Artetxe and Schwenk, 2019) and developed sentence encoders for all African languages of this evaluation. We then performed bitext mining against 21.5 billion English sentences from Common Crawl, and 3.3 million sentences in French, respectively. These resources as well as the sentence encoders were made available to the participants of this evaluation. A detailed description of this mining approach can be found in Heffernan et al. (2022).

4.1 Participating Teams

CAIR ANVITA (Vegi et al., 2022a). The ANVITA-1.0 MT system is an English-centric multilingual transformer model for 24 African languages. The authors applied several heuristics to filter the data released for the shared task. They showed that that using larger Transformer model (24 encoder, 6 decoder) performs much better than smaller Transformer model (6 encoder, 6 decoder). Furthermore, they obtained some improvements by using an ensemble of last two epochs of Deep Transformer (24 encoder, 6 decoder).

[9] https://github.com/pavanpankaj/Web-Crawl-African

[10] https://opus.nlpl.eu/

Cape Town (Elmadani et al., 2022). This system was focused on eight South and South-East African languages. The authors trained a multilingual NMT system (foreign to English and English to foreign, with some non English directions). The authors focused on exploring the best sub-word representation (BPE vs overlap-based BPE) and its effects on downstream performance for low-resource languages. Further, the authors explore creating synthetic data through back-translation and explore sampling techniques to balance the corpora.

GMU (Ibn Alam and Anastasopoulos, 2022). This system was based on on fine-tuning pretrained multilingual DeltaLM on 26 languages (625 translation directions). The fine-tuning was based on language- and language-family- (phylogeny) inspired adapter units (Faisal and Anastasopoulos, 2022) to improve its performance for African languages. The results show that a language-adapter-based fine-tuning significantly out-performs direct fine-tuning, but making use of family/sub-family adapters only helps in a few cases.

IIAI DenTra (Kamboj et al., 2022). This multilingual model combines a traditional translation loss with self-supervised tasks that can make use of unlabeled monolingual data. The resulting model performs denoising tasks (shuffling, masking) in conjunction with both translation and backtranslation. It then fine-tunes the model to in-domain data and covers 24 languages.

Masakhane (Abdulmumin et al., 2022). This model is based on M2M-100 which is fine-tuned on training data hat has been cleaned by an auxiliary language models. The pre-trained language models were fine-tuned on *positive* samples (clean data) vs. *negative* samples coming from automatically aligned data. The authors find significant improvements from using the filtered data.

Tencent Borderline (Jiao et al., 2022). The borderline model is a large transformer model (1.02B params.) which is augmented with data for zero-shot pairs through tagged back-translation and self-translation. In addition, it uses distributionally robust optimization (DRO) to alleviate the data imbalance. Finally it also uses family language information to group target languages and finetune separate models for each group.

Bytedance VolcTrans (Qian et al., 2022). This is an unconstrained system that uses different sources of parallel data (constrained data, NLLB, self-procured data) and monolingual data (e.g. VOA news, Wikipedia). This model is also trained on data cleaned through a rich set of heuristic rules to prevent punctuation mismatches, overly short/long sentences, among others; together with an approach based on minimum description length (MDL) that removes noisy sentences. The data is augmented with back-translation coming from pivot languages (Eng/Fra). The model is trained with target language tags added to both the encoder and decoder inputs. Finally, it includes post-processing rules for Yoruba accents.

SRPH-DAI (Cruz and Sutawika, 2022). This model is based on mT5, with additional adapters fine-tuned to each translation task, and then merged using adapter fusion to perform task-composition. The model is trained over data that is filtered using a set of heuristics. This model doesn't use other data-augmentation techniques (e.g. BT).

4.2 Automatic Evaluation

We follow last year's shared task in relying in spBLEU (Goyal et al., 2022) due to the well-known limitations of traditional BLEU. In particular we use a sentencepiece (Kudo and Richardson, 2018) tokenizer trained on all FLORES-200, in the hope of producing a *universal* tokenizer that can adequately handle all languages we are dealing with. Finally, to compute BLEU, we apply SPM tokenization to the system output and the reference, and then calculate BLEU at the sentence-piece level. For readability, in this paper we use BLEU and spBLEU interchangeably.

We additionally report chrF++ (Popović, 2017), another metric relying on character n-gram F-score (chrF) alongside word-level unigram and bigram F-score. This metric has been shown to correlate particularly well with human judgments for languages with rich morphology.

For all results we rely on statistical significance tests, using paired bootstrap resampling (Koehn, 2004) with 1000 samples. We first rank all the systems with spBLEU then we take the highest-scored system as a baseline and compare it with systems that are below its rank. If the p-value is greater than 0.05 we bundle those systems together. If for a system the p-value is less than 0.05 that means we have found a statistically significantly worse system and we make that system the new baseline system and continue to go on.

4.3 Human Evaluation

A fixed sample of the outputs of the primary submissions was grouped by the language pairs and split into tasks for evaluation by crowd human annotators. Each task comprised the source sentence and two translations of the source sentence that were to be scored from 0 to 100 indicating the general quality of the translations.

The annotation was conducted via crowdsourcing on the Toloka platform [11] where a crowd labeling project was set up for each language pair.

Guidelines for Evaluation The guidelines for the scale were roughly based on the theory of levels of translation equivalence by Komissarov (1990) and were simplified in order to facilitate their usage by annotators without linguistic background . The crowd annotators were asked to evaluate the translations on a 0..100 continuous rating scale (Graham et al., 2013) where 0 was considered a very bad and 100 — a very good translation (see Figure 1). The scale represents a combined approach that requires the annotators to give each translation one score assessing both accuracy and fluency at the same time and taking into account factors like grammaticality, naturalness, conveying the same meaning, having the same communicative goal, representing the same situation, having the same style and preserving as many shades of meaning of the source sentence as possible. The annotators were asked to evaluate the sentences as a whole and not word by word, pay attention to unmotivated additions of omissions, grammatical mistakes and untranslated parts, check if set expressions and metaphors were translated according to the expressions used in the target language and use their feel for the language in general.

Annotator Selection We ran the crowd annotation projects in Toloka and used the following criteria for annotator selection:

- Location: Africa according to the evaluator's IP address
- Both languages of the respective pair should have been among the list of languages known by the annotator as they had specified in their Profile
- Wherever possible, we showed the projects only to those annotators who had passed the respective language tests built in Toloka. The platform asks the annotators to verify their language skills via tests to get access to tasks with this prerequisite and it had such tests for English and French.

Potential annotators did not know about the requirements and did not see the projects if they did not meet the criteria. This approach prevented them from deliberate manipulation of their user settings to get access to the projects.

Quality Control The annotators whose profile matched our requirements, were shown the guidelines. The guidelines were translated into the target language of the respective pair as another way of testing the annotator's language skills.

Then the annotators were given an exam to test their ability to complete the task. The exam consisted of five tasks structurally identical to the main ones (see Figure 1). Thus each task consisted of the source sentence, two translations and a continuous scale for scoring. The exams were generated automatically from the list of source sentences paired with target sentences. The target sentences for the exam comprised:

- Reference translations
- Reference translations with randomized word order (while still having correct capitalization when needed and ending with the respective punctuation mark)
- "Gibberish" sentences. Being potentially unknown to virtually any annotator, Sumerian was chosen as the source of "gibberish" control sentences [12] for eliminating cheaters. Furthermore, being unrelated to the languages in the dataset, it didn't confuse diligent annotators in terms of what pair of languages needs to be evaluated.

Each translation was assigned a golden score to be used as a control answer (Chida et al., 2022). Since the evaluation scale used is subjective and can show high variance, control intervals were introduced with the matching interval scores (score 0–33 = 0, 34–66 = 50, 66+ = 100). Randomized sentences as well as sentences in Sumerian were given golden scores 0 and reference translations were given a 100. Thus, if the annotator scored a bad sentence in a range of 0-33 it meant that they gave a correct answer and so on.

The task was accepted if both translations were given correct scores and rejected otherwise. The accuracy of the performer in an exam was calcu-

Source sentence

"Lugverdediging eenhede het hulle konfronteer en hul forseer om te gaan nadat hulle van hul ammunisie in verlate gebiede laat val het sonder om skade aan mense of goedere te doen."

Translations

"The firefighting units confronted them and forced them to leave after they dropped some of their ammunition in deserted areas without causing damage to people or goods."

14

Very Bad Very Good

"Air defense units confronted them and forced them to leave after dropping some of their ammunition in deserted areas without causing damage to people or goods."

97

Very Bad Very Good

Figure 1: Screenshot of the interface with an annotated task comprising the source sentence and two translations randomly chosen from the outputs of the submitted models for the respective language pair (Afrikaans – English in the screenshot).

lated as the rate of accepted tasks among the five comprising the examination set. Exams where one of the languages (English or French) had been verified by the platform test required a 100% accuracy of completion (5/5 accepted tasks). For other languages the accuracy threshold was 80% to neutralize potential variance introduced by the automated creation of exams. These accuracy scores given in the exam were used as filters for the main pools of tasks, giving access to the main labeling only to the annotators who had passed the exam.

Another way of eliminating potential low-performers used both during the exam and the main set of tasks was banning the annotators for very fast responses. If an annotator submitted a page of five tasks within twenty seconds or less two times or more, they were banned from working on the project.

Score Normalization We convert the raw human scores to Z-scores:

$$z = \frac{x - \mu}{\sigma}$$

Note that we perform this operation at the annotator level; that means we compute the mean μ and standard deviation σ separately for each annotator and apply the transformation only on their scores.

Language Pairs Due to annotator availability, we only perform human evaluations in a smaller subset of our 100 language pairs. Hence the human score averages presented in all results only reflect averages for this subset, not all language pairs. The list of pairs is available in Table 15 in the Appendix.

5 Results

In this section we analyze both the human scores and automatic metrics for all the participants. We present the results and official ranking for the main task; the analysis of the performance from/to English, an to/from African languages; and the progress in performance w.r.t. to the previous year's task.

5.1 Main Results

The average results across the 100 evaluation language pairs are reported in Table 4. Note that we primarily only rank the *constrained* systems that were able to handle all language pairs.

System	# of pairs
Unconstrained	
Bytedance$_p$	52
Bytedance$_c$	48
Constrained	
Tencent$_p$	39
Tencent$_c$	26
GMU$_p$	17
DENTRA$_p$	9
GMU$_c$	7
Masakhane$_c$	1
SPRH-DAI$_c$	1
ANVITA, Masakhane$_p$ CapeTown, SPRH-DAI$_p$	0

Table 3: Number of evaluation language pairs (out of 100 total) that a system ranks (or ties for) best performance (spBLEU).

The best-performing constrained system on average is the Borderline (Tencent) system, followed by the GMU system with a little over 1 BLEU point difference between them. The only unconstrained submission is Bytedance's Volctrans, outperforming other systems by a significant margin of more than 4 BLEU points, but note however that it uses

Rank	System	Human	BLEU	spBLEU	chrF2
Systems handling all language pairs					
Constrained					
1	Tencent$_p$	0.39 ± 0.15	14.1 ± 1.1	17.6 ± 1.2	37.4 ± 1.3

Systems handling partial language pairs					
P	ANVITA$_p$	0.24 ± 0.19	24.3 ± 1.1	26.3 ± 1.2	44.9 ± 1.2
P	ANVITA$_c$		23.8 ± 1.1	25.9 ± 1.2	44.5 ± 1.2
P	Capetown$_p$	0.09 ± 0.24	17.4 ± 1.0	21.3 ± 0.8	43.7 ± 0.7
P	Masakhane$_p$	0.05 ± 0.13	16.6 ± 1.0	19.0 ± 1.0	39.3 ± 1.1
P	Masakhane$_c$		11.9 ± 0.7	14.1 ± 0.7	35.0 ± 0.8

Table 4: Average results (presented here: mean ± standard error across all 100 evaluation language pairs), sorted by spBLEU. We only ranked constrained systems that handle all language pairs. We denote *unconstrained* submissions with U, and systems covering partial language pairs with P.

unconstrained data. All metrics, including human evaluation, result in a similar ranking among the 4 systems handling all language pairs.[13]

Table 3 lists the number of evaluation pairs for which each system ranks or ties for best performance. Among the constrained systems, the Tencent ones rank first for 39 language pairs, with the GMU one following with 17, and DENTRA with 9. The Masakhane and SPRH-DAI contrastive systems also rank first in one language pair each.

5.2 Performance by Language

Table 5 presents the best and worst performing language pairs. As shown, some language pairs end up with very good systems (e.g. Afrikaans, Swahili, Northern Sotho – at least when pairing with English). Wolof, Umbundu, and Kamba are the languages that most often show up as targets in the language pairs that systems struggle in, with BLEU scores below 10.

Results by for each individual language pair can be found in the Appendix Tables 16–115.

Source	Target	spBLEU
eng	umb	4.1
eng	kam	5.9
fra	wol	8.3
swh	wol	8.5
hau	wol	8.6
afr	eng	60.1
swh	eng	49.0
eng	afr	46.0
nso	eng	43.5
eng	swh	42.0

Table 5: Top-5 worst (top) and best (bottom) language pairs (result from best system).

5.3 Performance by Groups

Table 6 presents the best performance across all systems, averaged over the different language groups we defined above. Note that having colonial languages (English and French) as the target perhaps unsurprisingly leads to generally high performance (average more than 33 BLEU). Languages from South Africa seem to be easier to translate (average ∼29 BLEU) while languages from West Africa, and especially Wolof, lead to worse performance as targets (average ∼15 BLEU).

5.4 Progress from Last Year

To assess the progress made in African languages, we compare this year's best results with DeltaLM (Yang et al., 2021), the best system from last year's shared task. Note that this analysis only includes 72 of our 100 evaluation pairs, as some of the languages (e.g. Kinyarwanda or Swati) were

[13] For a fair comparison, Appendix Tables 13 and 14 present average scores for the partial language pairs that the Masakhane and CapeTown systems handle.

Group	as src	as trg	as both
South	29.4	22.8	19.9
Horn	21.9	20.0	16.5
West	20.3	15.1	14.4
Central	21.7	20.0	16.2
Colonial	22.3	33.7	N/A

Table 6: Average spBLEU of the best performing system summarized per language group.

added this year. In addition, note that last year's systems were scored using a different sentencepiece tokenizer than this year's ones.[14]

Across all 72 pairs, the average improvement is around 7.5 BLEU points. For around 93% of the 72 language pairs (67 pairs), there are improvements over last year's best system. We show the top-10 improved language pairs in Table 7. Most of the English-centric language pairs improve significantly, but african-to-african pairs benefit too, like the Swahili to Dholuo (swh-luo) pair which shows more than 12 BLEU points improvement. When indeed improving, the average improvement is more than 8 BLEU points (max: 33.5, min: 0.94).

Source	Target	2021	2022	Δ
nso	eng	9.9	43.5	33.5
eng	nso	9.5	30.5	21.1
yor	eng	7.1	25.1	18.0
hau	eng	22.2	40.0	17.8
orm	eng	10.6	28.3	17.7
eng	hau	16.4	31.5	15.1
som	eng	20.8	35.0	14.2
eng	luo	3.5	16.6	13.1
swh	luo	2.8	15.0	12.2
eng	som	8.7	20.8	12.1
Average (72 pairs)		15.1	22.6	7.5

Table 7: The top-10 language pairs with the largest improvement over last year's best result. Average refers to all 72 language pairs.

On the other hand, 5 language pairs do not improve from last year. Importantly, though, the largest drop is a mere 1.9 BLEU points for English to Afrikaans, and around 1 BLEU point reduction for the opposite direction as well as English to Kamba. For the few cases where we indeed observe a reduction, the average reduction is only 1 BLEU point (min: -0.46, max: -1.9).

Source	Target	2021	2022	Δ
eng	afr	47.9	46.0	-1.9
eng	kam	6.9	5.9	-1.0
afr	eng	61.0	60.1	-1.0
fra	lin	20.7	20.0	-0.7
eng	umb	4.6	4.1	-0.5

Table 8: The bottom-5 language pairs with the largest performance degradation over last year's best result.

Table 9: Average results in all X-eng pairs, sorted by spBLEU. We only ranked constrained systems that handle all language pairs. We denote *unconstrained* submissions with U, and systems covering partial language pairs with P.

English-centric results (focusing on translating to and from English) are presented in Tables 10 and 9. The ranking of the system does not change depending on the direction. Note, however, that according to all metrics (including human evaluation) translating out of English and into the African languages is harder than the reverse direction for all systems.

5.6 Results on translation between African languages

Last, we present summary results on the average quality for translating between African languages,

[14] last year: spm tokenizer from FLORES-101; this year: spm tokenizer from FLORES-200.

Systems handling partial language pairs					
P	Capetown$_p$	0.24	10.2	14.4	37.9

Table 11: Average results in all African-African pairs, sorted by spBLEU. We only ranked constrained systems that handle all language pairs. We denote *unconstrained* submissions with U, and systems covering partial language pairs with P.

shown in Table 11. It is worth noting that, although the automatic metrics score imply that the systems are much worse than in the English-centric directions (compare, for example, spBLEU scores of 22.7 on eng-X to 15.5 on african-to-arfican for the ByteDance system), the human evaluation scores are not too different. For instance, the ByteDance system receives an average human Z-score of 0.55 on eng-X and 0.51 on african-african; the Tencent system, with respective scores of 0.33 and 0.40, receives even higher Z-scores for african-to-african languages.

6 Conclusion and Future Work

In this paper, we presented the results of the second shared task on Large-Scale Machine Translation Evaluation. In this edition of the shared task, we evaluate the progress on massively multilingual translation for African Languages in a non-English-centric way. From our findings, we observe that data is still an important factor in translation performance, and that systems that used more data, either in an unconstrained way, or through data augmentation techniques made the most progress.The quality of the data is also important, as most participants developed a set of heuristics to clean it. We also observed the popularity of pre-trained translation models such as: DeltaLM, M2M-100 and mT5, as most systems used a version of these when developing their final model. We observe that there has been a large progress in the quality of translation in since the last iteration of this shared task: there is an improvement of about 7.5 BLEU points across 72 language pairs, and the average BLEU scores went from 15.09 to 22.60. We observe that it is usually harder to translate into than out of African Languages, and it is particularly difficult to translate into West African Languages like Wolof. We also observed that there has been significant progress translating into and out of Northern Sotho, Hausa, and Somali.

Acknowledgements

We thank Kevin Heffernan for developing LASER3 encoders, Onur Çelebi for work on mined bitext and Kenneth Heafield for work on mined bitext and open sourcing. We are also grateful to Toloka for running the human evaluation, as well as to the annotators who contributed with their expertise. We thank Dmitry Ustalov and Mariya Shmatova for sharing their expertise in human evaluation of machine translation. We thank Microsoft Research for contributing Azure compute credits for some participating teams. We are thankful to GMU's ORC computing cluster, where the automatic system test set generation and evaluation was hosted and ran. Mahfuz Alam, Fahim Faisal, and Antonios Anastasopoulos are generously supported by NSF awards FAI-2040926, IIS-2125466, and a Sponsored Research Award from Meta.

C Appendix: Human Evaluation Guidelines

C.1 About

In the interface you will see a source sentence and two translations. Your task is to evaluate the quality of translations on a 0-100 scale where 0 is ridiculously bad and 100 is a perfect translation.

By doing this you will help us a lot to improve the quality of machine translation for African languages in all their glory and diversity.

C.2 How To Evaluate

The evaluation slider can go from 0 to 100. While choosing the most appropriate score, please consider the following features of a good translation starting from the most important:

1. Acceptable translation is grammatically correct, looks natural and makes sense to the reader.
2. Acceptable translation also has the same general meaning and communicative goal (what did it want to say?) as the source sentence
3. OK translation must be completely fluent and natural in addition to the above
4. Good translation keeps the style of the source sentence (e.g. formal or informal, colloquial style) in addition to being fluent and conveying the same meaning
5. Great translation keeps as much meaning and nuances as the source sentence in addition to being perfectly fluent.
6. Amazing translation also chooses the same means to describe the situation as the source sentence wherever the destination language has the same ways of doing it: the same metaphors, set expressions and such.

While performing the task, please do not use any automatic translation as the goal is to evaluate it with the help of human experts. You can use a dictionary if you found a word that you don't know.

C.2.1 Tips

- Evaluate the phrases as a whole and not word by word
- Check if any meaning was lost or unnecessarily added
- Check if there are any grammatical mistakes
- Check if anything remained untranslated
- Check if set expressions and metaphors were translated simply word by word (bad) or as a whole and according to the expressions used in the destination language (good)
- Use your own feeling as the speaker: do you consider the translation good, natural, clear and easily understandable

Findings of the WMT 2022 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT

Marion Weller-Di Marco and Alexander Fraser
Center for Information and Language Processing
LMU Munich
`{dimarco,fraser}@cis.uni-muenchen.de`

Abstract

We present the findings of the WMT2022 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT with experiments on the language pairs German to/from Upper Sorbian, German to/from Lower Sorbian and Lower Sorbian to/from Upper Sorbian. Upper and Lower Sorbian are minority languages spoken in the Eastern parts of Germany. There are active language communities working on the preservation of the languages who also made the data used in this Shared Task available.

In total, four teams participated on this Shared Task, with submissions from three teams for the unsupervised sub task, and submissions from all four teams for the supervised sub task. In this overview paper, we present and discuss the results.

1 Introduction

For a large majority of the world's languages, only limited resources are available to train and provide NLP tools. The need for parallel data in a (supervised) translation scenario aggravates this problem further. The Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT aim at promoting the research on translating low and very low resourced languages.

Following the Shared Tasks in the two previous years (Libovický and Fraser, 2021; Fraser, 2020), we continue to cooperate with the Sorbian community, namely the Sorbian Institute[1] and the Witaj Sprachzentrum (Witaj Language Center)[2] for this year's Shared Task. We offer all translation directions between the languages Upper Sorbian, Lower Sorbian and German, for both supervised and unsupervised translation.

Upper and Lower Sorbian are minority languages spoken in the eastern part of Germany in the federal states of Saxony and Brandenburg. With only 30k and 7k native speakers, there are only few resources available. However, as western Slavic languages, Upper and Lower Sorbian are closely related to Polish and Czech and can thus make use of the comparatively large data sets available for those languages.

In this year, four teams participated in the Shared Task, resulting in three to four submissions for each language pair for both the supervised and unsupervised variants.

2 Tasks and Evaluation

In contrast to the previous Shared Tasks, all language combinations between Upper Sorbian, Lower Sorbian and German are considered, resulting in the six following translation pairs:

- Upper Sorbian ↔ German
- Lower Sorbian ↔ German
- Upper Sorbian ↔ Lower Sorbian

Factoring in the variants supervised and unsupervised translation for each language pair, there is a total of 12 translation pairs.

For the evaluation, we follow the strategy employed in the previous Shared Task and use BLEU scores (Papineni et al., 2002) and chrF scores (Popović, 2015) as implemented in sacreBLEU (Post, 2018).[3] Furthermore, we evaluate the submissions using BERTScore (Zhang et al., 2020)[4] with XLM-RoBERTa Large (Conneau et al., 2020) as an underlying model for translations into German[5].

HSB ↔ DE	449.057	parallel sentences
DSB ↔ DE	40.193	parallel sentences
DSB ↔ HSB	62.564	parallel sentences

DSB	220.419	monolingual sentences
HSB	1.132.850	monolingual sentences

Table 1: Training data per language pair. The data sets have been made available by the Sorbian Institute (monolingual data) and The Witaj Sprachzentrum (both parallel and monolingual data).

We decided against using COMET Scores (Rei et al., 2020). This metric considers both the source language and the target language, but because it relies on XLM-R models, it does not support the Sorbian languages.

3 Data

To allow for a direct comparison between the different submissions, we only allowed training based on the resources released for the task, as well as resources for related languages (German, Czech and Polish data from the WMT news tasks[6] or available in the OPUS project[7]). In particular, the use of large models pre-trained on large data sets was not allowed. Table 1 gives an overview of the parallel and monolingual training data for the Sorbian languages.

For the unsupervised translation sub-task, we restricted the the data set as follows: all released Upper/Lower Sorbian data could be used, with the exception of the parallel Upper Sorbian ↔ Lower Sorbian corpus. Furthermore, the German side of the parallel German ↔ Upper Sorbian and German ↔ Lower Sorbian training corpora was excluded. This setup allowed us to make maximum use of the low-resourced languages without providing parallel data.

4 Submitted Systems

Four teams participated in the supervised sub-task[8], and three teams participated in the unsupervised sub-task. We present a brief system description of each team's submission, with an overview of the results listed in tables 2 to 7. Table 8 gives a brief overview of some relevant details; for more detailed information, we refer the reader to the respective system description papers.

AIC (Shapiro et al., 2022) For the unsupervised system, they trained an unsupervised phrase-based statistical machine translation (UPBSMT) system on each pair independently. They trained a De-Slavic mBART model from Scratch (Random initialization) on the following languages: Polish (pl), Czech (cs), German (de), Upper Sorbian (hsb), and Lower Sorbian (dsb). They then fine-tuned their mBART on the synthetic parallel data generated by the UPBSMT model along with authentic parallel data (de ↔ pl, de ↔ cs). They further fine-tuned their unsupervised system on authentic parallel data (hsb ↔ dsb, de ↔ dsb, de ↔ hsb) to submit the supervised low-resource system.

MUNI NLP (Signoroni and Rychlý, 2022) This team submitted supervised NMT systems for the Lower Sorbian-German and Lower Sorbian-Upper Sorbian language pairs, in both translation directions. They employed a new subword tokenization algorithm, High Frequency Tokenizer (HFT), to obtain more meaningful subword vocabularies. They tested this against BPE in the first round of experiments where they trained two different models on the data tokenized with each tokenizer, so four systems in total: two standard Transformers and two Transformers with hyperparameters optimized for the dataset size. They then followed the Data Diversification procedure (Nguyen et al., 2020) generating and collating authentic and synthetic data alternatively from each previous system and the original parallel data to create an augmented dataset. Then, they trained a Transformer model on these new data, tokenized with HFT, to obtain the final system. Thus, the approach is based only on the original parallel corpus.

Huawei TSC (Li et al., 2022) Huawei Translation Services Center participated in all 6 supervised tracks. Their systems are build on deep Transformer models with a large filter size. First, they selected a base multilingual model with German-Czech (DE-CS) and German-Polish (DE-PL) parallel data for all of the 6 tracks. They then utilized regularized dropout (R-Drop), back translation, fine-tuning and ensemble multilingual models to improve on the best individual system performance. For the unsupervised task submission, they applied their pre-trained multilingual system with zero-shot.

PICT	DE (53.3k)	–	BPE	Fairseq Facebook's XLM

Table 8: Overview of methods and data.

PICT NLP (Vyawahare et al., 2022) They implemented the XLM's Masked Language Model (MLM) for unsupervised learning. They trained it only using the monolingual data provided by the organizers and the OPUS project. Finally, they also applied XLM preprocessing to the data before training.

For supervised learning, they trained language models such as LSTM and attention based transformer models with the help of the Fairseq library. They trained it using monolingual data provided by the organizers. They applied the inbuilt tokenization provided by Fairseq on the data.

5 System Results

Tables 2 to 7 list the results of the submitted systems in terms of BLEU and chrF2 for all systems, and additionally BERT scores for those translating into German. For the BERT scores, we list both BERT_F and BERT_F with idf weighting to give less weight to commonly occuring words. The ordering of the systems is consistent across all metrics.

The supervised systems obtain higher results than the unsupervised systems. The language pair DSB ↔ HSB obtained comparatively high scores for both supervised and unsupervised translation which is very probably due to the high similarity between the two languages.

Overall, we see no winner across all tasks: HuaweiTSC has the best scores across all supervised translation tasks, followed by MUNI-NLP for the DE-to/from-DSB and DSB-to/from-HSB translations. These two language pairs only have comparably small parallel data sets which are, notably, the sole basis of MUNI-NLP's submissions.

For the unsupervised translation (where MUNI-NLP did not participate), AIC has the strongest results with the exception of DSB-to/from-DE, where HuaweiTSC is leading.

6 Conclusion

In the WMT 2022 Shared Task on Unsupervised and Very Low Resource MT, we provided the participants with resources for all possible translation directions for the three languages Upper Sorbian, Lower Sorbian and German, of which Upper Sorbian ↔ Lower Sorbian is a new language pair in comparison to last year's shared task.

The participating teams submitted strong systems relying on a wide range of methods. Using modeling techniques such as pre-training on parallel data of related languages is important, as is the creation of synthetic data for which we saw the application of different methods. However we also saw that careful modeling on a small data set only can lead to good results.

We hope that this Shared Task will continue to increase the interest in research on methods for under-resourced languages, both for supervised and unsupervised approaches.

Abstract

In this paper, we present an overview of the WMT 2022 shared task on code-mixed machine translation (MixMT). In this shared task, we hosted two code-mixed machine translation subtasks in the following settings: (i) monolingual to code-mixed translation and (ii) code-mixed to monolingual translation. In both the subtasks, we received registration and participation from teams across the globe showing an interest and need to immediately address the challenges with machine translation involving code-mixed and low-resource languages.

1 Introduction

Code-mixing (or code-switching) is an interesting manifestation of multilingualism in communities across the globe. Lately, we observe an uptick in the interest and efforts of the computational linguistic community to solve a multitude of challenges with code-mixed languages. Several interesting resources and computational models have been proposed for problems such as language identification (Barman et al., 2014; Thara and Poornachandran, 2021), text generation (Gupta et al., 2020; Rizvi et al., 2021), and sentiment analysis (Chakravarthi et al., 2020; Patwa et al., 2020).

Machine translation which is an active area of research and development for monolingual languages is at the outset for code-mixed languages (Chen et al., 2022). In this shared task, we aim to explore the machine translation task involving a popular code-mixed language i.e., Hinglish (code-mixing of Hindi and English). Through both subtasks, we aim to address the challenges in building a real-world multilingual translation system involving code-mixed language as the source/target.

Similar to the recent events on code-mixed languages (Chen et al., 2022; Srivastava and Singh, 2021b; Patwa et al., 2020), the MixMT shared task has received participation and engagement with teams from across the globe. In total, we received registration from 38 teams. Throughout the competition, seven teams actively participated and submitted their system for the development phase, test phase, and human evaluation phase.

2 MixMT: Code-mixed Machine Translation

2.1 The two subtasks

In the MixMT shared task, we hosted two subtasks involving a code-mixed language i.e. Hinglish. A brief description of both subtasks is given below:

1. **Monolingual to code-mixed machine translation (M2CM)**: In this subtask, Hindi and English are the two source languages and the target language is Hinglish. The source Hindi and English sentences are translations of each other. The Hindi language sentences are written in the Devanagari script whereas the target Hinglish language text is written in the Roman script.
2. **Code-mixed to monolingual machine translation (CM2M)**: In this subtask, Hinglish is the source language and the target language is English. Both the English and Hinglish text are written in Roman script.

2.2 Dataset

Training datasets: We provide the following training datasets for both subtasks:

1. **M2CM**: For this subtask, HinGE (Srivastava and Singh, 2021a) is the primary training dataset. It contains parallel English-Hindi sentences along with multiple human-generated Hinglish sentences. For each data instance, it also contains two synthetically generated Hinglish sentences. The dataset was also used as part of the HinglishEval shared task (Srivastava and Singh, 2021b). We provide the entire HinglishEval data of $\approx$ 2k samples (train, validation, and test set together) as part of the training data for the MixMT shared task.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 806 - 811
December 7-8, 2022 ©2022 Association for Computational Linguistics

2. **CM2M**: For this subtask, PHINC (Srivastava and Singh, 2020) is the primary training dataset. It contains 13,738 parallel sentences in the Hinglish and English languages.

Evaluation datasets: To evaluate both the subtasks, we have created an in-house hidden evaluation dataset. For both subtasks, the validation dataset contains 500 samples and the test dataset has 1500 samples. The evaluation dataset is available here: `bit.ly/3UZLdFm`.

2.3 Baseline system and evaluation

We use Google Translate as a baseline for both subtasks. For *M2CM* subtask, we translate Hindi sentences (in Devanagari script) into English and evaluate them against the reference Hinglish sentences. For *CM2M* subtask, we translate the Hinglish sentences into English by setting the language of the Hinglish text as Hindi.

Evaluation: We use two evaluation metrics for both the subtasks: ROUGE-L (F1-score) and Word Error Rate (WER). Also, we perform a human-based qualitative evaluation of both subtasks. Table 1 shows the policy of the human-based evaluation of both subtasks.

2.4 Constrained system

We distinguish between the constrained and unconstrained systems based on the following criteria:

1. The system using an external dataset (apart from HinGE and PHINC datasets) will be considered unconstrained.
2. We allow public pre-trained models in a constrained system given that it is accessible to all the teams.

3 Submissions

We received the submissions from seven teams (listed alphabetically):

1. **CNLP-NITS-PP** (Laskar et al., 2022): They leverage the external parallel corpus (Samanantar (Ramesh et al., 2022)) to train their translation model which is built using OpenNMT-py framework (Klein et al., 2017) with the default setting. To generate the synthetic dataset, they transliterate and align the words in parallel sentences. Finally, they augment the provided dataset with the synthetic dataset to train their model.
2. **Domain Curricula for Code-switched MT (DC)** (Raheem and Elrashid, 2022): They experiment with different combinations of pre-training fine-tuning setups. They leverage the synthetic code-mixed dataset generated using the IIT-B parallel corpus (Kunchukuttan et al., 2018) and matrix language theory (Myers-Scotton). Further, the mixed data pretraining with synthetic and task-specific data shows the best result on the evaluation dataset. To build the translation model, they use transformers (Vaswani et al., 2017) and fairseq toolkit (Ott et al., 2019).
3. **Gui** (Gahoi et al., 2022): They leverage the multilingual pre-trained models to build their translation system. For *M2CM* task, they fine-tune multilingual-BART (Liu et al., 2020) on the task-specific data with reduced vocabulary. They reduce the vocabulary using the tokens present in the task dataset, IIT-B parallel corpus (Kunchukuttan et al., 2018), and the Dakshina dataset (Roark et al., 2020). They also perform the post-processing on the output generated from the fine-tuned model. For *CM2M* task, they finetune Salesken.AI's pre-trained model provided on Huggingface Transformers which is a finetuned Helsinki's OPUS-MT model on AI4Bharat's Samanantar dataset (Ramesh et al., 2022).
4. **MUCS** (Hegde and Shashirekha, 2022): Their translation model for both the task is built around transliteration (Bhat et al., 2015) and fine-tuning the IndicTrans pre-trained model (Ramesh et al., 2022). They generate synthetic parallel data using the Samanantar corpus (Ramesh et al., 2022). They further fine-tune the IndicTrans model jointly with the synthetic and task-specific datasets.
5. **NICT** (Dabre, 2022): They propose a synthetic code-mixed data based pre-training and a multi-way fine-tuning strategy. To generate the synthetic dataset, they leverage the Samanantar corpus (Ramesh et al., 2022), the transliteration toolkit[1], and a min-max based approach for word alignment (Zenkel et al., 2021). They pre-train a multilingual model on the synthetic Hinglish-English and English-synthetic Hinglish dataset. To perform the multi-way fine-tuning, they fine-tune the pre-trained model on Hinglish to English and English to Hinglish jointly using a small subset of the English side

[1] `https://github.com/anoopkunchukuttan/indic_nlp_library`

Rating	*M2CM*	*CM2M*
5	Best Generated Hinglish sentence	Correctly translated sentence conveying the exact same information as the source sentence
4	A Hinglish sentence with minimal grammtical mistakes but less likely in general parlance	A translated sentence with minimal grammatical mistakes
3	A Hinglish sentence that contains mainly grammtical mistakes	A translated sentence that contains mainly grammatical mistakes
2	A Hinglish sentence containing fairly large volumes of lexical and grammatical mistakes	A translated sentence containing fairly large volumes of lexical and grammatical mistakes
1	Worst Generated Sentence. They are monolingual either in Romanized Hindi or English	A translated sentence with poor semantics and irrelevant to the source sentence

Table 1: Human-based evaluation policy for *M2CM* and *CM2M* subtasks. The underlined phrase highlights the center of attention for the corresponding rating.

of the synthetic data and the entire parallel corpus (PHINC & HinGE) together. They use a denoising strategy similar to BART (Lewis et al., 2020) by randomly masking English words in the source sentence. They use the YANMTT toolkit (Dabre and Sumita, 2021) to their translation model.

6. **SIT-NMT** (Khan et al., 2022): They experiment with a variety of multilingual pre-trained models such as multilingual BART (Liu et al., 2020) and multilingual T5 (Xue et al., 2021). They fine-tune these pre-trained models on external datasets. For *M2CM task*, they use Kaggle Hi-En (Chokhra, 2020) and MUSE Hi-En dictionary (Lample et al., 2018). For *CM2M* task, they use CMU movie reviews data (Zhou et al., 2018) and CALCS'21 dataset (Chen et al., 2022). They also use selected WMT'14 News Hi-En sentences (Bojar et al., 2014) and the MTNT Fr-En and Ja-En data (Michel and Neubig, 2018). In addition, they also increase the size of the dataset by back-translating samples of the English side of Tatoeba Spanish dataset to the English (Project, 2022) and Sentiment140 dataset (Go et al., 2009) into Hinglish using Google translate. Further, to enhance the model's performance, they perform the validation tuning on the task-specific validation dataset and use a multi-run ensemble (Koehn, 2020) to combine multiple model's best checkpoints.
7. **UEDIN** (Kirefu et al., 2022): Their submission focuses on data generation using back-translation from monolingual resources. For *M2CM* subtask, they explore the impact of constrained and unconstrained decoding strategies. They use the Samanantar corpus (Ramesh et al., 2022) as an external resource for back-translation. For *CM2M* subtask, they explore several pretraining techniques, ranging from simple initialization from existing machine translation models to aligned augmentation (Pan et al., 2021) which is a denoising-based pretraining technique.

4 Results and Analysis

In this section, we present the results from automatic and human-based evaluation of the submissions from the seven teams. As discussed in Section 2.3, we use ROUGE-L F1 score (R-L) and Word Error Rate (WER) for automatic evaluation. R-L score can vary from 0 to 1 whereas WER can take a value greater than or equal to 0. A high R-L score and a low WER score are preferred.

Table 2 shows the results of the automatic evaluation for both subtasks. For *M2CM* subtask, the Gui team's submission achieves best R-L score whereas the team UEDIN and SIT-NMT achieve the second and third best R-L scores respectively. SIT-NMT's submission outperforms the other systems and scores the lowest WER for this subtask. For *CM2M* subtask, SIT-NMT is the best-performing team followed by UEDIN and MUCS on both metrics.

Table 3 shows the human-based evaluation of the submissions from different teams. The evaluation policy is given in Table 1. Following the evaluation policy, we evaluate the output of 20 samples for each subtask from each team. SIT-NMT ranks first

Team	*M2CM*		*CM2M*	
	R-L	WER	R-L	WER
Baseline	0.280	0.926	0.250	1.021
CNLP	0.238	0.926	0.330	0.88
DC	0.033	1.560	0.061	1.694
Gui	0.616	0.633	0.414	0.808
MUCS	0.358	0.760	0.550	0.647
NICT	0.462	0.792	0.528	0.715
SIT-NMT	0.57	0.547	0.629	0.607
UEDIN	0.579	0.561	0.621	0.624

Table 2: Evaluation results on the test set. We color code the best, second best, and third best team on a given metric for a subtask.

on both subtasks followed by UEDIN. Gui stood at the third position for *M2CM* task whereas MUCS is ranked third for *CM2M* subtask. Interestingly, MUCS and NICT get a consistent one score showing poor quality output consisting of lexical and grammatical mistakes. It further highlights the inefficacy of evaluation metrics for code-mixed natural language generation tasks as pointed out in several previous works (Garg et al., 2021; Srivastava and Singh, 2022).

Team	*M2CM*	*CM2M*
CNLP	2.1 ± 0.64	1.35 ± 0.74
DC	1.75 ± 0.71	1.55 ± 1.09
Gui	3.75 ± 1.20	1.8 ± 1.1
MUCS	1 ± 0	2.9 ± 1.51
NICT	1 ± 0	2.85 ± 1.30
SIT-NMT	3.85 ± 1.38	4.1 ± 1.07
UEDIN	3.85 + 1.53	3.75 + 1.16

Table 3: Human-based evaluation of submitted systems on the test set. We color code the best, second best, and third best team for a subtask.

Further, we analyze the submissions based on the dataset and the models used in the experiment. In Section 2.4, we have highlighted the two criteria for the submission to be considered as constrained. In Table 4, we summarize the submissions based on these two criteria.

We observe that almost all the teams have used at least one external dataset for both subtasks with Gui's submission for *CM2M* subtask being the only exception. We attribute this behavior to the fact we designed both subtasks in a low-resource setting. The submissions by four teams (i.e., CNLP, DC, NICT, and UEDIN) are completely unconstrained for both subtasks as they are using an external dataset and training their own system from scratch.

5 Discussion

In this paper, we present the findings from the MixMT shared task. We hosted two subtasks involving a code-mixed language i.e. Hinglish. Given the low-resource nature of the code-mixed languages (and the subtasks), the majority of the submissions rely on data augmentation either synthetically or from other external sources. The lack of dedicated pre-trained models for code-mixed languages pushed the teams to explore the available alternatives along with bold attempts to train the models from scratch. We posit several open challenges with code-mixed machine translation such as creating large-scale parallel data, efficient data augmentation strategies, and robust evaluation measures. The insights and findings from this task will be useful to future works on machine translation involving code-mixed and low-resource languages. They will broaden the horizon for works on multilingual machine translation.

Abstract

Recent years have witnessed rapid advancements in machine translation, but the state-of-the-art machine translation system still can not satisfy the high requirements in some rigorous translation scenarios. Computer-aided translation (CAT) provides a promising solution to yield a high-quality translation with a guarantee. Unfortunately, due to the lack of popular benchmarks, the research on CAT is not well developed compared with machine translation. In this year, we hold a new shared task called Word-level AutoCompletion (WLAC) for CAT in WMT. Specifically, we introduce some resources to train a WLAC model, and particularly we collect data from CAT systems as a part of test data for this shared task. In addition, we employ both automatic and human evaluations to measure the performance of the submitted systems, and our final evaluation results reveal some findings for the WLAC task.

1 Introduction

In past decades, the machine translation community has witnessed a significant evolution from statistical machine translation (Koehn et al., 2003; Chiang, 2005; Koehn, 2009b) to neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017). NMT has achieved a rapid and tremendous advancement in translation performance (Barrault et al., 2019). Despite its success in many real-world applications, its translation quality still can not satisfy the high requirements in some scenarios. In such rigorous scenarios, one promising approach is to leverage machines to assist human translation, such as Computer-aided Translation (CAT) (Bowker, 2002; Koehn, 2009a; Foster et al., 1997; Langlais et al., 2000; Barrachina et al., 2009; Alabau et al., 2014; Knowles and Koehn, 2016; Santy et al., 2019).

However, the development in CAT is much slower than in machine translation. For example, there are hundreds of research papers on machine translation in natural language processing conferences each year, whereas only a few papers on CAT are published. One of the main reasons is that there are few popular benchmarks or shared tasks for CAT research, which enable researchers to make continuous progress in this area. Consequently, in WMT this year, we hold a new shared task, Word-level AutoCompletion (WLAC), to facilitate the research in CAT. Generally, WLAC aims to autocomplete a word when a human translator types a sequence of characters (Huang et al., 2015; Li et al., 2021). As a basic functionality in many CAT systems, WLAC is used to accelerate the editing process for human translators and it plays an important role in CAT.

In this paper, we describe the overview for the shared task of WLAC in WMT 2022, such as task description, datasets, participants and their evaluations. The shared task involves two language pairs, including Chinese-English and German-English and it contains four subtasks corresponding to all four directional pairs. For data preparation, since it is too costly to collect realistic data with a considerable scale to train WLAC models, we follow the standard practice to construct the training data from a bilingual corpus by simulation. Moreover, to make the testing stage resemble the realistic scenario in CAT, we collect some data from two CAT systems as a part of test data. In this shared task, we receive 27 submissions in total for all subtasks from five participants which are quickly summarized in this paper. To evaluate the submissions, we particularly conduct human evaluation in addition to automatic evaluation. After evaluation, we finally obtain some findings from the submission results, which we hope may inspire future advancements for the WLAC task.

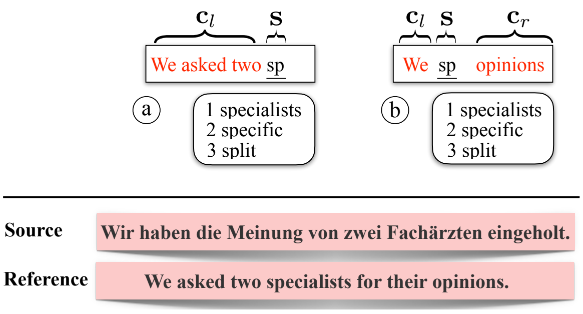

Figure 1: Illustration of WLAC task. The translation context $\boldsymbol{c}$ for a source sentence $\boldsymbol{x}$ includes the left context $\boldsymbol{c}_l$ and right context $\boldsymbol{c}_r$, underlined text "sp" is the human typed characters $\boldsymbol{s}$ and the words in the rounded rectangles are word-level autocompletion candidates.

2 Task Description and Data Preparation

2.1 Task Description

Suppose $\boldsymbol{x}$ is a source sequence, $\boldsymbol{s}$ is a sequence of human typed characters and $\boldsymbol{c} = (\boldsymbol{c}_l, \boldsymbol{c}_r)$ is a translation context. The translation pieces $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ are on the left and right hand sides of $\boldsymbol{s}$, respectively. Formally, given the tuple $(\boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s})$, the WLAC task aims to predict the target word w with $\boldsymbol{s}$ as its prefix, which is the most appropriate to be placed between $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ (Huang et al., 2015; Li et al., 2021).

To make the task more general in real-world scenarios, WLAC task assumes that the left context $\boldsymbol{c}_l$ and right context $\boldsymbol{c}_r$ can be empty, which leads to the following four types of context:

- Zero-context: both $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ are empty;
- Suffix: $\boldsymbol{c}_l$ is empty;
- Prefix: $\boldsymbol{c}_r$ is empty;
- Bi-context: neither $\boldsymbol{c}_l$ nor $\boldsymbol{c}_r$ is empty.

Figure 1 ⓐ and ⓑ show two examples about the WLAC task. According to the above criterion, Figure 1 ⓐ belongs to Prefix type and Figure 1 ⓑ belongs to Bi-context type.

2.2 Data Preparation

The WLAC task in WMT2022 involves following two language pairs: English⇔Chinese and English⇔German. Each language pair corresponds to two directional subtasks, leading to four subtasks.

Training Data In fact, it is too costly to manually annotate the training dataset consisting of tuples $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$ for WALC task. We alternatively follow Li et al. (2021) to construct the simulated training data for WLAC from existing bilingual data.[1] The key idea of such simulation is that it randomly samples a target word w and context $\boldsymbol{c}$ from the reference translation $\boldsymbol{y}$ of $\boldsymbol{x}$, a human typed sequence $\boldsymbol{c}$ for the target word w to obtain an example, e.g., a tuple of $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$.

	En-De	En-Zh
Sentences	4,465,840	15,886,041
Words	120M/114M	441M/395M

Table 1: The statistics of English-German and English-Chinese bilingual datasets for training.

For training on English-German language pair, we use the WMT14 En-De training dataset preprocessed by Stanford NLP Group[2], which consists of about 4.5M sentence pairs. For training on English-Chinese language pair, we take the "UN Parallel Corpus V1.0" dataset[3] from WMT17 consisting of 15M sentence pairs. We use Moses scripts[4] to tokenize English and German sentences and jieba[5] to segment Chinese words for each sentence. The detailed statistics of bilingual datasets are shown in Table 1.

Note that in this shared task, participants must use the above bilingual data and it is illegal to any other bilingual data beyond. However, to achieve better performance, any monolingual data is allowed as well as the pre-trained language models such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019).

Test Data To ensure authenticity and reliability, the test data for WLAC is not from existing open-source bilingual data. We create the test data by ourselves: the test datasets are obtained in two different ways, leading to two types of test data. One type (**Type I**) is the simulation on bilingual data similar to the creation of training data and the other type (**Type II**) is from CAT translation systems.

For the Type I test data, we first create a new bilingual dataset and then obtain the simulated tuples $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$ from the bilingual dataset. Specifically, to ensure that the ground-truth word w is not

(a) The proportion on Zh⇒En **(b)** The proportion on En⇒Zh

Figure 2: The proportion of the bins of w typed by human translators from CAT systems according to word frequency in bilingual corpus on German-English language pair. Bin 1 and Bin 10 respectively denote the most infrequent word bin and the most frequent bin.

exposed to the training data, we first crawl bilingual news from Internet websites in the latest 3 years. After crawling the raw bilingual data, we employ professional translators to check and screen the low quality bilingual data to obtain high-quality bilingual sentences. Finally, we follow the simulation way to obtain the training tuples $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$ based on the crawled bilingual data described above.

The Type II test data is collected from two CAT systems LILT[6] and TranSmart[7] (Huang et al., 2021). Specifically, given a source sentence $\boldsymbol{x}$, a human translator works on a CAT system to generate a translation $\boldsymbol{y}$. In the log file from the CAT system, only the information about $w \in \boldsymbol{y}$ typed by human is stored, while other dynamic information such as typed characters and context for each w is not available. Therefore, we create both $\boldsymbol{c}$ and $\boldsymbol{s}$ from $\boldsymbol{y}$ for each w by simulation as before. In other words, for each example $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$, both $\boldsymbol{c}$ and $\boldsymbol{s}$ are simulated but w is realistic. Note that each sentence from the Type II data is also not included in the training data.

For En⇒De task, the entire test data is the type II from the CAT system LILT. For Zh⇒En, En⇒Zh and De⇒En tasks, the test data is the combination of both types, i.e., some test data is Type I from the simulation over bilingual data and the other test data is Type II from the CAT system TranSmart.

To pre-process the test data (e.g., word tokenization), we adopt the same pre-processing way as used in training data. Table 2 summarizes the detailed statistics in terms of sentences and words for the test data, and Table 3 reports the number of ex-

amples for four different context types in test data. Note that each source sentence $\boldsymbol{x}$ may correspond to multiple examples $\langle \boldsymbol{x}, \boldsymbol{c}, \boldsymbol{s}, w \rangle$ and thus, the total number of sentences in Table 2 is not the same as the total number of examples in Table 3.

Furthermore, one may be curious about the characteristics of the words typed by human translators. We understand the human typed words from the perspective of word frequency. We first group the target vocabulary into ten bins with equal size according to word frequency computed in the bilingual corpus, we collect all typed words w together and then assign a bin for each word, and finally we calculate the proportion of each bin. The statistics are shown in Table 2 and Table 3, where bin 1 denotes the most infrequent words while bin 10 denotes the most frequent words. From these tables, it is observed that human translators usually type infrequent words. This observation is reasonable because it is easy for machine translation systems to make a correct translation decision on a frequent word.

3 Evaluation Metric

We use both automatic evaluation and human evaluation to measure all submitted systems.

Automatic Evaluation To measure the performance of the submitted systems, we choose accuracy as the automatic evaluation metric (Li et al., 2021) as follows :

$$\text{ACC} = \frac{N_{match}}{N_{all}} \tag{1}$$

where N_{match} is the number of correct predicted words and N_{all} is the number of **all** test examples.

Although automatic evaluation is convenient, it still has some limitations because there may be multiple ground-truth words w (i.e., ground truth is a word set) which suffice to the constraint of $\boldsymbol{s}$ and are compatible with $\langle \boldsymbol{x}, \boldsymbol{c} \rangle$, especially for a short $\boldsymbol{c}$ and $\boldsymbol{s}$. For instance, when $\boldsymbol{c}$ and $\boldsymbol{s}$ are empty, any translation of a source word in $\boldsymbol{x}$ may be a ground-truth word if it suffices to the constraint of $\boldsymbol{s}$. Therefore, we additionally conduct human evaluation for more faithful evaluation on the submissions.

Human Evaluation Human evaluation is appealing, but it is too costly to evaluate all testing examples. Instead, we conduct human evaluation on a small subset of test data for efficiency. Specifically, for all four subtasks, we randomly sample **400** test examples derived from the Type II part of the test data as the human evaluation dataset. After participants submit their systems, we gather their predicted words to constitute a prediction set for each test example. Then we hire professional translators to annotate the correct ones in the prediction set. Finally, we use the manually annotated ground-truth word set to re-evaluate submitted systems and the human score is defined by the percentage of predicted words annotated as correct words by human. Since more than one target word can be annotated as the correct word, the human evaluation score is higher than the automatic score in general.

4 Submitted Systems and Results

In this year, there are five teams participating in this shared task and we receive 27 submissions from them. In this section, first, we quickly describe the participants and their submitted systems, then we present their evaluation results in terms of both automatic and human evaluations, and finally, we shed light on some findings according to evaluation results.

4.1 Participants and Submitted Systems

HW-TSC (Yang et al., 2022b) The Huawei Translation Services Center (HW-TSC) participates in Zh⇒En, De⇒En and En⇒De language directions. They model the WLAC task as a structured prediction (or generation) task, which iteratively generates a subword to compose the prediction word. Specifically, they first train a vanilla Transformer on machine translation task as a baseline. Then they fine-tune the baseline with WLAC data and BERT-style MLM data to get the final model.

Systems	Fullset	Subset	
	Acc. (Rank)	Human. (Rank)	Acc. (Rank)
HW-TSC	59.40 (#1)	91.25 (#1)	69.25 (#1)
THU IIGroup-1	54.05 (#2)	85.00 (#6)	59.75 (#6)
THU IIGroup-2	51.11 (#3)	83.75 (#7)	57.25 (#7)
DCU-NCI-4	50.41 (#4)	86.75 (#3)	63.25 (#2)
DCU-NCI-3	50.26 (#5)	86.75 (#3)	62.25 (#3)
DCU-NCI-2	49.35 (#6)	86.00 (#5)	61.75 (#5)
DCU-NCI-1	49.06 (#7)	87.00 (#2)	62.00 (#4)

Table 4: Official results of WLAC task for Zh⇒En. Acc. and Human. represent automatic and human evaluations, respectively. Rank denotes the ranking according to the corresponding metric.

Systems	Fullset	Subset	
	Acc. (Rank)	Human. (Rank)	Acc. (Rank)
THU IIGroup-1	53.98 (#1)	83.25 (#1)	54.50 (#1)
THU IIGroup-2	48.90 (#2)	77.50 (#2)	48.75 (#2)
DCU-NCI-2	31.94 (#3)	57.75 (#3)	37.75 (#4)
DCU-NCI-1	31.94 (#4)	57.25 (#4)	38.00 (#3)

Table 5: Official results of WLAC task for En⇒Zh. Acc. and Human. represent automatic and human evaluations, respectively. Rank denotes the ranking according to the corresponding metric.

It is worth noting that they use a character embedding method to encode the information of a human typed sequence to the model. Moreover, they adopt some basic strategies to improve the performance, including back translation, averaging and ensemble techniques.

PRHLT (Ángel Navarro et al., 2022) The team of PRHLT submits their systems for De⇒En and En⇒De subtasks. They first cast the WLAC task as a segment-based IMT task. More concretely, they consider the translation context as the sequence of segments validated by the user in IMT and the sequence of human typed characters as partially-typed word correction. They experiment with both RNN architecture and Transformer architecture.

DCU-NCI (Moslem et al., 2022) DCU-NCI proposes to address the WLAC task with the help of pre-trained NMT models and available libraries, which is a new way to solve the WLAC task. Their systems do not need any additional training to address the WLAC task.Specifically, they use OPUS pre-trained models[8] and employ CTranslate2 [9] as an inference engine. During the decoding stage, they find that random sampling restricted with the best 10 candidates perform better than beam search. Furthermore, they also try to adopt different sampling temperatures (ST) to change the randomness of the generation. We denote the system trained with ST=1.0 as DCU-NCI-1, the system with ST=1.3 as DCU-NCI-2, the system with ST=1.3 and detokenization as DCU-NCI-3 and the system trained with ST=1.0 and detokenization as DCU-NCI-4.

Lingua Custodia (Ailem et al., 2022) The team of Lingua Custodia submits systems for De⇒En and En⇒De tracks. They also treat the WLAC task as a structured prediction task and adopt the Transformer architecture for generation. Specifically, they use a Transformer Encoder to encode the source sentence, translation context and human typed characters, and a Transformer Decoder to generate a sequence of subwords to constitute a target word step by step. In addition, they propose several data-cleaning strategies to pre-process the bilingual translation data. We denote the system trained with the initial corpus as Lingua Custodia-1 and the system trained with the cleaned corpus as Lingua Custodia-2.

THU IIGroup (Yang et al., 2022a) THU IIGroup participates in Zh⇒En, En⇒Zh, De⇒En and En⇒De directions. They propose a generator-reranker framework to tackle the WLAC task. Specifically, they adopt the baseline model based on Transformer as a generator to yield a set of candidate words. Moreover, they additionally train a reranking model to rerank the candidate words to get the final prediction. We denote the generator as THU IIGroup-1 and the reranker as THU IIGroup-2.

Summary on submitted systems All submitted systems in this year choose the powerful Transformer architecture by stacking multiple layers of attention as the backbone for the WLAC task. To tackle the constraint of the human typed character sequence, some submitted systems consider it as a hard constraint while others (HW-TSC and Lingua Custodia) considering it as a soft constraint: they differ in that the model architecture in the former is aware of the constraints but the later matters. In addition, most systems formalize the WLAC task as a classification task where the target word w is actually a label, but one system (HW-TSC) treats WLAC as a structured prediction task: the target w is decomposed into a sequence of BPE units and it is beneficial to predict the out-of-vocabulary words.

4.2 Evaluation Results

Since human evaluation is only conducted on the partial test dataset consisting of 400 examples and automatic evaluation can be evaluated on both the full and partial test datasets, we evaluate all the submitted systems on two different types of test data, i.e., full test data set and partial test data set as follows. All of their results on Zh⇒En, En⇒Zh, De⇒En and En⇒De are listed in Table 4,5,6 and 7.

Results on Full Test Set From the four tables, it can be shown that the systems of HW-TSC shows impressive performance and achieve the best for Zh⇒En, De⇒En and En⇒De, and THU IIGroup yields the best performance for En⇒Zh. As we can see, there are some gaps in performance among different systems, which means there is a significant opportunity for growth in the WLAC task.

Results on Partial Test Set As described in Section 3, it is not surprising that human evaluation scores are much higher than automatic evaluation scores. In addition, it is observed that on the partial test set, the human evaluation results are almost in line with the automatic evaluation result although there indeed is a slight inconsistency. This fact demonstrates that automatic evaluation metric can act as a good alternative for evaluation. Moreover, it is interesting that, in terms of automatic evaluation, the rankings between the full and partial test datasets are clearly different on Zh⇒En, although they are mostly consistent on other tasks. This observation indicates that a small test dataset may lead to a biased conclusion.

4.3 Discussion

In this section, we shed light on some key findings among all the submitted systems which we hope will push forward the development of the WLAC task in the future.

First, it would be preferable to treat the WLAC task as a structured prediction task rather than a classification task according to the prediction accuracy. One advantage of the structured prediction perspective is that it can decompose the predicted word into a sequence of tokens at the subword level to tackle out-of-vocabulary words. This is appealing specially because most of the typed words by human translators are low frequent words as observed in our analysis. However, it is noteworthy that a structured predition model requires more computing time than a classification model during the inference stage.

Second, WLAC task may benefit from NMT based pre-training. It is noticed that one participant employs such a pre-training strategy: it first trains a standard NMT model on the bilingual dataset and then it fine-tunes the model with the WLAC data to obtain a WLAC model. It is reasonable since in NMT task, every token in the target-side serves as a label, while in WLAC task, only the target token serves as a label. The former can facilitate the training procedure and provide a good weight initialization for WLAC tailored model.

Third, leveraging monolingual data is a common practice to improve the performance in many NLP tasks, including machine translation. For example, a pre-trained model trained on monolingual data such as XLM (Lample and Conneau, 2019) and MASS (Song et al., 2019) are successful to improve translation quality, and back translation (Sennrich et al., 2015; Edunov et al., 2018) is also an effective strategy by construction synthetic bilingual data from target monolingual data. In WLAC task, one participant tries to enhance the WLAC model by using back translation similar to NMT and it is promising to design new ways customized for WLAC.

5 Conclusion

Word-level AutoCompletion is a basic functionality in computer-aided translation systems to facilitate the editing efficiency for translators. In WMT this year, the Word-level AutoCompletion shared task is introduced and it covers two language pairs including four directional subtasks. We provide high-quality test datasets and human evaluation to evaluate different systems fairly. On all subtasks we receive 27 submissions from five participants which address the WLAC task from different perspectives. Automatic and human evaluations on these submissions reveal some key findings which may provide valuable insights for future research on this task. Finally, we hope that WLAC task will attract more researchers to participate in the exploration of computer-aided translation.

Acknowledgements

We would like to thank Huayang Li for valuable discussions and Cheng Yang for data pre-processing on the shared task, and especially appreciate the annotators for their creating test data and manual evaluation on the submitted systems. In addition, we thank the participants for their contributions on this shared task.

Abstract

We report the result of the first edition of the WMT shared task on Translation Suggestion (TS). The task aims to provide alternatives for specific words or phrases given the entire documents generated by machine translation (MT). It consists two sub-tasks, namely, the naive translation suggestion and translation suggestion with hints. The main difference is that some hints are provided in sub-task two, therefore, it is easier for the model to generate more accurate suggestions. For sub-task one, we provide the corpus for the language pairs English-German and English-Chinese. And only English-Chinese corpus is provided for the sub-task two.

We received 92 submissions from 5 participating teams in sub-task one and 6 submissions for the sub-task 2, most of them covering all of the translation directions. We used the automatic metric BLEU for evaluating the performance of each submission.

1 Introduction

Computer-aided translation (CAT) (Barrachina et al., 2009; Green et al., 2014; Knowles and Koehn, 2016; Santy et al., 2019) has attained more and more attention for its promising ability in combining the high efficiency of machine translation (MT) (Cho et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) and high accuracy of human translation (HT). A typical way for CAT tools to combine MT and HT is PE (Green et al., 2013; Zouhar et al., 2021), where the human translators are asked to provide alternatives for the incorrect word spans in the results generated by MT. To further reduce the post-editing time, researchers propose to apply TS into PE, where TS provides the sub-segment suggestions for the annotated incorrect word spans in the results of MT, and their extensive experiments show that TS can substantially reduce translators' cognitive loads and the post-editing time (Wang et al., 2020; Lee et al., 2021).

As there is no explicit and formal definition for TS, we observe that some previous works similar or related to TS have been proposed (Alabau et al., 2014; Santy et al., 2019; Wang et al., 2020; Lee et al., 2021). However, there are two main pitfalls for these works in this line. First, most conventional works only focus on the overall performance of PE but ignore the exact performance of TS. This is mainly because the golden corpus for TS is relatively hard to collect. As TS is an important sub-module in PE, paying more attention to the exact performance of TS can boost the performance and interpretability of PE. Second, almost all of the previous works conduct experiments on their in-house datasets or the noisy datasets built automatically, which makes their experiments hard to be followed and compared. Additionally, experimental results on the noisy datasets may not truly reflect the model's ability on generating the right predictions, making the research deviate from the correct direction. Therefore, the community is in dire need of a benchmark for TS to enhance the research in this area. To address the limitations mentioned above and spur the research in TS, we make our efforts to construct a high-quality benchmark dataset with human annotation, named *WeTS*,[1] which covers four different translation directions.

The main motivation of this shared task is two-fold. The first goal is to analyze the challenges in the area of TS, which can provide some new directions for the further researches and applications in this area. Secondly, we want to make the researchers notice the gaps between the golden and automatically generated synthetic corpus. And we want to see the performance of different techniques on the golden corpus. As the source and translation sentence are both the inputs of TS, it is interesting to see how the interactions between the source and

[1] *WeTS*: We Establish a benchmark for Translation Suggestion

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 821 - 829
December 7-8, 2022 ©2022 Association for Computational Linguistics

translation sentences can improve the final suggestions.

In order to evaluate the quality of the participating systems, we use the automatic metric, BLEU (Papineni et al., 2002). Specifically, we adopt the widely used toolkit, sacrebleu (Post, 2018) to calculate the BLEU score for the top-1 suggestion against the reference sentences.[2] For Chinese, the BLEU score is calculated on teh character with the default tokenizer for Chinese. As for English, the BLEU score is calcualted on the case-sensitive words with the default tokenizer 13a.

Five teams participated in this first campaign of the Translation Suggestion shred task, most of them cover the four translation directions. We will describe each system which submits the technical paper in detail.

2 Task Description

This section describes the task definition in the first edition of TS shared task. We finely divide the task of TS into two sub-tasks, namely *vanilla TS* and *TS with hints*, according to whether the translators' hints are considered.

Vanilla TS. Given the source sentence $\boldsymbol{x} = (x_1, \ldots, x_s)$, the translation sentence $\boldsymbol{m} = (m_1, \ldots, m_t)$, the incorrect words or phrases $\boldsymbol{w} = \boldsymbol{m}_{i:j}$ where $1 \leq i \leq j \leq t$, and the correct alternative $\boldsymbol{y}$ for $\boldsymbol{w}$, the task of *vanilla TS* is optimized to maximize the conditional probability of $\boldsymbol{y}$ as follows:

$$P(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{m}^{-\boldsymbol{w}}, \theta) \tag{1}$$

where θ represents the model parameter, and $\boldsymbol{m}^{-\boldsymbol{w}}$ is the masked translation where the incorrect word span $\boldsymbol{w}$ is replaced with a placeholder. [3]

TS with Hints. In the sub-task *TS with hints*, the hints of translators are considered as some soft constraints for the model, and the model is expected to generate suggestions meeting these constraints. The format of the translator's hint is very flexible, which usually requires only a few types on the keyboard by the translator. For English and German, the hints can be the character sequence which includes the initials of words in the correct alternative. As for Chinese, the hints can be the character sequence which includes the initials of the phonetics of words in the correct alternative. In this setting, the model is optimized as:

$$P(\boldsymbol{y}|\boldsymbol{x}, \boldsymbol{m}^{-\boldsymbol{w}}, \boldsymbol{h}, \theta) \tag{2}$$

where $\boldsymbol{h}$ indicates the hints provided by translators.

Related tasks. Some similar techniques have been explored in CAT. Green et al. (2014) and Knowles and Koehn (2016) study the task of so-called translation prediction, which provides predictions of the next word (or phrase) given a prefix. Huang et al. (2015) and Santy et al. (2019) further consider the hints of the translator in the task of translation prediction. Compared to TS, the most significant difference is the strict assumption of the translation context, i.e., the prefix context, which severely impedes the use of their methods under the scenarios of PE. Lexically constrained decoding which completes a translation based on some unordered words, relaxes the constraints provided by human translators from prefixes to general forms (Hokamp and Liu, 2017; Post and Vilar, 2018; Kajiwara, 2019; Susanto et al., 2020). Although it does not need to re-train the model, its low efficiency makes it only applicable in scenarios where only a few constraints need to be applied. Recently, Li et al. (2021) study the problem of auto-completion with different context types. However, they only focus on the word-level auto-completion, and their experiments are also conducted on the automatically constructed datasets.

3 Data Description

This section introduces the proposed dataset *WeTS* used in the shred task, which is a golden corpus for four translation directions, including English-to-German, German-to-English, Chinese-to-English and English-to-Chinese.

Translation Direction	Train	Valid	Test
En⇒De	14,957	1000	1000
De⇒En	11,777	1000	1000
Zh⇒En	21,213	1000	1000
En⇒Zh	15,769	1000	1000

Table 1: The sizes for cases in train/valid/test sets. "En⇒De" refers to the direction of English-to-German, and "En⇒Zh" refers to English-to-Chinese.

[2] https://github.com/mjpost/sacrebleu

[3] $\boldsymbol{w}$ is null if i equals j, and the model will predict whether some words need to be inserted in position i.

Source Sentence	他们也许并不知道这是一个“假理财”骗局，但也察觉到了诸多可疑之 ta men ye xu bing bu zhi dao zhe shi yi ge jia li cai pian ju, dan ye cha jue dao le zhu duo ke yi zhi chu 处，然而最终还是按照张颖的指使进行了违法违规操作。 ran er zui zhong hai shi an zhao zhang ying de zhi shi jin xing le wei fa wei gui cao zuo
Translation	They may not know this is a "fake financial management" scam, but also aware of many suspicious, and ultimately conduct illegal operations according to Zhang Ying's instructions.
Suggestions	1. suspects 2. doubtful points 3. questionable points

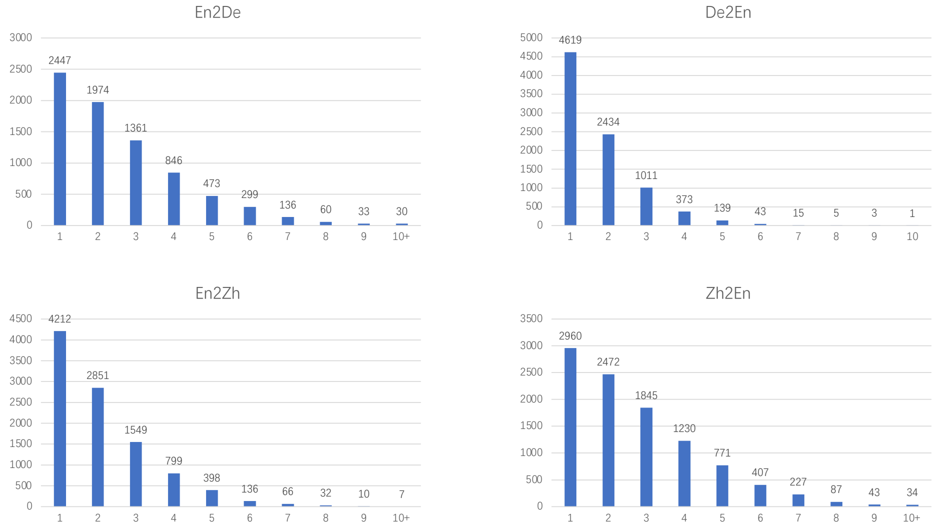

Figure 2: The number of incorrect span in each annotated example.

3.1 Annotation Guidelines

It is non-trivial for annotators to locate the incorrect word spans in the MT sentence. The main difficulty is that, the concept of “translation error" is ambiguous and each translator has his own understanding about translation errors. To easier the annotation workload and reduce the possibility of making errors, we group the translation errors on which we aim to focus into three macro categories:

- Under-translation or over-translation: While the problem of under-translation or over-translation has been alleviated with the popularity of Transformer, it is still one of the main mistakes in NMT and seriously destroys the readability of the translation.

- Semantic errors: For the semantic error, we mean that some source words are incorrectly translated according to the semantic context, such as the incorrect translations for entities, proper nouns, and ambiguous words. Another branch of semantic mistake is that the source words or phrases are only translated superficially and the semantics behind are not translated well.

- Grammatical or syntactic errors: Such errors usually appear in translations of long sentences, including the improper use of tenses, passive voice, syntactic structures, etc.

Another key rule for translators is that annotating the incorrect span as local as possible, as generating correct alternatives for long sequences is much harder than that of shorter sequences.

3.2 Data Construction

As the starting point, we collect the monolingual corpora for English and German from the raw Wikipedia dumps, and extract Chinese monolingual corpus from various online news publications. We first clean the monolingual corpora with a language detector to remove sentences belonging to

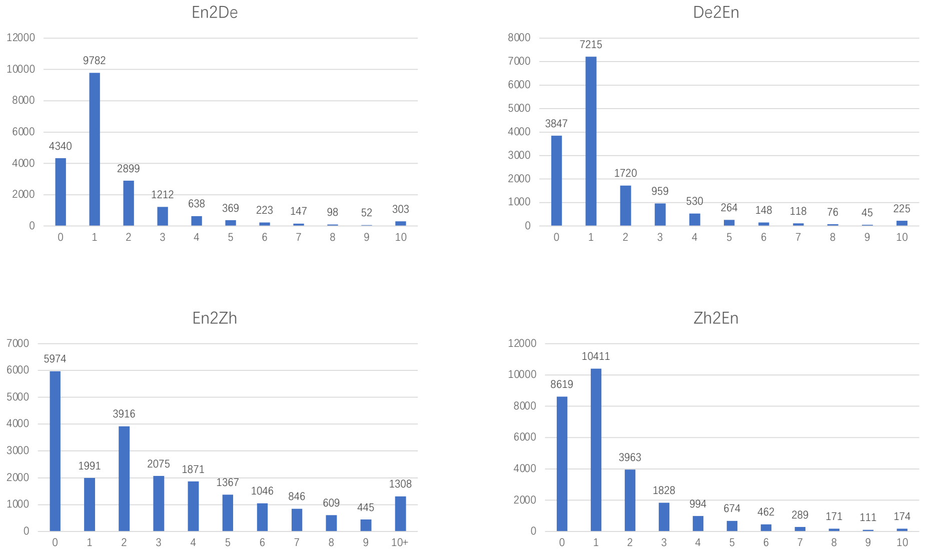

Figure 3: The length of the incorrect span.

other languages.[4] For all monolingual corpora, we remove sentences that are shorter than 20 words or longer than 80 words. In addition, sentences which exist in the available parallel corpora are also removed. Then, we get the translations by feeding the cleaned monolingual corpus into the corresponding fully-trained NMT model. The NMT models for English-German language pairs are trained on the parallel corpus of WMT14 English-German. For Chinese-English directions, the NMT models are trained with the combination between the WMT19 English-Chinese[5] and the same amount of in-house corpus. [6]

Finally, the translators are required to mark the incorrect word spans in the translation sentence and provide at least one alternative for each incorrect span, by using the annotation guidelines. The team is composed by eight annotators with high expertise in translation and each example has been assigned to three experts. There are two phases of agreement computations. In the first phase, an annotation is considered in agreement among the experts if and only if they capture the same incorrect word spans. If one annotation passes the first agreement computation, it will be assigned to other three experts in charge of selecting the right alternatives from the previous annotation. In the second phase of agreement computation, an annotation is considered in agreement among the experts if and only if they select the same right alternatives. With the two-phase agreement checking, we ensure the high quality of the annotated examples. For the annotated examples with multiple incorrect word spans, we can extract multiple examples which have the same source and translation sentences, but different incorrect word span and the corresponding suggestions. Finally the extracted examples are randomly shuffled and then split into the training, validation and test sets.[7] One training example for the translation direction of Chinese-to-English is presented in Figure 1 and the sizes for the train/valid/test sets in *WeTS* are collected in Table 1.

3.3 Detailed Statistics

The number of the incorrect span Each annotated example may contain multiple incorrect spans, we show the number of the incorrect span in each annotated example as Figure 2. We can see that most examples have only a few incorrect spans, and there are more than 70 percent examples containing less than 3 incorrect spans for each translation direction.

The length of the incorrect span Figure 3 represents the length distribution of the incorrect spans. We can find that most of the incorrect spans contain less than 3 words or Chinese characters. This is mainly because of our key rule for annotating the incorrect span as local as possible. Additionally, for all of the four translation directions, the

[4] `https://github.com/Mimino666/langdetect`

[5] `https://www.statmt.org/wmt19/translation-task.html`

[6] We have released the models and inference scripts utilized here to make our results easy reproduced.

[7] To keep the fairness of *WeTS*, we ensure the examples among the training, validation and test sets have different source and translation sentences.

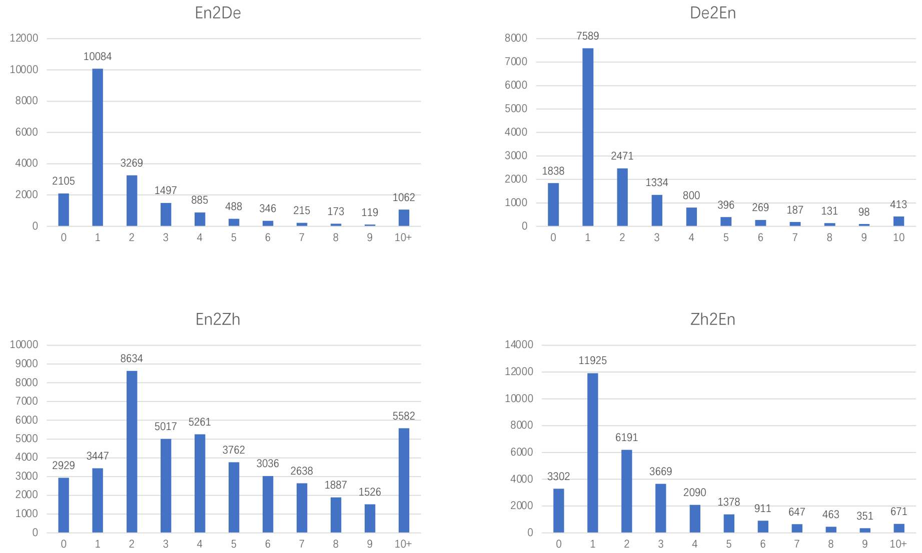

Figure 4: The length of the suggestion.

number of the incorrect spans with length 0 ranks top-2 among all the length buckets. This shows that under-translation is still a frequent error of the existing NMT models.

The length of the suggestions Figure 4 shows the length distribution of the suggestions. We can see that in English-to-German, German-to-English and Chinese-to-English, most of the suggestions contain only one word. For English-to-Chinese, most suggestions contain two Chinese characters. Additionally, we can also find that there are quite a few of suggestions with length zero in each translation direction. This shows that over-translation is a non-negligible problem for the existing NMT models.

4 Participants

Five participants submitted their systems to the subtask one of TS shared task. And two participants submitted their systems to the second sub-task. In sub-task one, 92 runs were submitted in total (each team is only allowed to submit less than 15 runs). Table 2 summarizes the participants and their affiliations.

4.1 Systems

Here we briefly describe each participant's systems as described by the authors and refer the reader to the participant's submission for further details. Since some participants did not submit their papers, we only describe the systems in the submitted papers.

Team	Institution

Table 2: The participating teams and their affiliations.

4.1.1 Baseline

We take the naive Transformer-base (Vaswani et al., 2017) as the baseline and directly apply the implementation of the open-source toolkit, fiarseq.[8] We construct the synthetic corpus based on the WMT parallel corpus, and we refer the readers for details about constructing the synthetic corpus in the paper (Yang et al., 2021). For training, we apply the two-state training pipeline, where we pre-train the model on the synthetic corpus in the first stage, and then fine-tune the model on the golden corpus in the second stage.

4.1.2 IOL Research

The team of IOL Research participates the two sub-tasks and focuses on the En-Zh and Zh-En translation directions. They use the ΔLM as their backbone model. ΔLM is a pre-trained multilingual encoder-decoder model, which outperforms various strong baselines on both natural language generation and translation tasks (Ma et al., 2021). Its encoder and decoder are initialized with the

[8] https://github.com/pytorch/fairseq

pre-trained multilingual encoder InfoXLM (Chi et al., 2020). Their model has 360M parameters, 12-6 encoder-decoder layers, 768 hidden size, 12 attention heads and 3072 FFN dimension. For the training data, they construct the synthetic data with two different methods according to its constructing complexity. During training, they use the two-stage fine-tuning, where they apply the synthetic data to fine-tune the original ΔLM in the first stage and then fine-tune the result of the first stage with the golden corpus. In their experiments, they find that the accuracy indicator of TS can be helpful for efficient PE in practice. Overall, they achieved the best scores on 3 tracks and comparable result on another track.

4.1.3 Avocados

The team of Avocados tries different model structures, such as Transformer-base (Vaswani et al., 2017), Transformer-big (Vaswani et al., 2017), SA-Transformer (Yang et al., 2021) and DynamicConv (Wu et al., 2019). They test different ensemble approaches for better performance. For more details, we refer the readers to their paper (Zhang et al., 2022). Their main efforts are paid on building the synthetic corpus. They apply three different ways to construct the synthetic corpus. Firstly, they randomly sample a sub-segment in each target sentence of the golden parallel data, mask the sampled sub-segment to simulate an incorrect span, and use the sub-segment as an alternative suggestion. Secondly, the same strategy as above is used for pseudo-parallel data with the target side substituted by machine translation results. Finally, they use a quality estimation model to estimate the translation quality of words in translation output sentence and select the span with low confidence for masking. Then, an alignment tool to find the sub-segment corresponding to the span in the reference sentence and use it as the alternative suggestion for the span. To bridge the domain difference between the large-scale synthetic data and human-annotated golden corpus, they apply the pre-trained BERT to filter data similar to the golden corpus as in-domain data, which are used as pre-training for the next phase after pre-training model with a large-scale synthetic corpus. Overall, they rank second and third on the English-German and English-Chinese bidirectional tasks respectively.

4.1.4 mind-ts

The team of mind-ts participate in the English-German and English-Chinese translation directions in the sub-task one, and their submissions are ranked first in three of four language directions. For English-German, they initialize the weights with NMT models released by teh winner of WMT19 (Ng et al., 2019). For English-Chinese, the one-to-many and many-to-one mBART50 models are used (Tang et al., 2020). Their main contribution is to construct the synthetic corpus with word alignment. They use the well-trained alignment models between source and target languages to filter out high-quality augment data. Specifically, they first use the Fast Align toolkit to extract the token alignments. Then, they remove tokens that appear in both MT and reference to get the trimmed result. They trim these common tokens because they want the model to focus more on the incorrect span and its alternative. Additionally, they use the dual conditional cross-entropy model to calculate the quality score of the pair between the source and masked translation sentences. If the cross-entropy quality score meets the threshold, they treat the masked translation and the alignment segments as the good examples for TS. Similarly, they also use the two-phase pre-training pipeline to get the final models.

4.2 Submission Summary

The submissions for this year's TS shared task cover different approaches from the pre-trained LMs and the encoder-decode NMT models. From the submissions, we find that the pre-trained models are very useful for the final performance. Additionally, almost all of the submissions have tried different approaches for constructing the synthetic corpus. As the amount of the golden corpus is limited, it is very important to find efficient ways to construct the synthetic corpus. The main problem for constructing synthetic corpus is how to make the synthetic corpus similar to the golden corpus in domain or other aspects. Finally, how to efficiently apply the synthetic corpus also needs much more efforts to investigate. All submissions adopt the two-stage training pipeline to train the models.

4.3 Evaluation Results

We report the BLEU scores of the submissions. The BLEU is calculated automatically with the sacrebleu toolkit. For each run, the participating team need to submit their top-1 suggestions for each sentence in the test set. Each participating team can submit at most 15 times for each track. We only report the best score for each team. Table 3 and 4 report the results on English-Chinese and English-German respectively in the sub-task one. Table 5 report the results on English-Chinese in the sub-task two.

Team	En-Zh	Zh-En
Baseline	31.02	25.84
mind-ts	33.92(2)	30.07 (1)
Avocados	33.33 (3)	28.56 (3)
IOL Research	39.71 (1)	28.42 (4)

Table 3: Evaluation results on the language pair for English-Chinese in the sub-task one. The number in bracket is the ranked position.

5 Discussion and Analysis

Comparing the results of the BLEU scores of all submissions with our baseline systems, there is a significant gap between the submitted and baseline systems. This shows that there is a large space for us to try different techniques to improve the performance of TS. By comparing the results of different submitted systems, we find that different pre-training models have a large difference on the final performance. This is a similar trend with other NLP tasks. Therefore, we believe that this is an interesting and promising direction for us to pay much more efforts.

All submitted systems have investigated different approaches for constructing the synthetic corpus and almost all of them have achieved much improvements with the synthetic corpus. The noise in the synthetic corpus is a major problem which negatively affects the final performance. Therefore, how to filter or decrease the noise is an open question. The team of mind-ts applies the pre-trained LM to filter the synthetic corpus and obtain better performance on 3 out of 4 tracks based on the high-quality synthetic corpus. We can investigate more effective approaches to detect and filter the noise in the synthetic corpus.

However, another interesting direction which are not investigated by the submissions is modeling the interaction between the source and translation sentences efficiently. Compared to MT, the main difference for TS is that the input for TS is dual-source, namely the source and translation sentence. We believe that efficiently modeling the interaction between the source and translation sentences can improve the final performance.

6 Conclusion

We present the results of first edition of the Translation Suggestion shared task. For the goal of this task, we create and release the first golden benchmark dataset, called *WeTS*, which covers the language pairs for English-Chinese and English-German. We wish the released corpus can spur the researches in this area. This year we received 92 submissions from 5 participating teaming in the sub-task one and 6 submissions for the sub-task 2, most of them covering the two translation directions. Results of these submissions show that the pre-trained models and synthetic corpus are two important factors for the final performance.

Acknowledgements

We would like to thank Yaou Li and Ning Zhang for their helps on building the official website of the shared task. The authors would also like to thank the anonymous reviewers of this paper, and the anonymous reviewers of the previous version for their valuable comments and suggestions to improve our work.

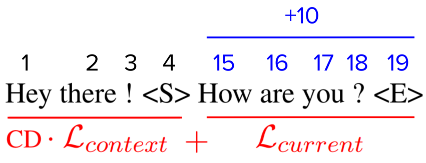
Abstract

A straightforward approach to context-aware neural machine translation consists in feeding the standard encoder-decoder architecture with a window of consecutive sentences, formed by the current sentence and a number of sentences from its context concatenated to it. In this work, we propose an improved concatenation approach that encourages the model to focus on the translation of the current sentence, discounting the loss generated by target context. We also propose an additional improvement that strengthen the notion of sentence boundaries and of relative sentence distance, facilitating model compliance to the context-discounted objective. We evaluate our approach with both average-translation quality metrics and contrastive test sets for the translation of inter-sentential discourse phenomena, proving its superiority to the vanilla concatenation approach and other sophisticated context-aware systems.

1 Introduction

While current neural machine translation (NMT) systems have reached close-to-human quality in the translation of decontextualized sentences (Wu et al., 2016), they still have a wide margin of improvement ahead when it comes to translating full documents (Läubli et al., 2018). Many works tried to reduce this margin, proposing various approaches to context-aware NMT (CANMT)[1]. A common taxonomy (Kim et al., 2019; Li et al., 2020) divides them in two broad categories: multi-encoding approaches and concatenation (single-encoding) approaches. Despite its simplicity, the concatenation approaches have been shown to achieve competitive or superior performance to more sophisticated, multi-encoding systems (Lopes et al., 2020; Ma et al., 2021). Nonetheless, it has been shown that Transformer-based NMT systems (Vaswani et al., 2017) struggle to learn locality properties (Hardmeier, 2012; Rizzi, 2013) of both the language itself and the source-target alignment when the input sequence grows in length, as in the case of concatenation (Bao et al., 2021). Unsurprisingly, the presence of context makes learning harder for concatenation models by distracting attention. Moreover, we know from recent literature that NMT systems require context for a sparse set of inter-sentential discourse phenomena only (Voita et al., 2019; Lupo et al., 2022). Therefore, it is desirable to make concatenation models more focused on local linguistic phenomena, belonging to the current sentence, while also processing its context for enabling inter-sentential contextualization whenever it is needed. We propose an improved concatenation approach to CANMT that is more focused on the translation of the current sentence by means of two simple, parameter-free solutions:



+10
1 2 3 4 15 16 17 18 19
Hey there ! <S> How are you ? <E>
CD · $\mathcal{L}_{context}$ + $\mathcal{L}_{current}$

Figure 1: Example of the proposed approach applied over a window of 2 sentences, with context discount CD and segment-shifted positions by a factor of 10.

- Context-discounting: a simple modification of the NMT loss that improves context-aware translation of a sentence by making the model less distracted by its concatenated context;
- Segment-shifted positions: a simple, parameter-free modification of position embeddings, that facilitates the achievement of the context-discounted objective by supporting the learning of locality properties in the document translation task.

We support our solutions with extensive experi-

[1] Unless otherwise specified, we refer to *context* as the sentences that precede or follow a *current* sentence to be translated, within the same document.

ments, analysis and benchmarking.

2 Background

2.1 Multi-encoding approaches

Multi-encoding models couple a self-standing sentence-level NMT system, with parameters θ_S, with additional parameters θ_C that encode and integrate the context of the current sentence, either on source side, target side, or both. The full context-aware architecture has parameters $\Theta = [\theta_S; \theta_C]$. Multi-encoding models differ from each other in the way they encode the context or integrate its representations with those of the current sentence. For instance, the representations coming from the context encoder can be integrated with the encoding of the current sentence outside the decoder (Maruf et al., 2018; Voita et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Maruf et al., 2019; Zheng et al., 2020) or inside the decoder (Tu et al., 2018; Kuang et al., 2018; Bawden et al., 2018; Voita et al., 2019; Tan et al., 2019), by making it attending to the context representations directly, using its internal representation of the decoded history as query.

2.2 Single-encoder approaches

The concatenation approaches are the simplest in terms of architecture, as they mainly consist in concatenating each (current) source sentence with its context before feeding it to the standard encoder-decoder architecture (Tiedemann and Scherrer, 2017; Junczys-Dowmunt, 2019; Agrawal et al., 2018; Ma et al., 2020), without the addition of extra learnable parameters. The decoding can then be limited to the current sentence, although decoding the full target concatenation is more effective thanks to the availability of target context. A typical strategy to train a concatenation approach and generate translations is by sliding windows (Tiedemann and Scherrer, 2017). An sKtoK model decodes the translation $\boldsymbol{y}_K^j$ of a source window $\boldsymbol{x}_K^j$, formed by K consecutive sentences belonging to the same document: the current (jth) sentence and $K-1$ sentences concatenated as source-side context. Besides the end-of-sequence token <E>, another special token <S> is introduced to mark sentence boundaries in the concatenation:

$$\boldsymbol{x}_K^j = \boldsymbol{x}^{j-K+1}{}_{\text{<S>}}\boldsymbol{x}^{j-K+2}{}_{\text{<S>}\ldots\text{<S>}}\boldsymbol{x}^{j-1}{}_{\text{<S>}}\boldsymbol{x}^{j}{}_{\text{<E>}}$$
$$\boldsymbol{y}_K^j = \boldsymbol{y}^{j-K+1}{}_{\text{<S>}}\boldsymbol{y}^{j-K+2}{}_{\text{<S>}\ldots\text{<S>}}\boldsymbol{y}^{j-1}{}_{\text{<S>}}\boldsymbol{y}^{j}{}_{\text{<E>}}$$

Both past and future contexts can be concatenated to the current pair $\boldsymbol{x}^j, \boldsymbol{y}^j$, although in this work we consider only the past context, for simplicity. At training time, the loss is calculated over the whole output $\boldsymbol{y}_K^j$, but only the translation $\boldsymbol{y}^j$ of the current sentence is kept at inference time, while the translation of the context is discarded. Then, the window is slid by one position forward to repeat the process for the $(j+1)$th sentence and its context. Concatenation approaches are trained by optimizing the same objective function as standard NMT over a window of sentences:

$$\mathcal{L}(\boldsymbol{x}_K^j, \boldsymbol{y}_K^j) = \sum_{t=1}^{|\boldsymbol{y}_K^j|} \log P(y_{K,t}^j | \boldsymbol{y}_{K,<t}^j, \boldsymbol{x}_K^j), \quad (1)$$

so that the likelihood of the current target sentence is conditioned on source and target context.

2.3 Closing the gap

Concatenation approaches have the advantage of treating the task of CANMT in the same way as context-agnostic NMT, which eases learning because the learnable parameters responsible for inter-sentential contextualization are the same that undertake intra-sentential contextualization. Indeed, learning the parameters responsible for inter-sentential contextualization in multi-encoding approaches (θ_C) has been shown to be challenging because the training signal is sparse and the task of retrieving useful context elements difficult (Lupo et al., 2022). Nonetheless, encoding current and context sentences together comes at a cost. In fact, when sequences are long the risk of paying attention to irrelevant elements increases. Paying attention to the "wrong tokens" can harm their intra and inter-sentential contextualization, associating them to the wrong latent features. Indeed, Liu et al. (2020) and Sun et al. (2022) showed that learning to translate long sequences, comprised of many sentences, fails without the use of large-scale pre-training or data-augmentation (e.g., like Junczys-Dowmunt (2019) and Ma et al. (2021) did). Bao et al. (2021) provided some evidence about this leaning difficulty, showing that failed models, i.e., models stuck in local minima with a high validation loss, present a distribution of attention weights that is flatter (with higher entropy), both in the encoder and the decoder, than the distribution occurring in models that converge to lower validation loss. In other words, attention struggles to learn the locality properties of both the language itself and the source-target alignment (Hardmeier, 2012; Rizzi, 2013). As a solution, Zhang et al. (2020) and Bao et al. (2021) propose two slightly different masking methods that allow both the encoding of the current sentence concatenated with context, and the separate encoding of each sentence in window. The representations generated by the two encoding schemes are then integrated together, at the cost of adding extra learnable parameters to the standard Transformer architecture.

3 Proposed approach

3.1 Context discounting

Evidently, Equation 1 defines an objective function that does not factor in the fact that we only care about the translation of the current sentence $\boldsymbol{x}^j$, because the context translation will be discarded during inference. Moreover, as discussed above, we need attention to stay focused locally, relying on context only for the disambiguation of relatively sparse inter-sentential discourse phenomena that are ambiguous at sentence level. Hence, we propose to encourage the model to focus on the translation of the current sentence $\boldsymbol{x}^j$ by applying a discount $0 \leq \text{CD} < 1$ to the loss generated by context tokens:

$$\begin{aligned}\mathcal{L}_{\text{CD}}(\boldsymbol{x}_K^j, \boldsymbol{y}_K^j) &= \text{CD}\cdot\mathcal{L}_{context} + \mathcal{L}_{current} \qquad (2)\\ &= \text{CD}\cdot\mathcal{L}(\boldsymbol{x}_{K-1}^{j-1}, \boldsymbol{y}_{K-1}^{j-1}) + \mathcal{L}(\boldsymbol{x}^j, \boldsymbol{y}^j).\end{aligned}$$

This is equivalent to consider an sKtoK concatenation approach as the result of a multi-task sequence-to-sequence setting (Luong et al., 2016), where an sKto1 model performs the *reference task* of translating the current sentence given a concatenation of its source with K-1 context sentences, while the translation of the context sentences is added as a secondary, complementary task. The reference task is assigned a bigger weight than the secondary task in the multi-task composite loss. As we will see in Section 4.5, this simple modification of the loss allows the model to learn a self-attentive mechanism that is less distracted by noisy context information, thus achieving net improvements in the translation of inter-sentential discourse phenomena occurring in the current sentence (Section 4.3), and helping concatenation systems to generalize to wider context after training (Section 4.5.3).

3.2 Segment-shifted positions

Context discounting pushes the model to discriminate between the current sentence and the context. Such discrimination can be undertaken by cross-referencing the information provided by two elements: sentence separation tokens <S>, and sinusoidal position encodings, as defined in (Vaswani et al., 2017). In order to facilitate this task, we propose to provide the model with extra information about sentence boundaries and their relative distance. (Devlin et al., 2019) achieve this goal by adding segment embeddings to every token representation in input to the model, on top of token and position embeddings, such that every segment embedding represents the sentence position in the window of sentences. However, we propose an alternative solution that does not require any extra learnable parameter nor memory allocation: segment-shifted positions. As shown in Figure 1, we apply a constant shift after every separation token <S>, so that the resulting token position is equal to its original position plus a total shift depending on the chosen constant *shift* and the index $k = 1, 2, ..., K$ of the sentence the token belongs to: $t' = t + k * shift$. As a result, the position distance between tokens belonging to different sentences is increased. For example, the distance between the first token of the current sentence and the last token of the preceding context sentence increases from 1 to 1 + *shift*. By increasing the distance between sinusoidal position embeddings[2] of tokens belonging to different sentences, their dot product, which is at the core of the attention mechanism, becomes smaller, possibly resulting in smaller attention weights. In other words, the resulting attention becomes more localized, as confirmed by the empirical analysis reported in Section 4.6.1. In Section 4.3, we present results of segment-shifted positions, and then compare them with both sinusoidal segment embeddings and learned segment embeddings in Section 4.6.2.

4 Experiments

4.1 Setup[3]

We conduct experiments with two language pairs and domains. For En→Ru, we adopt a document-level corpus released by Voita et al. (2019), based on OpenSubtitles2018 (with dev and test sets), comprised of 1.5M parallel sentences. For En→De, we train models on TED talks subtitles released by IWSLT17 (Cettolo et al., 2012). Models are tested

[2] Positions can be shifted by segment also in the case of learned position embeddings, both absolute and relative. We leave such experiments for future works.

[3] See Appendix A for more details.

on IWSLT17's test set 2015, while test-sets 2011-2014 are used for development, following related works in the literature.

Besides evaluating average translation quality with BLEU[4] (Papineni et al., 2002) and COMET[5] (Rei et al., 2020), we employ two contrastive test suites for the evaluation of the translation of inter-sentential discourse phenomena. For En→Ru, we adopt Voita et al. (2019)'s test suite for evaluation on deixis, lexical cohesion, verb-phrase ellipsis and inflection ellipsis. This test suite is comprised of a development set with examples of deixis and lexical cohesion, that we adopted for a preliminary analysis of context discounting. For En→De, we evaluate models on ambiguous pronoun translation with ContraPro (Müller et al., 2018), a large contrastive set of ambiguous pronouns whose antecedents belong to context. In order to validate the improvements achieved by our approaches on the test sets, we perform statistical significance tests, detailed in Annex A.1.

We experiment with two models: 1) **base**: a context-agnostic baseline following *Transformer-base* (Vaswani et al., 2017); 2) **s4to4**: a context-aware concatenation approach with the exact same architecture as *base*, but that adopts sliding windows of 4 concatenated sentences as source and target. An implementation of these models and the proposed approach can be found on github.[6]

4.2 Preliminary analysis

As a preliminary analysis, we evaluate the impact of various values of context discounting on the performance of concatenation approaches with sliding windows, in order to choose one value for all the subsequent experiments. We train En→Ru s4to4 models with context discounts ranging from 1 (no context discounting) to 0 (context loss is completely ignored): $\texttt{CD} = 1.0, 0.9, 0.7, 0.5, 0.3, 0.1, 0.01, 0$. We evaluate these models on the development sets by means of their average loss calculated over the current target sentence (*current loss*) and the average accuracy on the disambiguation of discourse phenomena. The results are plotted on Figure 2. We find out that the stronger the context discounting, the better the performance, with an improving trend from $\texttt{CD} = 1$ to $\texttt{CD} = 0.01$. Performance drops on the extreme case of $\texttt{CD} = 0$, likely because too much training signal is lost in this situation (all the training signal coming from the context is completely ignored). As such, we set $\texttt{CD} = 0.01$ for all of our following experiments.

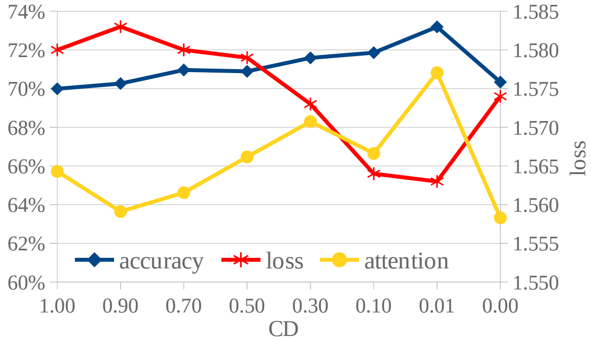


Figure 2: Evaluation of En→Ru s4to4 trained with various levels of context discounting, ranging from 1 to 0. We plot the best *current loss* obtained by each model on the development set (red), and its average accuracy on the development portion of the contrastive set on discourse phenomena (blue). In yellow, the average portion of attention that is focused on the current sentence (see Section 4.5.2).

4.3 Main results

Tables 1 and 2 display the main evaluation results measured in terms of accuracy on contrastive test sets (Disc.) and BLEU, for the En→Ru and En→De language pairs, respectively. We first observe that s4to4 is a strong context-aware baseline as it improves accuracy on contrastive sets by a large margin compared to the context-agnostic *base*, as already reported by previous works (Voita et al., 2019; Zhang et al., 2020; Lopes et al., 2020).

Average translation quality as measured by BLEU is virtually the same for all models. Indeed, our main focus is on contrastive evaluation of discourse translation, since average translation quality metrics like BLEU have been repeatedly shown to be ill-equipped to detect improvements in CANMT (Hardmeier, 2012). Learned average translation quality metrics like COMET might be more sensitive to inter-sentential discourse phenomena when applied at document-level, as we do. However, COMET differences are also negligible: all models perform on par according to statistical significance tests, except for the En→Ru model with context discount and segment shifting, that outperforms all the others with statistical significance.

When evaluating the accuracy on inter-sentential discourse phenomena, instead, we remark relevant

Table 2: Accuracy on the En→De contrastive sets for the evaluation of discourse phenomena (Disc., %), and BLEU score on the corresponding test sets. The accuracy on Disc. is detailed on its left with the accuracy on anaphoric pronouns with antecedents at different distances $d = 1, 2, ...$ (in number of sentences). The symbol * denotes statistically significant ($p < 0.05$) improvements w.r.t. base and s4to4.

performance improvements. In fact, adding a 0.01 context discounting (+ CD) improves the accuracy on all of the 4 discourse phenomena under evaluation in En→Ru, and for all distances of pronoun's antecedents in En→De, with the sole exception of $d > 3$, proving to be an effective solution. Adding segment-shifted positions further improves performance for 3 discourse phenomena out of 4, and for pronouns with antecedents at distances $d = 1, 2$, showing that sliding windows systems often benefit from enhanced sentence position information in order to achieve the discounted CANMT objective. For both language pairs, we adopt a segment-shifting equal to the average sentence length, calculated over the entire training corpus, i.e., +8 positions for En→Ru and +21 positions for En→De. Experiments with other shifting values are reported in Section 4.6.3.

As a further experiment, we apply our solutions to concatenation models with concatenated windows shorter than 4 sentences,[7] and evaluate them in the En→Ru setting. The results presented in Table 3 show that context discounting is effective for s2to2 and s3to3 too, while adding segment-shifted positions only helps s2to2 + CD. As in the case of s4to4, BLEU only displays negligible fluctuations.

System	Disc.	BLEU
s2to2	59.10	32.73
s2to2 + CD	60.28*	32.69

s3to3 + shift + CD	66.98*	32.45

Table 3: Accuracy on the En→Ru contrastive set for the evaluation of discourse phenomena (Disc., %), and BLEU score on the test set. The symbol * denotes statistically significant ($p < 0.05$) improvements w.r.t. s2to2/s3to3. Our approach is effective for different concatenation windows.

4.4 Benchmarking

For a wider contextualization of our results, we compare in Table 4 our best system with other CANMT systems from the literature. For the En→Ru language pair, we compare with all the systems from the literature that were trained and evaluated under the same experimental conditions as ours, to the best of our knowledge. In particular, we report the results by Chen et al. (2021), Sun et al. (2022)' *MR Doc2Doc*, Zheng et al. (2020), Kang et al. (2020)'s *CADec + DCS-pf* and Zhang et al. (2020). All of them are sophisticated CANMT systems that add extra trainable parameters to the

[7] We cannot evaluate with more sentences because 4 is the maximum size of documents in the test sets specialized on discourse phenomena.

Table 4: Benchmarking: accuracy (%) on the contrastive sets for the evaluation of discourse phenomena (Disc., %).

Transformer architecture. Despite being the simplest and the only parameter free approach, our method outperforms all the others on lexical cohesion and noun phrase inflection based on elided context, while it is only second to Zhang et al. (2020) on deixis and verb-phrase ellipsis. BLEU scores were not available for comparison on the same test set, except for Zhang et al. (2020), which scored 31.84 BLEU points against the 32.45 BLEU points of our method.

For the En→De language pair, we compare to the literature performing evaluation on Müller et al. (2018)'s test set and providing details about their accuracy on pronouns with antecedents at $d > 1$. In particular: Maruf et al. (2019)'s best offline system, Stojanovski and Fraser (2019)'s *pron-25→pron-0**, Lupo et al. (2022)'s *K1-d&r*, Müller et al. (2018)'s *s-hier-to-2.tied* and their evaluation of Voita et al. (2018)'s architecture.[8] All of these works but Maruf et al. (2019) adopt the much larger WMT17[9] dataset for training. Despite this advantage, our system outperforms each of them on all the discourse phenomena under evaluation, by a large margin.

Notably, from this comparison it might seem that our approach is proposed in opposition to the others reported in Table 4, but it can actually be complimentary to many of them, such as (Zhang et al., 2020)'s, hopefully in a synergistic way. We encourage future research to investigate this possibility.

4.5 Analysis of context-discounting

4.5.1 Loss distribution

In this section, we analyze the impact of context discounting on the ability of the model to predict the translation of the current sentence. On the left side of Figure 3 we plotted the evolution along training epochs of the loss calculated on the current target sentence (*current loss*), for the En→Ru language pair. The right side, instead, represents the ratio between the *current loss* and the average loss-per-sentence calculated on the context sentences belonging to the same sliding window. These results support empirically our idea of context discounting as a solution to improve model performance on the current sentence. They also confirm that a strong discounting works best. Interestingly, predictions are improved on the current sentence (left) partially as a result of a trade-off with context quality (right). In fact, the current/context loss ratio of context-discounted models increases along training even when the *current loss* is decreasing, indicating that, at the beginning of training, context discounting pushes the model to only care about current predictions, but later it allows for good predictions of the context too. Such behavior is in line with the intuition that a good translation of the current sentence, even if strongly prioritized, also requires a good translation of the context. Otherwise, it is not possible to systematically solve the translation ambiguities referring to context.

4.5.2 Attention distribution

In this section we show some empirical evidence in favor of our intuition that context-discounting improves performance by helping the self-attentive mechanism to be more focused on the current sentence (less distracted by context). We analyzed

[8] Whenever the cited works present and evaluate multiple systems, we compare to the best performing one. To the best of our knowledge, we are including all the relevant works available in the literature. BLEU scores are not compared because, besides using different training data, the cited works don't adopt the same test set neither, with the sole exception of (Lupo et al., 2022).

[9] http://www.statmt.org/wmt17/translation-task.html

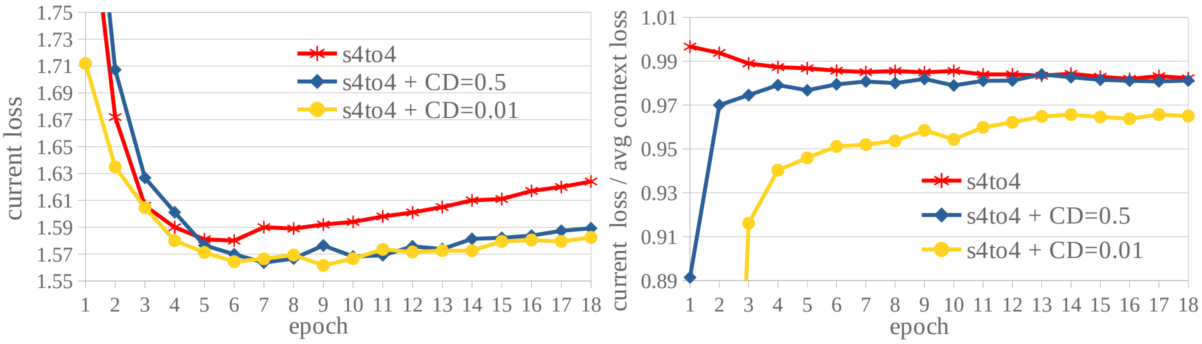

Figure 3: Context discounting enables better predictions of the current sentence (lower validation loss, on the left) at the expense of context sentences (lower current/context validation loss ratio, on the right). Language pair: En→Ru.

the distribution of the self-attention weights generated by the queries belonging to the current sentence (*current queries*), and how it is impacted by context discounting. Figure 2 clearly shows that context-discounting impacts the distribution of attention weights by skewing it towards the current sentence: a higher percentage of the total attention from *current queries* is directed towards tokens belonging to the (same) current sentence. As expected, the higher the context-discounting, the higher the portion of attention that is not dispersed towards context. The limit case of $CD = 0$ is not aligned with this trend, however. We suspect that the attention distribution is more flat in this case because the model encounters learning difficulties due to the training signal from the context being completely ignored (c.f. Bao et al. (2021) on non-fully-converged models having a flatter attention distribution).

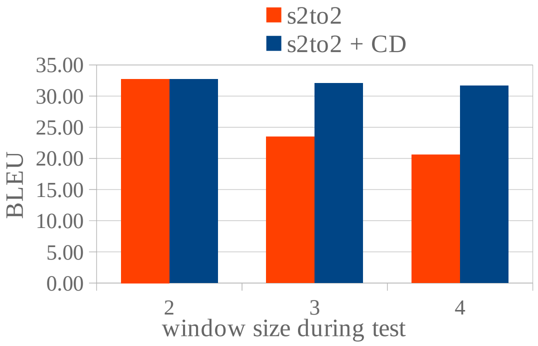

Figure 4: Our approach improves robustness of En→Ru s2to2 to window sizes unseen during training.

4.5.3 Robustness

Figure 4 shows that the s2to2 model is not robust to the translation of concatenation windows longer than those seen during training, i.e. longer than 2 sentences. Indeed, s2to2 loses 9.23 BLEU points when translating the same test set with windows of 3 sentences, and 12.14 BLEU points when translating with windows of 4. Instead, the context discounted model (blue bars) is very robust to unseen context lengths, being capable of translating them with minor degradation in average translation quality (-0.68 and -1.06 BLEU points for windows of 3 and 4, respectively). We observe a similar trend for s3to3, that loses 1.74 BLEU points when tested with windows of size 4, but recovers completely when equipped with context-discounting. The increased robustness of the concatenation models w.r.t. context size suggests once again that context discounting helps the models focusing on the current sentence.

4.6 Analysis of segment-shifted positions

4.6.1 Attention distribution

As a complementary evaluation, we tested if segment-shifted positions work as intended, i.e., by helping context-discounted models to learn the locality properties of both the language itself and the source-target alignment (Hardmeier, 2012; Rizzi, 2013). In other words, we expect segment-shifted positions to result in a more localized attention-distribution, in each of the sentences belonging to the concatenated sequence. To this aim, we computed the average entropy of the distribution of attention weights generated by all queries (both from current and context sentences), in both self and cross-attention. Results are shown in Table 5: context-discounting slightly reduces the average entropy, and this effect is amplified with the adoption of segment-shifted positions. Segment-shifted positions make attention more focused locally, as intended, which explains why the job of context

System	Attn entropy
s4to4	2.293
s4to4 + CD	2.276
s4to4 + shift + CD	**2.251**

Table 5: Average entropy of self and cross-attention weights decreases with the help of context-discounting and segment-shifted positions. All of the three values are different from one another with statistical significance (p<0.01).

	En→Ru		En→De	
System	Disc.	BLEU	Disc.	BLEU
s4to4 + shift + CD	73.56	32.45	**74.39**	29.20
s4to4 + lrn + CD	**73.68**	32.45	72.14	28.35
s4to4 + sin + CD	73.48	32.53	73.88	29.23

Table 6: Comparison between segment-shifted positions, learned segment embeddings and sinusoidal segment embeddings. Approaches are evaluated with accuracy on contrastive sets for the evaluation of discourse phenomena (Disc., %), and BLEU score on test sets. Differences across models are not statistically significant (p>0.05), except for s4to4+lrn+CD on En→De.

discounting is eased by this solution.

4.6.2 Comparison with segment-embeddings

In this section we compare our parameter-free approach to include explicit information on segment position (segment-shifted positions), with learned segment embeddings (Devlin et al., 2019), and sinusoidal segment embeddings. The latter are added to token and position embeddings at input, in the very same way as learned segment embeddings, with the only difference that their parameters are not learned but defined in the same way as sinusoidal position embeddings (Vaswani et al., 2017). In order to evaluate which approach helps best with context-discounting, we trained a context-discounted concatenation model with learned segment embeddings (s4to4+lrn+CD), and one with sinusoidal segment embeddings (s4to4+sin+CD), and compared them with s4to4+shift+CD. The results reported in Table 6 do not display any statistically significant differences across the three alternatives (p>0.05), except for learned embeddings, that underperform with statistical significance the other two variants on En→De. Instead, sinusoidal segment embeddings are competitive with segment-shifted positions on both language pairs. We leave a more in-depth analysis of segment-embeddings for concatenation approaches to future works.

System	Shift	Disc.	BLEU
s4to4 + shift + CD	100.00	73.46	32.41
s4to4 + shift + CD	avg-sequence	**73.86**	32.37
s4to4 + shift + CD	avg-corpus	73.56	32.45

Table 7: Accuracy on the En→Ru contrastive set for the evaluation of discourse phenomena (Disc., %), and BLEU score on the test set. Differences across models are not statistically significant (p>0.05).

4.6.3 Segment-shifting variants

In the experiments reported above, we always adopt a shifting value equal to the average sentence length calculated over the entire training corpus (avg-corpus), i.e., +8 positions for En→Ru, +21 positions for En→De. In this section we evaluate two alternative strategies for the selection of the shifting value: 1) applying a big shift of 100 units, one order of magnitude bigger than the average sentence length in the corpus (100); 2) applying a shifting value equal to the average sentence length of each window, calculated dynamically for each window of 4 concatenated sentences (avg-sequence). The results of this study are reported in Table 7. We do not observe relevant differences in average translation quality (BLEU) nor accuracy on the translation of discourse phenomena, and therefore confirm that the avg-corpus approach is a good alternative.

5 Conclusions

We presented a simple, parameter-free modification of the NMT objective for context-aware translation with sliding windows of concatenated sentences: context discounting. We analyzed the impact of our approach in the trade-off between current sentence predictions and context sentence predictions, showing that context discounting helps the model to focus on the current sentence, as intended. As a result, the concatenation model significantly improves its ability to disambiguate inter-sentential discourse phenomena, and becomes more robust to different context sizes. As an additional inductive bias towards locality, we equipped our model with segment-shifted positions, marking more explicitly the boundaries between sentences. This solution brings further improvements on targeted evaluation metrics. In the attempt of explaining the empirical functioning of the proposed solutions, we analysed their impact on the distribution of the attention weights, showing that they make it more focused and skewed towards the current sentence, as intended.

Limitations and future works

Our experiments are limited to the use case of short concatenated windows (up to 4 sentences). This is enough for capturing most of the ambiguous inter-sentential discourse phenomena, that usually span across a few sentences only (Müller et al., 2018; Voita et al., 2019; Lupo et al., 2022). However, recent works suggest that longer context windows might be helpful to increase average translation quality (BLEU) of concatenation approaches (Junczys-Dowmunt, 2019; Bao et al., 2021; Sun et al., 2022), and long-range discourse phenomena could be handled. We hope to investigate the impact of context discounting on longer sequences in future works. We also encourage to test the effectiveness of our approach on a wider range of data scenarios: from very limited document-level data to very abundant, including back translation (Ma et al., 2021) and monolingual pre-training techniques (Junczys-Dowmunt, 2019; Sun et al., 2022), to understand whether these methods are only alternative to context discounting or there exist synergies. Furthermore, experimenting with future context is also needed (c.f. Wong et al. (2020)).

A Details on experimental setup

All models are implemented in *fairseq* (Ott et al., 2019) and follow the *Transformer-base* architecture (Vaswani et al., 2017): hidden size of 512, feed forward size of 2048, 6 layers, 8 attention heads, total 60.7M parameters. They are trained on 4 Tesla V100, with a fixed batch size of approximately 32k tokens for En→Ru and 16k for En→De. As it has been shown that Transformers need a large batch size for achieving the best performance (Popel and Bojar, 2018). We stop training after 12 consecutive non-improving validation steps (in terms of loss on dev), and we average the weights of the 5 checkpoints that are closest to the best performing checkpoint, included. We train models with the optimizer configuration and learning rate (LR) schedule described in Vaswani et al. (2017). The maximum LR is optimized for each model over the search space $\{7e-4, 9e-4, 1e-3, 3e-3\}$. The LR achieving the best loss on the validation set after convergence was selected. We use label smoothing with an epsilon value of 0.1 (Pereyra et al., 2017) for all settings. We adopt strong model regularization (dropout=0.3) following Kim et al. (2019) and Ma et al. (2021). At inference time, we use beam search with a beam of 4 for all models. We adopt a length penalty 0.6 for all models. The other hyperparameters were set according to the relevant literature (Vaswani et al., 2017; Popel and Bojar, 2018; Voita et al., 2019; Ma et al., 2021; Lopes et al., 2020).

A.1 Statistical hypothesis tests

We perform statistical hypothesis testing with McNemar's test McNemar (1947) for comparing accuracy results on the contrastive test sets. For comparing BLEU performances and mean entropy (Table 5), we use approximate randomization (Riezler and Maxwell, 2005) with 10000 and 1000 permutations, respectively. For COMET, the official library[10] has a built in tool for the calculation of statistical significance with Paired T-Test and bootstrap resampling (Koehn, 2004).

B Details on experimental results

In this section, we report more details about the results presented in our Tables.

B.1 Evaluation of the translation of discourse phenomena

For each model that we evaluated by its accuracy on the contrastive sets for the evaluation of discourse phenomena (Disc., %), we include in Table 8 the accuracy achieved on the different subsets of the contrastive sets, as already done for Tables 1, 2 and 4. For the En→Ru set (Voita et al., 2019), we report the accuracy on each of the 4 discourse phenomena under evaluation; for the En→De test set (Müller et al., 2018), the accuracy on anaphoric pronouns with antecedents at different distances $d = 1, 2, ...$ (in number of sentences). As it can be noticed, our approach mostly outperform baselines and other variants on the majority of the evaluation subsets. We also include the column Disc$_{\text{avg}}$, which is calculated, for both language pairs, as the average of the 4 columns before the vertical dashed line.

$$Disc. = \frac{d1 * 7075 + d2 * 1510 + d3 * 573 + (d > 3) * 442}{9600},$$

$$Disc_{\text{avg}} = \frac{d1 + d2 + d3 + d > 3}{4}.$$

Disc$_{\text{avg}}$ represents the average accuracy on the disambiguation of the discourse phenomena present in the contrastive sets, as if they were all present with the same frequency. Instead, Disc. represents the overall accuracy on the contrastive set, which is equivalent to the average over the same 4 columns, but weighted by the sample size (last row) of each penomenon represented by the columns. While Disc. is a proxy of the ability to correctly translate a distribution of inter-sentential discourse phenomena as represented in the contrastive set, Disc$_{\text{avg}}$ is a proxy for the average ability to translate each of the inter-sentential phenomena under evaluation. Interestingly, Disc$_{\text{avg}}$ captures more evidently than Disc. the improvement achieved by adding segment-shifted positions to the context-discounted concatenation models. Finally, Disc$_{all-d}$ is calculated like Disc. but it also take into account pronouns whose antecedent belong to the same sentence ($d = 0$, i.e., they don't require context).

Does Sentence Segmentation Matter for Machine Translation?

Rachel Wicks[1] and **Matt Post**[1,2]

[2]Human Language Technology Center of Excellence
Johns Hopkins University
{rewicks@,post@cs.}jhu.edu

Abstract

For the most part, NLP applications operate at the sentence level. Since sentences occur most naturally not on their own but embedded in documents, they must be extracted and segmented via the use of a segmenter, of which there are a handful of options. There has been some work evaluating the performance of segmenters on intrinsic metrics, that look at their ability to recover human-segmented sentence boundaries, but there has been no work looking at the effect of segmenters on downstream tasks. We ask the question, “does segmentation matter?" and attempt to answer it on the task of machine translation. We consider two settings: the inference scenario, where sentences are passed into a black-box system whose training segmentation is mostly unknown, and the training setting, where researchers have full control over the process. We find that the choice of segmenter largely does not matter, so long as its behavior is not one of extreme under- or over-segmentation. For such settings, we provide some qualitative analysis examining their harms, and point the way towards document-level processing.

1 Introduction

Contemporary machine translation assumes a sentence-level paradigm. However, data doesn’t exist naturally at the sentence level, requiring the use of automatic segmenters to split the data at both training and inference time. Training data is prepared with the use of sentence segmenters,[1] which are preprocessing steps that occur prior to alignment and bitext creation. At test time, deployed models also require the use of a segmenter. Many times, for downloaded models, especially, this inference-time application must be made without knowing what segmenter was used to train the model, introducing a potential misalignment or discrepancy and resulting performance degradation.

Sentence segmentation itself has received only a little attention in the research literature, although there has been a recent uptick (Moore, 2021; Wicks and Post, 2021). But to our knowledge, no work has been done investigating the effects of segmentation on machine translation. In fact, most research papers do not deal with the question at all, relying as they do on pre-segmented parallel data for both training and test time. This is a practical problem for deployment scenarios, where segmentation must be considered. It is also a deeper problem, since segmentation is ultimately a modeling decision that should be noted and made available with any published models, such as is done for other modeling decisions affecting input text, such as normalization, tokenization, and subword processing.

To understand whether and to what extent segmentation matters, we ask a series of questions: (1) What segmenter is best used at inference time? (2) When training a model, how important is the choice of segmenter? We break down this last question into two settings: (i) the standard training procedure in which sentences from parallel documents are aligned (Gale and Church, 1993), and (ii) more recent “mining” approaches, which use sentence representations to find sentence pairs without regard for document boundaries.

We find that

- for two black-box models trained with unknown segmentation, inference-time segmentation largely does not matter;
- when training new models, more aggressive segmentation generally produces better models, but these models are less robust to training-/inference-time segmentation mismatch;
- Global bitext mining approaches generally outperform document-based alignment tech-

[1] Sometimes called *sentence breakers*.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 843 - 854
December 7-8, 2022 ©2022 Association for Computational Linguistics

niques, but the latter is more robust to under-segmented data at inference.

2 Evaluation

Our research questions address two scenarios. In the first, a researcher has downloaded a shared model and wishes to use it to translate new data. In many instances—perhaps most—the providers of the model have neither shared nor reported what segmenter they used. Likely the model was trained on "standard" provided datasets such as those from WMT. We would like to have some understanding of the effect of different segmentations when we don't have control over the training segmentation.

Alternatively, we have a "glass box" model. In this setting, we are training the model, and have full flexibility over the choice of segmentation. By reconstructing the entire NMT pipeline with segmentation as the first step of dataset preprocessing, the researcher has complete control over the resulting model. This settings provides us with a more granular look at the effect of segmenter choice.

2.1 Metric Settings

In order to evaluate in either of these settings, we need to address a difficulty: automatic metrics for machine translation, whether source-based or reference-based, compare the machine translation output for sentences on a *pre-segmented*. For example, the WMT20 en-de test set (Barrault et al., 2020) has 1,418 pre-segmented sentences,[2]. In order to evaluate the effect of segmenters, we need to run three steps:

1. Remove the provided segmentation
2. Re-segment and translate
3. Align the translation outputs to the original references

This alignment step is necessary because metric scores cannot be compared across different reference segmentations. And it is complicated because we have no guarantee that the new segmentation will line up cleanly with the existing one.

We address this problem with three different alignment approaches.

Preserve keeps the provided segmentation, skipping step (1) above. Segmenters are applied to each sentence separately. It is easy to restore the original segmentation by simply keeping track of the number of sub-splits that were created with each line. On the downside, it does not allow the segmenter its full flexibility.

Document is possible when the sentences of a test set are grouped into documents. In this setting, step (1) above is done, but only at the document level. The segmenter is applied to the sentences in each document. Step (3) is undertaken by treating each document as a single line. Because of this, the number of references changes, and numbers computed from this approach cannot be compared to the other two.

Realign provides full flexibility to each segmenter. For step (3), we concatenate all outputs, and then align its words to the original reference segmentation using a search algorithm described in Section 2.2.

As many of the test sets originate from news articles and include header information (which typically includes a designated line break), we additionally insert sentence-final punctuation where it is not provided. This allows all segmenters to recover this segmentation.

2.2 Aligning outputs to references

Assume a source sequence (S) comprising tokens $(s_1, s_2, s_3, ...s_n)$, which aligns to reference r_i and a subsequent source sequence (T) comprised of $(t_1, t_2, t_3, ...t_m)$, which aligns to reference r_j. In the released test set, there exists an explicit segmentation between s_n and t_1. If we maintain this segmentation, the realignment of the translated tokens is obvious: any sub-sequence spawned from S aligns to r_i and we can re-concatenate the translations for scoring.

However, in production, there isn't an explicit segmentation between these tokens. Therefore, to give the segmenters the full degree-of-freedom that one would find in production, we must remove these segmentations. In this scenario, a segmenter may create the subsequences of (s_1, s_2, s_3), $(s_4, ...s_n, t_1, t_2)$, and $(t_3, t_4, ...t_m)$. Translation can also re-order tokens which makes the realignment non-obvious.

The realignment can be reduced to a search problem. To limit the search, we can impose hard constraints on the alignment based on subsequence matching. The field of Biomedical Engineering has a similar problem when trying to align two similar (but not identical) DNA sequences. We

Sub-search over {r3}

Figure 1: Example of the realignment method. Top row indicates the reference with grouped tokens each belonging to r_1, r_2, and r_3. The hard constraints are determined via longest subsequence matching (indicated with underlines). Note that not all matching surface forms may be determined as hard constraints based on token ordering. These hard constraints fix certain alignment points so the search algorithm (described in Section 2.2) has a limited reference set.

use an off-the-shelf capability[3] which maximizes subsequence matching length. This aligns some tokens to references so we search *between* the already aligned tokens. This is further illustrated in Figure 1.

Between a start and end token (t_i and t_j respectively) that are aligned to two references (r_x and r_y), we search for the best alignment of all intermediate tokens (t_k such that $i < k < j$) to a reference (r_z such that $x < z < y$). Plainly, this maintains a monotonicity: subsequent tokens can only be aligned to the same or a future reference.

We additionally require alignments to be consecutive sequences–no produced alignment to a reference can be a subsequence of an alignment to a different reference.

We optimize the alignment via the following costs:

- **Length-Ratio:** An optimal alignment should be the same length as the reference. This feature is the ratio of the shorter sequence to the longer sequence.
- **Final Punctuation:** A binary feature that determines if the aligned sentence and the original reference both end in punctuation.
- **N-gram Probability:** For unigrams and bigrams, the $p(t_k|r_z)$ or $p(t_{k-1}, t_k|r_z)$, respectively.
- **Start Word:** A binary feature that determines if the aligned sentence and the original reference both start with the same word.
- **End Word:** A binary feature that determines if the aligned sentence and the original reference both end with the same word.
- **Initial Capitalization:** A binary feature that determines if the aligned sentence and the original reference both start with a capitalized word.

We let the alignment cost be:

$$a_k = \sum_{i=0}^{k} a_i + \sum_{j} w_j * f_j(\text{alignment of } t_k)$$

where w_j is an associated weight on feature f_j. We perform a beam search with these features, expanding with each token t_k.

We use this methodology to re-align translations to references when the original segmentations are not maintained. We also note that this technique and toolkit can be used to reproduce alignments in other fields when the model's segmentation is not identical to that of the test sets as one might see in speech translation.

3 Experimental Setup

We focus on our investigation on English and German. We make this choice because this language pair has sufficient document-level information in datasets released by WMT. For many language pairs, datasets with true document pairs do not exist. A wider consideration of language pairs is not possible without further work to cultivate document-pair datasets.

Given document pairs in German and English, we extract sentences with a variety of segmenters and apply a typical document-based aligner to create bitext. Each segmenter creates a unique training set which we use to train a neural machine translation model.

Traditional alignment methodologies assume true document pairs. A search through both the source and target assumes alignments will be found

[3] https://biopython.org

in roughly sentence order. Vecalign (Thompson and Koehn, 2019) is an example of one of these document-based aligners. This method has the benefit of being capable of recovering erroneous segmentation because over-segmented sequences will still be consecutive during the search.

The growing field of bitext alignment has created new trends that search for sentence pairs outside the context of a document. One method of extracting sentences from all documents and searching globally for a sentence pair has created massive datasets such as CCMatrix (Schwenk et al., 2021b), WikiMatrix (Schwenk et al., 2021a), and CCAligned (El-Kishky et al., 2020). To compare the effects of segmentation in conjunction with both alignment techniques, we train models on data produced from all segmenters using both a document-based alignment method and a global, context-less based aligner.

3.1 Data

German–English has three datasets that preserve document-level boundaries in German-English—Europarl v10.[4] News Commentary v16.[5] and DGT[6] available through OPUS (Tiedemann, 2012). We find these datasets sufficient to train NMT models without other supplementary data.

Europarl comes from proceedings of the European Parliament. Aligned sentences are released as well as document IDs. The aligned sentences are roughly sentence-level. News Commentary is similarly produced from news articles.

DGT is a set of manually produced translations released by the European Commission's Directorate-General for Translation (DGT) from their translation memory. This dataset has substantial over-segmentation where one clause or phrase may be segmented onto its own line.

We use the Workshop on Machine Translation 2020 (WMT20) news task test sets and sacreBLEU[7] (Post, 2018) to score.

The sizes of the data before and after segmentation are available in Table 6 in the Appendix.

3.2 Segmentation models

We compare the following segmenters:

- **ORIGINAL:** The provided segmentations.

- **ALWAYS:** An over-segmentation approach that treats every piece of potentially sentence-ending punctuation as unambiguous.

- **ERSATZ:** A neural model that uses context windows to produce segmentations (Wicks and Post, 2021).

- **MOSES:** Always splits on punctuation, unless the previous token is in a pre-defined list of acronyms and abbreviations (Koehn et al., 2007).

- **PUNKT:** An unsupervised approach that uses thresholding to produce segmentations based on features such as casing, token length, and word frequency (Kiss and Strunk, 2006).

- **SPACY:** A "Rule-based" technique that varies on language.[8]

- **PAIRS:** The DGT dataset is oversegmented, and many lines contain less than one whole sentence. Lines must be merged in order to have complete sentences. In this setting, we merge the original bitext (instead of inserting segmentations). To implement, we simply combine every two lines together and treat as one "sentence." This merging also adds many-to-many sentence alignments for training in the Europarl and News Commentary datasets. *We only consider this "segmentation" method at training as the test data is sufficiently undersegmented.*

4 Segmentation at Inference with a Black Box System

In order to replicate a real-world use-case, we use an off-the-shelf pre-trained model. Datasets used to train these models are reported, but for the most-part, segmentation is unknown. We consider test sets in a variety of language pairs[9] for comprehensiveness. For model consistency, we chose a multilingual NMT model. We use the Prism (Thompson and Post, 2020) as a blackbox translation model,

After applying the segmentation methods described in Section 2, we translate with Prism.

[5] `https://data.statmt.org/news-commentary/v16/training/`

[6] `https://opus.nlpl.eu/DGT.php`

[7] We considered COMET (Rei et al., 2020) as an alternative but did not find significant differences in trends

[8] v2.3.5, `https://spacy.io`

[9] `cs-en`, `de-en`, `en-cs`, `en-de`, `en-pl`, `en-ru`, `en-zh`, `pl-en`, `ru-en`, `zh-en`

	PRESERVE	REALIGN	DOCUMENT
	PRISM	PRISM	PRISM
ORIGINAL	27.1	27.5	28.9
ALWAYS	28.7	29.1	30.5
ERSATZ	29.0	29.4	30.8
MOSES	29.0	29.5	30.8
PUNKT	29.0	29.4	30.8
SPACY	28.7	29.3	30.6

Table 1: PRESERVE maintains original segmentations before applying the segmenter and aligns all produced sentences to the original corresponding reference. DOCUMENT removes segmentations from the original source before applying segmenter and aligns all translations to a single reference sentence (the entire document). REALIGN removes original segmentations and applies the alignment technique in Section 2.2 before scoring. Note that columns are not directly comparable. Differences between segmenters are not statistically significant.

We report results in Table 1 by averaging BLEU scores across the languages. As shown in the table, different segmenters are consistent within each alignment technique. The original test sets from some language pairs (namely `cs-en`, `en-cs`, `de-en`, and `en-de`) were undersegmented in the release to encourage document-level MT. For this reason, the average with the ORIGINAL segmentation is lower—the Prism model trained primarily on sentence-level data does not generalize as well to multiple sentence inputs. PRESERVE and REALIGN have the same number of references while DOCUMENT doesn't. PRESERVE and REALIGN are more directly comparable but REALIGN still may introduce realignment errors. DOCUMENT is used as an additional score to contextualize the performance. More about the realignment methodologies is in Section 2.

5 Segmentation at Training with a Glass Box System

Segmentation occurs at an early stage in the NMT pipeline, so it is intuitive to think it could have a large effect: Incorrect segmentations can lead to incorrect alignments; incorrect alignments lowers the quality of the training data; and low quality training data will produce worse models.

In order to study the effects on training, we recreate the NMT pipeline by segmenting documents and aligning bitext to train models. We apply each segmenter to the training data resulting in a new unique set of “sentences" for each segmenter. We can then align these sentences to create a unique dataset.

5.1 Document-based Alignment

The standard training paradigm for machine translation identifies bilingual document pairs, segments the sentences on both sides, and then aligns. The alignments are ideally one-to-one, but often many-to-one (or one-to-many) alignments are also permitted. The product of this is (ideally) tens of millions of sentence pairs that can be used to train machine translation models.

To replicate this, we take monolingual datasets that we know to contain parallel documents. The document alignment is known and labelled. Using these document alignments, we segment and manually re-align the sentences using a document-based aligner.

The document-based aligner we use is Vecalign (Thompson and Koehn, 2019) which uses LASER[10] (Artetxe and Schwenk, 2019) sentence embeddings to compute alignment and also considers many-to-one or one-to-many alignments. This system is a document aligner because it aligns within document context–considering surrounding sentences for many-to-one (or one-to-many) alignments and also constrains the search to alignments along the diagonal (i.e., sentences aligned to each other should occur within a similar placement within their documents).

The number of sentences recovered from the alignment, as well as the average length of source and target in the resulting dataset is shown in Table 2. The difference in size of the resulting datasets is important to note and likely explains the differences in models.

5.2 Global Search Alignment

Recent releases of WikiMatrix (Schwenk et al., 2021a), CCMatrix (Schwenk et al., 2021b), and CCAligned[11] (El-Kishky et al., 2020) have increased the scaling of bitext mining by doing away with the need for bilingual documents.

These techniques extract sentences from monolingual data and attempt to align them with techniques by combining sentence embeddings and clever search algorithms. In such settings, it stands to reason that proper segmentation might be even

[10] `https://github.com/facebookresearch/LASER`

[11] CCAligned somewhat limits the globalness of the search by aligning pseudo documents based on domains.

	Unaligned	Aligned Bitext

Table 2: Training data sizes before (left, Unaligned) and after (right, Aligned Bitext) segmentation and alignment. For each row, the top number denotes the source (`de`) size while the bottom denotes the target (`en`) size. For each segmentation method, displays the total number of retrieved sentence pairs, the total number of tokens (based on white-space), and the average number of tokens in a sentence.

more important, since all alignments are one-to-one. The scaling potential of this technique allows for massive datasets with billions of aligned sentences to produced in many languages. We use the same toolkit used to produce these datasets which uses LASER embeddings and FAISS indexing for quick retrieval.[12]

5.3 Experimental Details

We train a 32,000 joint unigram subword vocabulary using SentencePiece[13] (Kudo, 2018; Kudo and Richardson, 2018) using the original data. We use a Transformer (Vaswani et al., 2017) architecture with 6 encoder and 6 decoder layers. We train with a batch size of 16k tokens validating at the end of each epoch and stopping if the validation has not improved after 10 validations. We validate on WMT19 test sets (with original segmentations). For a comprehensive list of hyperparameters, please Table 7 in the Appendix.

5.4 Results

The amount of data produced by each segmenter and alignment method varied significantly. Data quantity after segmentation and alignment is displayed in Table 2. Vecalign is fairly consistent in the amount of data aligned—roughly 180M tokens with Always creating the highest variance. Vecalign also produces more data in terms of number of sentences compared to the alternative global search method. The global search also varies more significantly with a 10M token difference between the smallest and largest datasets (excluding Always).[14]

We compute the full cross-product of segmentations at training and inference. Results are reported in Table 3. Once again, we find that within a given model, performance is relatively consistent at inference regardless of segmentation. The exception is the Original row as these inputs are under-segmented. This strong mismatch between training and testing points to hallucinations which are further explored in Section 6.

Generally, we see more variation in model performance based on training data segmentation rather than inference segmentation. One of the best performing models was the model trained on the Original data—made by preserving the original segmentations. The prominent feature of its training data was the prevalence of sub-sentence segmentations. We hypothesize this helped in two ways: 1) it was not reliant on a strong end-of-sentence signal (§ 6) and 2) the true alignments were more likely to exist in the training set. If errors in segmentation make alignment difficult, it is beneficial to have segments that are *guaranteed* to correctly align to something. Because the DGT dataset was transla-

Table 3: German–English (de-en) results. The rows denote the segmenter used at *inference* while the columns denote the segmenter used to create the *training data*. The diagonal, thus, has a matching segmenter for both training and inference. The LASER global search alignment method was used to create bitext. Bold denotes significance (p < 0.05) run by paired bootstrapping with sacreBLEU.

tion memory, most segments had a true alignment.

In the ORIGINAL inference-time setting, models trained with Vecalign-produced bitext performed better than their Global counterparts. We hypothesize this is because Vecalign was able to recover many-to-one or one-to-many alignments where the Global aligner was not. This made the models more robust to many-sentence inputs and outputs.

Lastly, we note that the choice of segmenter *does* affect the training data, and thus the final trained model. The ORIGINAL model often had the highest BLEU score across inference-time segmentations. The differences between the ORIGINAL model, and the ERSATZ and PAIRS models were not statistically significant in most cases. Models trained on data created by PUNKT, SPACY, or MOSES (often used to create MT datasets) were not as competitive.

6 Qualitative Analysis

Hallucinations, or addition of content during translation, and deletions are common in neural machine translation. These models are no exception. Qualitative analysis reveals two types of errors that are worth investigating further: 1) seemingly arbitrary deletion of content when the input is unsegmented 2) addition of content without a true signal in the source. We suspect the explanations for these behaviors are 1) a lack of many-sentence inputs occurring in training data and 2) incorrect segmentations leading to poorly aligned data. We display some examples in Table 4.

6.1 Deletion

Almost all models fail when given unsegmented data at inference (the ORIGINAL row). Upon inspection of these translations, it is obvious the reasons for these scores. In Table 4, we show an instance of this in the first column. The source input has three sentences. Some models trained with segmenters (ERSATZ, MOSES, PUNKT, and SPACY) drop the majority of these sentences. The models trained with the ORIGINAL segmentations and the ALWAYS segmentation method incorporate information across sentences and hallucinate new conjunction methods (inserting “with" or using commas). The model trained with the PAIRS setting does a combination. As this setting often has two sentences per line in the bitext, this translation also is limited to two lines and similar, to PUNKT and ORIGINAL, hallucinates ways to combine these sentences. We can infer the reason for the drop in BLEU scores in the unsegmented setting is because most models are *deleting* content. In order to report the prevalence of deletion, we report how many sentences were deleted during translation.

There are 785 lines in the test data but most of the lines contain more than one sentence. We can use Moses (one of the segmenters that is quite conservative—prone to undersegmenting) to count how many sentences occur in the source input as well as how many sentences occur in the translated outputs. In Table 5, we display this information.

The fact that PAIRS translates more sentences is logical as its training data often had *pairs* of sentences in the training data. The ORIGINAL setting translating more sentences than other models seems counterintuitive as the training data was shorter on average (see Table 2). We suspect that the reason for this is more related to the fact that many training examples in the ORIGINAL setting *did not end in punctuation* since they were below the sentence level. In the ERSATZ training data, for example, 98% of training example's target sequences end with a period. Conversely, 62% of the ORIGINAL data ended with a period. We reason that the model was not highly likely to end the sequence after de-

	DELETION	ADDITION
SOURCE	Für Online-Händler sind viele zurückgeschickte Pakete verlorene Ware. Rund 20 Millionen Retouren landen so auf den Müll. Doch gibt es eine Alternative.	Der Premier droht damit, das Land am 31. [Oktober ohne Abkommen aus der EU zu führen...]
ORIGINAL	For online traders, many returned packages are lost commodities, with around 20 million retours pouring into the rubbish, but there is an alternative.	The Prime Minister is threatening the country on 31 December.
ALWAYS	For online traders, many returned packages are lost, but there is an alternative.	The Prime Minister is threatening to leave the country on 31 December.
ERSATZ	Some 20 million retours thus end up in the rubbish.	The Prime Minister is threatening to hold the country on 31 May.
MOSES	For online traders, many returned packages are lost goods.	The Prime Minister is threatening to do so, the country on 31 December.
PUNKT	For online dealers, many returned packages are lost goods.	The Prime Minister is threatening to see the country on the 31st day of the month.
SPACY	For online traders, many returned packages are lost goods.	The Prime Minister is threatening the country on 31 December.
PAIRS	For online traders, many returned packages are lost goods, with some 20 million retours ending up in rubbish. But there is an alternative.	The Prime Minister is threatening the country on 31 December.

Table 4: Examples of differences in translations. The SOURCE denotes input to the model. Content in square brackets was not part of input but has been included for context to reader. The DELETION column shows examples of different models deleting content during translation due to unsegmented input. The ADDITION column shows models hallucinating content when an incomplete input was given.

coding a period due to these trends.

All segmenter models were affected by this behavior, but SPACY had more issues. SPACY, in a manner different to the other segmenters, also includes punctuation such as ':' as final punctuation meaning it oversegments in many scenarios. In sentences including colons, we see similar deletion from SPACY. For instance, the SPACY model translates ***“Katastrophe abgewendet: Großbrand in französischem Chemiewerk gelöscht."*** simply as ***“Avoiding disaster:"***

Of the 157 sentences in the test data that included a colon, SPACY translated *only* the first segment in 78 of them; in 52 it translated only the second segment; in 27 it translated parts of both.

6.2 Additions

When Raunak et al. (2021) studied the causes of hallucinations, they attributed hallucinations to errors in bitext alignment. It follows that segmentation, as a precursor to bitext alignment, might also affect hallucinations. The most obvious hallucination we see in the translations is surrounding dates. German often uses a format of “Freitag, 27. September 2019" for “Friday, September 27, 2019". Erroneous segmentation around the punctuation in the date causes alignment issues or bad input to the translation model. We see the effects of both.

The former, bad alignment, we see in the case of the overly-aggressive segmenter (ALWAYS). Because the data was always split on the date in this construction, the alignment suffers severely. We see examples in the training data such as:

Source: Juli 2016 an.
Target: Done at Brussels, 20 July 2016.

The training data frequently contains dates like this and the global search aligner was unable to detect that additional information appeared on the target side. The ALWAYS model memorized this extraneous information and generated it 8 times in these experiments.

In the second case, where the input to the model has been over-segmented, we see a similar effect. When an ALWAYS segmenter is used at inference, the models struggle on the incomplete information. In the second column of Table 4, a complete sentence has been segmented erroneously into two incomplete sentences. For clarity the end of the sentence (which was segmented into a separate input) is included in square brackets. The incomplete input has a two-fold effect: 1) the models hallucinate months to attach to the date 2) ALWAYS, ERSATZ, and PUNKT hallucinate verbs (to leave, to hold, to see respectively).

7 Related Works

To the best of our knowledge, not much work has been done about the effects of segmentation on down stream tasks. Raunak et al. (2021) investigates corpus-level noise and empirically links noise patterns to types of NMT hallucinations. Other work has focused on the effects that punctuation has on neural language models (Ek et al., 2020; Karami et al., 2021). In online simultaneous speech segmentation, Wang et al. (2019) proposes an online sentence segmentation approach which improves downstream BLEU scores.

There is much more work pushing away from the sentence-level paradigm and encouraging document translation. Sun et al. (2022) has recently shown that modern neural architectures still achieve strong performance with longer, multi-sentence inputs. A spate of recent work has gone into better document evaluation metrics (Jiang et al., 2022; Vernikos et al., 2022). Document pairs contain the additional context needed to correctly translate certain discourse phenomenon such as coreference resolution and consistent lexical choices. Further, mining documents instead of sentences circumvents the error propagation from using various segmentation methodologies during bitext mining.

8 Conclusion

An NMT system trained on segmented data requires segmentation at inference; however, the exact method of segmentation at inference seems to have little quantitative effect. The larger impact of segmentation occurs during the creation of bitext. Whether the effect stems from the quality of the produced sentence pairs or the limitations of different alignment methods cannot be determined based on these results. Despite this, various segmentation and alignment method combinations create significantly different amounts of bitext to train models on–something that needs to be investigated further. The differences in the resulting data produce models that perform differently. Lastly, we note that when models are trained on segmented data, they dramatically hallucinate at inference with unsegmented data by deleting long segments. By adding some amount of unsegmented data in the training data, this effect can be mitigated to recover upwards of 4 BLEU points.

Together, we might conclude that avoiding segmentation is the path forward. When the segmentation and alignment techniques failed, half a million sentence pairs were sometimes lost or left unaligned. Additionally, we see that less-segmented bitext produces models that are more robust to unsegmented data at inference. The biggest hurdle in training document-level models is the lack of sufficient document-level annotations. If true document pairs exist in larger web-scraped corpora, most of the original document structure (and informative context) has been removed via bitext filtering and deduplication. Future work might explore potential solutions to mining document-level data, and circumvent these segmentation tools and their respective noise.

9 Limitations

Most of this work relies on interactions between the segmenters and the aligners. It's the production of training data—and the resulting quality and quantity that is causing the differences in models. We used off-the-shelf configurations for these aligners and didn't do significant hyper-parameter searching. It's possible that other toolkits or different hyperparameters might normalize the effects of erroneous segmentation.

We also noted that Vecalign was able to recover erroneous segmentation in the one-to-many and many-to-one settings while showing that the global method was not. Having a global search method does not directly preclude these recoveries, but to the best of our knowledge it hasn't been investigated.

Lastly, we limit ourselves to `de-en` as a language pair here because of the availability of document pairs. The ambiguity in puncutation surrounding these two languages make them interesting for segmentation. Also, German often uses a different word order than English which can make aligning erroneous segmentations difficult. These effects might be minimized or non-existant in other language pairs.

A Appendix

A.1 Data

In Table 6 is a further breakdown if the amount of sentences extracted from the datasets via each segmenter. In most cases, a segmenter produces more segmentations than the ORIGINAL dataset. This is not true of the DGT dataset which shows how over-segmented it was. Moses is the most conservative segmenter with high-precision and lower recall.

A.2 Hyperparameters

In Table 7, the hyperparameters used to train the Fairseq NMT models are listed. When the parameters are not listed, the defaults were used. Further, we also list the settings used with the Vecalign aligner in Table 8.

Abstract

Neural machine translation models often contain large target vocabularies. The calculation of logits, softmax and beam search is computationally costly over so many classes. We investigate the use of locality sensitive hashing (LSH) to reduce the number of vocabulary items that must be evaluated and explore the relationship between the hashing algorithm, translation speed and quality. Compared to prior work, our LSH-based solution does not require additional augmentation via word-frequency lists or alignments. We propose a training procedure that produces models, which, when combined with our LSH inference algorithm increase translation speed by up to 87% over the baseline, while maintaining translation quality as measured by BLEU. Apart from just using BLEU, we focus on minimizing search errors compared to the full softmax, a much harsher quality criterion.

1 Introduction

The computation of the output logit, softmax and beam search (the *output layer*) are some of the most compute-intensive tasks in current Neural Machine Translation (NMT) models, often taking the majority of inference time for many models, on many hardware architectures, especially in deployment settings. This is mainly due to the large vocabulary size relative to other dimensions in the model. Methods that reduce the effective vocabulary size can have a major impact on inference speed. Vocabulary selection is one such method.

However, a known downside of vocabulary selection methods is the risk of search errors if the desired output token $\hat{y}_t$ is not a member of the reduced vocabulary $\overline{V}$, forcing the beam search to choose a sub-optimal token. Even when the impact of such search errors on BLEU is minimal, search errors caused by lexical shortlisting degrade human judgements of quality (Domhan et al., 2022).

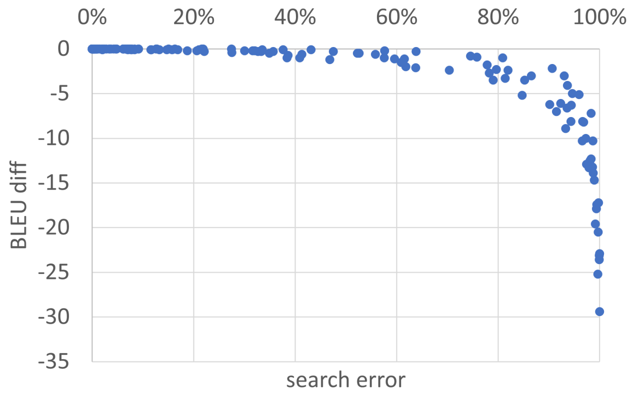

Figure 1: Search errors vs. decrease in BLEU for all experiments in the paper. We vary the two main hyperparameters of our LSH implementation: number of hash functions and the size k of our selected vocabulary subset. 60% of sentences have a search error before we observe a 1 BLEU point degradation.

The degradation in human judgement is less surprising if we inspect Figure 1 which shows that translation quality, as measured by BLEU, is resilient to search errors caused by LSH. Only when over 60% of translations exhibit search errors is there significant BLEU degradation.

We examine vocabulary selection using Locality Sensitive Hashing (LSH), and evaluate specifically in the context of Neural Machine Translation. We introduce an LSH-based vocabulary selection algorithm and compatible models such that:[1]

1. the models have translation quality that is better than or comparable to the baseline model;
2. the LSH-based vocabulary selection algorithm introduces minimal search errors across a number of models and language pairs, including no search errors at all for certain configurations;
3. inference is up to 87% faster than the baseline.

2 Methods of vocabulary selection

The output layer for a target vocabulary V, performs the following computations:

$$\begin{aligned} p(y_t|y_{1:t-1}, x; \theta) &= \text{softmax}(Wh + b) \\ \hat{y_t} &= \text{argmax}\, p(y_t|y_{1:t-1}, x; \theta), \end{aligned} \tag{1}$$

where $W \in \mathbb{R}^{|V| \times d}$ is the weight matrix, $b \in \mathbb{R}^{|V|}$ is the bias vector, $h \in \mathbb{R}^d$, d is the hidden dimension size of the decoder state, and $p(y_t|y_{1:t-1}, x; \theta) \in \mathbb{R}^{|V|}$ is the softmax probabilities. This is computationally expensive due to the target vocabulary size, $|V|$.

Vocabulary selection create a small subset, $\overline{V} \subset V$. This will reduce the size of weight matrix, $\overline{W}$, and bias vector, $\overline{b}$, where $|\overline{V}| \ll |V|$, $\overline{W} \in \mathbb{R}^{|\overline{V}| \times d}$ and $\overline{b} \in \mathbb{R}^{|\overline{V}|}$.

Equation 1 is then replaced with the more efficient Equation 2 which uses $\overline{W}$ and $\overline{b}$ instead.

$$\begin{aligned} \overline{p}(y_t|y_{1:t-1}, x; \theta) &= \text{softmax}(\overline{W}h + \overline{b}) \\ \overline{\hat{y_t}} &= \text{argmax}\, \overline{p}(y_t|y_{1:t-1}, x; \theta), \end{aligned} \tag{2}$$

The aim is now to find the subset, $\overline{V}$, such that $\overline{\hat{y_t}} = \hat{y_t}$.

Depending on the method, vocabulary selection (and therefore construction of $\overline{V}$, $\overline{W}$ and $\overline{b}$) can be static or happen dynamically per sentence (or batch), per decoder time step, or even per individual decoder hypothesis.

We restrict our overview of the concept of vocabulary selection to the case where the original softmax layer remains largely unmodified except for sub-selection. Methods that require complex structural reformulations of the softmax layer during training like hierarchical softmax (Morin and Bengio, 2005), adaptive softmax (Grave et al., 2016) or binary code prediction (Oda et al., 2017) are outside the scope of this work.

In-depth overviews of past and current vocabulary selection methods are provided by L'Hostis et al. (2016), Shi and Knight (2017), and more recently Domhan et al. (2022). We only repeat concepts that are either common or required to differentiate our work from previous approaches.

2.1 Word frequency-based methods

For simplicity's sake, when describing word frequency-based methods, we assume that vocabulary identifiers correspond to frequency rank (according to a training corpus or other reference corpus) and hence the top-K first items in a vocabulary list are the top-K most frequent words/segments from the training corpus. The choice of K determines a static subset V_f of V where $|V_f| = K$. Then $\overline{V} = V_f$ and the parameters $\overline{W}, \overline{b}$ of the softmax output layer are sub-selected accordingly.

Word frequency-based vocabulary selection is not a viable method on its own — the quality degradation is simply too large to be acceptable (Shi and Knight, 2017) — but it constitutes an important common back-bone for several of the more accurate methods discussed below as it is an easy way to include common segments like function words, punctuation, etc. in the output vocabulary.

2.2 Word alignment-based methods

Word alignment-based vocabulary selection (Jean et al., 2015a) has been part of the NMT toolbox since the earliest competitive NMT systems. Jean et al. (2015b) first introduce the concept in essentially the form it is widely being used today[2] in their submission to the WMT15 shared task (Bojar et al., 2015). Later work (Mi et al., 2016; L'Hostis et al., 2016; Shi and Knight, 2017) rediscover mostly the same setup or confirm it to be one of the strongest methods amongst a number of other approaches.

Given a source sentence $x_{1:m}$ and a word-alignment dictionary with alignment probabilities between source and target segments $p_a(y|x)$, this method creates $V_a = \bigcup_{t \in 1:m} V_a(x_t)$, where for instance $V_a(x_t) = \{y \in V : p_a(y|x_t) \geq \overline{p}\}$ for a given threshold $\overline{p}$. Other criteria for constructing $V_a(x_t)$ are possible: such as K' most probable aligned target words or combinations of multiple criteria.

Finally, the alignment-based method is typically combined with the frequency-based method as $\overline{V} = V_f \cup V_a$. Word alignment thus extends and refines the target word-frequency method by mapping source sentence context to plausible target language vocabulary candidates (ranked or selected by translation probability). Note, that V_a is constructed dynamically once per source sentence or batch which forces a dynamic construction of $\overline{V}$.

2.3 Earlier LSH-based approaches

Locality Sensitive Hashing (LSH) as a way to accelerate the computation of inner products has been

[2] See submissions to the recent shared tasks on efficient NMT (Hayashi et al., 2019; Heafield et al., 2020, 2021).

investigated as early as 2014 (Vijayanarasimhan et al.) for handling large vocabularies and remains an active area of research for more general neural network training (see e.g. Chen et al., 2020).

Previous work on using LSH in NMT (Shi and Knight, 2017; Shi et al., 2018) takes an approach that is analogous to the alignment-based methods in the sense that a static vocabulary based on word frequency is extended with target vocabulary items that are plausible in the dynamic context of the decoded sentence. However, instead of mapping source segments to target segments via alignment dictionary look-up, the decoder hypothesis state vector h is used to find set $V_l(h)$ of the k target vocabulary items y with the corresponding output layer embedding vector w_y most *similar* to h. As before, the static word-frequency based vocabulary set is merged with the contextual set to form $\overline{V}(h) = V_f \cup V_l(h)$. Note however, that $\overline{V}$ now depends dynamically on each decoder state h.

The specifics of how similarity between the vectors is defined determine the speed and accuracy of the method. The output layer itself can be seen as a similarity function (inner product with softmax normalization) that has perfect accuracy but is least interesting in terms of speed.

Shi and Knight (2017) and Shi et al. (2018) use Winner-Take-All (WTA; Yagnik et al., 2011) hashing with banding to approximate the output layer. However, the type of similarity as expressed via WTA hashing seems to result in fairly low accuracy and therefore needs to be merged with several thousand most frequent vocabulary items to remain competitive in terms of translation quality compared to the full vocabulary.

2.4 Selection as binary classification

L'Hostis et al. (2016) and more recently Domhan et al. (2022) propose to approach the vocabulary selection problem as a per target vocabulary item binary classification problem where each of $|V|$ binary classifiers decides if the corresponding target vocabulary item should be included in the sentence-level (or batch-level) target vocabulary.

L'Hostis et al. (2016) train a suite of $|V|$ binary SVM classifiers which are learned independently from the neural model. The set of words in the source sentence serves as a sparse bag-of-words feature set.

Domhan et al. (2022) train their "neural vocabulary selection" model jointly with the translation model via a multi-objective cost function. They construct $z = \sigma(\text{maxpool}(WH + b))$ where $H \in \mathbb{R}^{d \times m}$ is the hidden encoder context, $W \in \mathbb{R}^{|V| \times d}$, $b \in \mathbb{R}^{|V|}$ and $z \in \mathbb{R}^{|V|}$.

Generally, for both methods, given the binary classifier z_y corresponding to the vocabulary entry y, we have $\overline{V} = \{y \in V : z_y(x_{1:m}) \geq \lambda\}$ where λ is the decision threshold for including y in $\overline{V}$. $\overline{V}$ is constructed dynamically once per sentence and both methods do not need to be merged with the word-frequency-based vocabulary list V_f. The threshold λ seems to be sufficient to control for speed versus accuracy trade-offs.

3 Our LSH-based method

Our work contrasts with prior research on LSH for NMT by Shi and Knight (2017); Shi et al. (2018) in that:

1. We use SimHash hash instead of WTA hash.
2. We do not need to expand the LSH vocabulary subset $\overline{V}$ by merging with a static list of the most frequent words.
3. We do not need to merge $\overline{V}$ across batch and beam entries.
4. We create $\overline{V}$ by finding the top-k smallest Hamming distances, rather than banding hashes and Cuckoo lookups.
5. Our target vocabulary is smaller than most experiments in the above works which experimented with target vocabulary sizes of 66k, 50k, 40k and 25k. We believe larger vocabularies are unnecessary as a result of the use of sub-word units (Sennrich et al., 2016) and their variants. We use sub-word units while the above works do not.
6. We are concerned with search errors introduced by vocabulary selection as well as with translation quality degradation. Quality metrics are often insensitive to errors caused by deviation from an otherwise unfiltered vocabulary.

3.1 SimHash for Softmax approximation

Prior research on the application of LSH for NMT by Shi and Knight (2017); Shi et al. (2018) relies on WTA hashing. We found SimHash (Charikar, 2002) to result in much lower search error.

For a random normal vector $r \in \mathbb{R}^d$ and an input vector v (of the same size as r), SimHash introduces the following hash function H_r:

$$\mathrm{H}_r(v) = \begin{cases} 1 & \text{if } v \cdot r \geq 0 \\ 0 & \text{if } v \cdot r < 0 \end{cases}$$

which maps v to a single bit. The above is generalized to c bits by generating and applying c different random vectors and concatenating the results. This can be simplified via multiplying with a projection matrix $R \in \mathbb{R}^{d \times c}$ and the same dimension-wise mapping to bits of the result.[3] We call this function $\mathrm{H}_R(v) : \mathbb{R}^d \rightarrow \{0, 1\}^c$ and use it to obtain the LSH representation of v. Further, $\mathrm{D}(\mathrm{H}_R(u), \mathrm{H}_R(v))$ denotes the bit-wise Hamming distance between the hashed binary representations of vectors u, v.

SimHash has been designed in such a way that for two vectors u, v for which the angle $\theta(u, v)$ between these vectors is small, the Hamming distance D over their hashed binary vectors should be small as well.[4] Naturally, the cosine similarity $\cos(\theta(u, v))$ will be high for such cases.

It is this property which allows us to apply a series of transformations and approximations to find a promising candidate for the most probable vocabulary item $\hat{i}$ for a decoder state vector h (and the output layer parameters W and b) using fast Hamming distance computation:

$$\begin{aligned} \hat{i} &= \operatorname*{argmax}_{i \in V} \operatorname*{softmax}_{i}(Wh + b) && (3) \\ &= \operatorname*{argmax}_{i \in V} w_i \cdot h + b_i && (4) \\ &\approx \operatorname*{argmax}_{i \in V} w_i \cdot h && (5) \\ &\approx \operatorname*{argmax}_{i \in V} \cos(\theta(w_i, h)) && (6) \\ &\approx \operatorname*{argmax}_{i \in V} \cos\left(\mathrm{D}(\mathrm{H}_R(w_i), \mathrm{H}_R(h)) \frac{\pi}{c}\right) && (7) \\ &= \operatorname*{argmin}_{i \in V} \mathrm{D}(\mathrm{H}_R(w_i), \mathrm{H}_R(h)). && (8) \end{aligned}$$

In every step above which leads with $\approx$, we introduce a new approximation to the previous step, potentially reducing the accuracy of the search for $\hat{i}$. When moving from Equation 4 to Equation 5, we drop the bias term b_i as it cannot be easily incorporated in the search in Hamming space. For models with large values in the bias vector b, this will inadvertently lead to search errors. The easy solution to this problem is to drop the bias term during training as well. More on this in Section 5.1.

In Equation 6 we ignore the magnitude of the vectors. This seems to not matter much for the search and we leave investigating the effects or potential mitigation for future work.[5]

Equation 7 sees the introduction of the SimHash LSH as we approximate the angle θ via the Hamming distance. Finally, in Equation 8 we can find the most promising vocabulary candidate by directly minimizing the Hamming distance; note that we flipped from argmax to argmin.

3.2 Integrating LSH with beam search

In Section 2, we categorized methods of vocabulary selection by how and when they construct the set of subselected vocabulary $\overline{V}$.

Before translation begins, the output embedding weights W are hashed once using the SimHash function $\mathrm{H}_R(W)$ to create a set $L \in \{0, 1\}^{|V| \times c}$ of LSH keys, one for each target vocabulary entry from V:

$$L = \{l_1, \ldots, l_{|V|}\} = \mathrm{H}_R(W). \qquad (9)$$

Similar to the other LSH-based methods from Section 2.3, we construct $\overline{V}(h)$ dynamically for every decoder state h. During each decoding step the same hash function is applied to the decoder state h to obtain a hashed binary query $q \in \{0, 1\}^c$:

$$q = \mathrm{H}_R(h).$$

If the transformations in Equation 3 to Equation 8 were exact, we would only need to find the vocabulary candidate i corresponding to key $l_i \in L$ with the lowest Hamming distance from the query q (in the case of greedy decoding). However, all the approximations lead to search errors and we investigate a set of k best scoring candidates. This set

[3] Following the LSH implementation in FAISS, we use a Gaussian random rotation matrix $R \in \mathbb{R}^{d \times c}$. If $c \geq d$, FAISS constructs a matrix $R \in \mathbb{R}^{c \times c}$ composed of c orthonormal column vectors via QR factorization and then drops rows until we have $R \in \mathbb{R}^{d \times c}$.

[4] See Charikar (2002) for details. In short, the probability that the hash values for two vectors u, v match is given as $Pr(\mathrm{H}_r(u) = \mathrm{H}_r(v)) = 1 - \frac{\theta(u,v)}{\pi}$. When hashing to bit vectors of length c, the Hamming distance between these bit vectors $\mathrm{D}(\mathrm{H}_R(u), \mathrm{H}_R(v))$ approximates $\frac{\theta(u,v)}{\pi} c$.

[5] The magnitudes of decoder states and weight vectors probably do not vary a lot. However, decoder states h would be normalized to norm $\sqrt{d}$ via layer normalization at no additional computational cost if we dropped the affine transformation after layer normalization. The weight vectors of the output layer could be normalized to unit length after each parameter update during training or via weight normalization (Salimans and Kingma, 2016).

Dataset	de-en	*#sentences* fr-en	es-en

dev2006 (Dev)	2,000	2,000	2,000
nc-dev2007 (Test)	1057	1,057	1,057

Table 1: Data used for training, validation and testing.

is our per decoder state vocabulary subset $\overline{V}(h)$:

$$\overline{V}(h) = \operatorname*{argmin}_{\substack{V' \subset V \\ |V'|=k}} \sum_{i \in V'} \mathrm{D}(q, l_i).$$

In cases where there are more than k elements that would qualify based on their Hamming distance, we retrieve only the first k found. Note, this concludes our construction of $\overline{V}$ and unlike Shi et al. (2018), we do not need to extend $\overline{V}$ with a large word-frequency list.

Next, for every decoder state h, $\overline{W} \in \mathbb{R}^{|\overline{V}| \times d}$ and $\overline{b} \in \mathbb{R}^{|\overline{V}|}$ are subselected from the output layer parameters W and b, respectively, by restricting entries to those corresponding to vocabulary indices in $\overline{V}$. $\overline{W}$ and $\overline{b}$ replace W and b in calculating softmax and the best output token, $\hat{y}_t$, replacing the standard output layer computation in Equation 1 with Equation 2.

The number of hashes per input vector c and the number of target vocabulary to keep k are hyperparameters in our LSH implementation.

4 Experimental Setup

We train a model with 6-layer Transformer (Vaswani et al., 2017) encoder with 6-layer SSRU (Kim et al., 2019) decoder, trained using Marian (Junczys-Dowmunt et al., 2018) and using the same toolkit for inference. This is a strong and realistic model for production MT environments which balances translation quality and efficiency.

We use SentencePiece (Kudo and Richardson, 2018) with 32,000 tokens for all models, shared between both source and target language.

We use the FAISS (Johnson et al., 2019) implementation of SimHash hash described in Section 3.1.

We trained with four translation directions (German-English, English-German, Spanish-English, and French-English) Europarl corpus (Koehn, 2005), validated on the held out development set from the same corpus (*'dev2006'*) and tested on the out-of-domain New Commentary test set (*'nc-dev2007'*). See Table 1 for data set sizes. Results are reported for German-English in Section 5, results for other language pairs are available in the Appendix 7.2.

We use a two stage training procedure. In the first stage, we train a translation model directly on the parallel data. We create a synthetic parallel corpus by translating the source side of the parallel corpus with the initial model. The original source is paired with these translations to form the synthetic corpus for stage two. For the second stage of training, we then consider two cases: (1) where the 2nd stage model topology is identical (i.e. the original model and the new model both have or lack the output bias) and (2) where there is some change in model topology.

For case (1), we use *self-training*: the first-stage model are fine-tuned using the synthetic corpus. For case (2): we use sequence-level *knowledge distillation*: new models are distilled (Hinton et al., 2015) by training from scratch on the synthetic corpus. By abuse of terminology, in both scenarios, we call the first-stage model the *teacher*, and the fine-tuned or distilled model the *student*.

Translation quality was measured using SacreBLEU (Post, 2018). We define *search errors* as the number of lines changed in the translation output when vocabulary selection is applied.

We measure the time taken to do inference on one core of a 12 core Intel Xeon CPU, on a PC with 16GB RAM, running Ubuntu 20.04 within a WSL2 hypervisor.

For short listing, we create a candidate list of target sub-word translations for each source sub-word by using word alignments obtained from FastAlign (Dyer et al., 2013). A shortlist of target sub-words is created before the translation of each sentence to constrain the possible output sub-words.

5 Results and analysis

Table 2 shows results on the full teacher-student training procedure, compared to the baseline, teacher, and lexical shortlisting. Our proposed method maintains the same translation quality as greedy search, with a 57% to 80% speedup. By contrast, shortlisting has search errors in 12% to 25% of sentences, with a speedup of between 67% to 74%.

	de-en			fr-en			es-en

Table 2: Translation speed (sent./sec.), quality (BLEU) and search error for the teacher model, student model with full vocabulary, student model with the shortlist, and student model with LSH vocabulary selection. Hyperparameters chosen for lowest possible search error. Models trained with no bias and with label smoothing, and use a beam size of 1.

	Baseline	Using LSH	
Model	BLEU ↑	BLEU ↑	search error ↓
With bias	28.9	0.1	100%
With bias LS	**29.7**	0.0	100%
No bias	29.1	29.1	7%
No bias LS	29.2	29.2	6%

Table 3: Translation quality (BLEU) for baseline teacher models, and when using LSH ($k = 1024$, $c = 2048$).

In order to understand the contributions of different aspects of the method, we perform additional experiments for analysis.

5.1 The effect of output bias

While the softmax of Equation 1 is dependent on the output bias b as well as output weights W, there is no easy way to include the bias b in the hashed representation of L in Equation 9. To see what effect this omission by the LSH hashing function has on translation, we will train and evaluate models with and without the output bias.

The first column in Table 3 compares the translation quality between models with and without output bias, based on BLEU scores. Models with output bias and training with label smoothing (LS) of 0.1 improve translation quality.

Column two and three in Table 3 show the consequences of applying LSH with the output vocabulary size of $k = 1024$ and the number of hashes set to $c = 2048$ to the baseline models. LSH causes overwhelming search errors in models with output biases, leading to catastrophic collapse in BLEU. This is unsurprising as the LSH does not take the bias into account when computing similarity. On the other hand, models without output bias are not hugely affected by LSH. Between 2% to 7% of the translations suffer from search errors but this has a negligible affect on translation quality.

Model	Beam 1	Beam 4
Teacher with bias	28.9	29.9
+ Student no bias	29.1	29.9
+ Student no bias LS	29.6	30.4
Teacher with bias LS	29.7	30.3
+ Student no bias	28.7	29.3
+ Student no bias LS	29.6	30.2
Teacher no bias	29.1	29.8
+ Student no bias	30.1	**30.9**
+ Student no bias LS	**30.2**	30.8
Teacher no bias LS	29.2	29.9
+ Student no bias	30.0	30.4
+ Student no bias LS	29.9	30.5

Table 4: Translation quality of distilled models on held-out test set (BLEU) with different beam widths.

Based on these results, further experiments with LSH only use models without output bias.

5.2 Comparison with lexical shortlisting

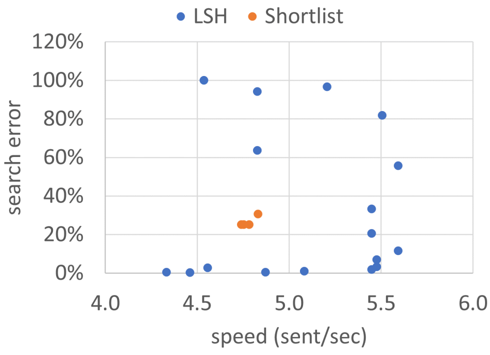

Figure 2: Comparison of translation speed (sent./sec.) vs search error between LSH and lexical shortlisting.

	Beam 1			Beam 4		
	speed ↑	BLEU ↑	search error ↓	speed ↑	BLEU ↑	search error ↓
Teacher model	2.84	29.2		1.52	29.9	
Student model	2.71 (-5%)	29.9		1.47 (-3%)	30.5	
LSH	3.94 (+39%)	29.9	0%	2.01 (+32%)	30.5	13%

Table 5: Translation speed (sent./sec.), quality (BLEU) and search error for student model (trained and distilled with label smoothing, without bias). Compared with teacher without bias or label smoothing. LSH is using parameters 1024-best vocab items, and a hash size of 2048.

Figure 2 shows the translation speed / search error trade-off for LSH and lexical shortlisting for various hyperparameter settings. For shortlisting, We experimented with $|V_f| = 100$ and $|V_a| = 10, 25, 50, 75$ and 100. We have not observed significant changes for larger $|V_a|$. The methods were applied to a model trained, then distilled with no output bias and with layer normalization. Our training procedure and LSH inference algorithm is not only faster than shortlisting but also result in less search errors.

5.3 LSH in teacher-student training

The Hamming distance of the hash vectors in Equation 7 is used in an approximate similarity measure between the decoder state h and each embedding vector corresponding to vocabulary items in V. We would like to increase this similarity for the correct output and decrease it for incorrect output at each time step. Kim and Rush (2016) demonstrated that knowledge distillation create student models with a more peaked distribution, i.e. the probability mass is concentrated around only few vocabulary words. This likely carries over into the space of Hamming distances, separating similar vector pairs from dissimilar ones, a potentially useful phenomenon that the search can take advantage of. See also Section 5.6 for similar considerations on the effects of label smoothing.

Figure 3 shows the trade-off between the LSH top-k versus search errors, for teacher models without and with output bias, and student models without bias, respectively. Similarly, Figure 4 shows the trade-off with the number of hashes c used in LSH. These plots also show that:

1. teacher-student training significantly reduces LSH search errors,
2. teacher models *with* label smoothing have lower search errors,
3. student models *without* label smoothing have lower search errors,
4. all student models converges to minimal, or even zero, search errors with increased top-k.

5.4 Translation speed vs hash size

Predictably, translation speed increases if the LSH parameters decreases. For example, Figure 5 shows the translation speed when the number of hashes are varied. At very low hash counts, the systems often output lengthy sentences with repetitive gibberish, lowering speed. Of course, this has a negative impact on search errors and translation quality.

5.5 Larger beam size

Table 5 shows translation quality when using a larger beam which, as expected, is higher in all cases than using beam width 1.

However, LSH vocabulary selection causes more search errors for larger beam sizes. Figure 6 compare the search errors for the same model using beam width 1 and 4 by varying the LSH hyperparameters. The same conclusion can be drawn from Table 5 (Beam 4).

A possible cause for this increased search error is in the calculation of the softmax denominator. The denominator for each beam is the sum of logits in the beam. When using vocabulary selection, the denominator is approximated by calculating it only over a k-best subset of the logits. The softmax probability would be distorted if the excluded logits contain significant probability mass.

This is not an issue with beam size 1 as an approximation error in the denominator would change the absolute probabilities but won't affect the relative probabilities within the beam.

However, for beam size larger than one, probabilities across different beams are compared. A logit approximation error in this case would distort the

comparison between vocabulary items in different beam, leading to search errors.

5.6 Label smoothing

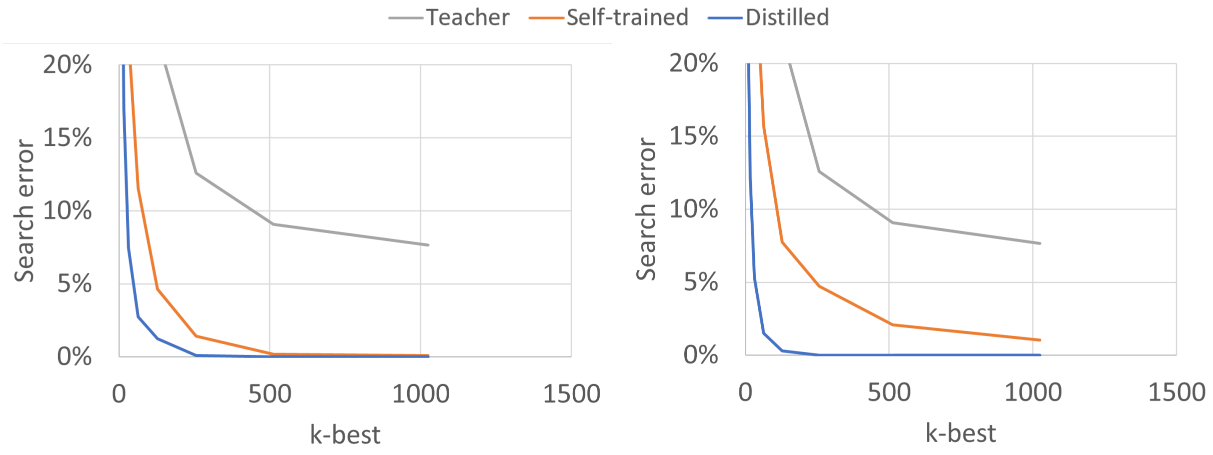
While label smoothing (Szegedy et al., 2016) can improve translation quality—by spreading the probability over many output classes to avoid overfitting— models with label smoothing are detrimentally affected by larger beam widths when LSH is used. Figure 7 shows that both student and teacher models have higher search errors when trained with label smoothing. Since label smoothing distributes a portion of the probability mass over the entire vocabulary, the excluded logits will contain a larger amount of the total probability mass, exacerbating the problem caused by the larger beam size. Since label smoothing may also reduce information transfer in knowledge distillation (Müller et al., 2019), we recommend training students without label smoothing, especially when using larger beams.

5.7 Self-training vs distillation

Thus far, we have fined-tuned ('self-trained') models where the second stage model is architecturally identical to the first, otherwise we distilled a student model from the first stage model.

For first stage models with no bias, Table 6 shows that fine-tuning result in better translation quality than training from scratch with the synthetic data.

However, the fine-tuned models have slightly higher search errors, nevertheless both training strategies result in models which have much lower search errors than the original first stage model, Figure 8.



(a) no label smoothing

(b) label smoothing 0.1

6 Conclusion

We demonstrate that, with the proper training procedure, using locality sensitive hashing for vocabulary selection can significantly boost translation speed while consistently producing negligible search errors.

We make the following recommendations for use in practice:

For existing models and greedy search, perhaps where we may not know the exact training procedure and model, we can create a model that works with LSH vocabulary selection by distilling the original model to a comparable model without output bias. Using label smoothing in the distillation can improve its translation quality if the original model was not trained with it. There will be minimal search errors in using LSH while achieving significant speed improvement.

To train a new model for use with greedy search, a two stage procedure should also be used where the second stage is fine-tuned on the output of the first. Both stages should train models without output bias. Again, the fine-tuned models can be trained with label smoothing without affecting the effectiveness of LSH.

LSH vocabulary selection introduce search errors for larger beam sizes, especially when label smoothing is used during fine-tuning. Therefore, if using larger beams in inference, it is recommended not to use label smoothing in the distillation or fine-tuning step.

7.1 Practical Considerations

Here, we discuss some practical considerations for use of the LSH decoding.

To train a Marian model without an output bias, add the following switches.
Marian training command:[6]

```
--output-omit-bias
```

To train without label smoothing:

```
--label-smoothing 0
```

To use the LSH vocabulary selection during inference, execute marian-decoder with the following switches:

```
--output-approx-knn [k] [c]
```

where [k] is the number of k-best vocabulary items and [c] is the number of hashes to use.

Abstract

Leveraging shared learning through Massively Multilingual Models, state-of-the-art machine translation (MT) models are often able to adapt to the paucity of data for low-resource languages. However, this performance comes at the cost of significantly bloated models which are not practically deployable. Knowledge Distillation is one popular technique to develop competitive lightweight models: In this work, we first evaluate it's use to compress MT models focusing specifically on languages with extremely limited training data. Through our analysis across 8 languages, we find that the variance in the performance of the distilled models due to their dependence on priors including the amount of synthetic data used for distillation, the student architecture, training hyper-parameters and confidence of the teacher models, makes distillation a brittle compression mechanism. To mitigate this, we explore the use of post-training quantization for the compression of these models. Here, we find that while distillation provides gains across some low-resource languages, quantization provides more consistent performance trends for the entire range of languages, especially the lowest-resource languages in our target set.

1 Introduction

While NLP has made giant strides in producing more accurate models, these benefits are often not transferred representatively to end-users who would eventually use a language-technology (Ethayarajh and Jurafsky, 2020; Caselli et al., 2021). Bloated sizes, cumbersome inference times (Tao et al., 2022a) and a limited set of languages that these models serve are a few reasons for this. More specifically, their usage is hindered by access bottlenecks such as (a) **Infrastructural Obstacles**: A large percentage of end-users do not have sustained access to internet or high-compute devices to enjoy a stable access to cloud-inferencing of current NLP models (Ranathunga and de Silva, 2022; Diddee et al., 2022), (b) **Latency Requirements**: Certain NLP services (chat-bots, real-time assistance interfaces, etc.) require very low-inference time which requisite lightweight-models (c) **Privacy Constraints**: The outflow of sensitive user data which is fed for inferencing to remotely hosted NLP models also has well documented issues (Srinath et al., 2021; Huang and Chen, 2021; Huang et al., 2020; Diddee and Kansra, 2020).

Within the research that focuses on evaluating and mitigating these practical constraints, the focus on low-resource language setups has been fairly limited (Ganesh et al., 2021). For instance, while the compression of large language models has received consistent attention through analysis of pruning (Behnke and Heafield, 2020; Behnke et al., 2021), distillation (Bapna et al., 2022; Mghabbar and Ratnamogan, 2020; Kim and Rush, 2016; Junczys-Dowmunt et al., 2018) and even quantization (Bondarenko et al., 2021; Zadeh et al., 2020) - much of this work has focused on compressing language models for high-resource languages.

In this paper, we report the results of a comparative analysis of the performance of distillation and quantization. By focusing on compressing seq2seq multilingual models across a range of languages with data ranging from 7000 to 3M samples - we especially demonstrate the different priors that need to be ascertained for the successful distillation of the model. We are unaware of any previous study that demonstrates the performance of these mechanisms on such low resource languages.

The utility of this work is in commenting on the feasibility of these two compression techniques for rapid development and deployment of MT Models for low resource languages (Joshi et al., 2020). More specifically, we believe that distillation's reliance on several priors can be addressed naively through a resource-intensive exercise, where the optimal values of these priors are computed exhaustively. However, in the absence of such a budget, we expect this to be a major impediment in the development of lightweight models for such languages. Since low resource language communities may also be marginalised in other ways, exhaustive investment of data and compute might not be feasible for such communities as well as the language technologists working on these languages (Zhang et al., 2022; Diddee et al., 2022; Markl, 2022).

The main contributions of this work are:

1. We distill competitive baseline models for 8 low-resource languages (Bribri, Wixarica, Gondi, Mundari, Assamesse, Odia, Punjabi and Gujarati) and evaluate the sensitivity of the generated models to priors including (a) amount of synthetic Data being used for training (b) The architecture of the student model (c) the training hyper-parameter configuration and (d) the confidence of the teacher models.

2. We, then, quantize these models to observe if quantization provides a more consistent compression mechanism for these languages. Based on our analysis, we conclude that the suprising stability of naive Post-Training Quantization, especially in the compression of extremely-low resource languages (training data between 5000 and 25000 samples) over distillation.

We release a combination of lightweight, offline support MT models for these languages along with the scripts for generation and offline inference to further reproducible research in this domain[1].

2 Approach - Model and Size Adaptations

In this section, we describe the languages (2.1), architectures under consideration (2.1), the adaptations that we make for training and fine-tuning these models (2.2) and the adaptations we make to compress their size.

2.1 Languages

We perform our analysis on the eight languages shown in Table 1. These languages cover a wide range of availability of monolingual and parallel data, spanning from classes 0 to 3 as defined in Joshi et al. (2020). Additionally, they differ in scripts and their inclusion in pretraining corpus which result in interesting modelling adaptions that are needed to be performed for the development of their baselines. In this work, we only study the *High-Resource Language* (HRL) → *Low-Resource Language* (LRL) translation direction. The source languages for all our target languages are mentioned in Table 1.

Family of Models For this work, we leverage two model classes to carry out our analysis: **I)** seq2seq transformer (Vaswani et al., 2017), hereafter referred to as vanilla transformer: With 6 Encoder and Decoder Layers, Vocabulary size - varying between 8k to 32k and 8 attention heads. and **II)** mT5-small (Xue et al., 2021): With 8 Encoder and Decoder Layers, Vocabulary Size - 250100 and 6 attention heads.

We train the vanilla transformer from scratch, hereafter referred to as transformer, to develop a naive baseline for our experiments, and further finetune the mT5-small, hereafter referred to as mT5, with certain adaptations for all the languages, as discussed in section 2.2.

For ease of reporting, we define the highest-performing-model (denoted by HM) over our family of models as:

$$\mathrm{HM} = \operatorname*{argmax}_{\mathrm{M}} \mathrm{A(M)}$$

where M is a model class with performance A(M) after training (where A is a metric like BLEU (Papineni et al., 2002) or chrF (Popović, 2016) used to monitor the task-specific performance of the model).

2.2 Model Adaptations: Language Specific Approaches

Here we describe the strategies required to adapt these models to different low-resource languages: During fine-tuning, we adapt the pretrained mT5 tokenizer to unseen scripts (encountered for Odia) by transliterating it to the closest, highest-resource language included in the pretraining corpus of the pretrained model (Khemchandani et al., 2021; Ramesh et al., 2021, 2022). For our extremely low-resource languages, we used Lexicon-Adaption (Wang et al., 2022) for the augmentation of target-side monolingual data for languages wherever a bilingual lexicon could be leveraged - Detailed performance with Hindi-Gondi is provided in the Appendix section A.2. However since such methods were not extensible to all the languages in our target language set, we report final experimental results on the models

Table 1: Languages Under Consideration: Note that the except the language's inclusion in the pretraining corpus of our chosen pretrained language models, all factors are independent of our experimental setup. Source language column enlists the source language of the translation pairs

which did not leverage any additional data other than the data mentioned in A.1. Since we analyze the HRL to LRL direction and 4 out of 8 (Bribri, Wixarica, Gondi and Mundari) of our target languages have little to negligible monolingual data - we were also unable to leverage Back-Translation to augment our language-specific parallel corpus (Edunov et al., 2018).

2.3 Size Adaptation: Knowledge Distillation

Knowledge distillation involves training a smaller student network to mimic the token level probabilities of a larger, more accurate teacher model. We distill our models using Hard Distillation (Kim and Rush, 2016): we utilize a set of monolingual sentences in the HRL - and forward translate using the HM to generate synthetic labels that a lighter student model is then trained on.

2.3.1 Estimation of Optimal Values for Priors

We define a prior as any attribute of the compression mechanism that needs to be initialized meaningfully and/or optimized for optimal performance - akin to hyperparameters. We use this term specifically so as to put all the dependent variables - such as training data, prediction confidence of the uncompressed models, etc in a single bucket: rather than using a term like hyperparameters that already holds traditional significance in literature. The experimental sweeps for these priors are briefly explained in this section. Note that we focus largely on distillation while estimating for these priors, because quantization provides competitive models even with the default choices established by literature whereas with distillation - the estimation of these priors is critical to achieve a competitive compressed model variant in most cases.

Prior 1: Optimal Student Architecture Following prior work like Bapna et al. (2022), we experimented with 3 candidate architectures, two of which used deep encoders and shallower decoders. We sweeped across 3 candidate architectures - all variants of a seq2seq transformers with (a) 8 Encoder + 6 Decoder Layers (b) 6 Encoder + 4 Decoder Layers and (c) 6 Encoder + 3 Decoder Layers. We chose the architecture that gave the best BLEU performance after 30 epochs. Sweeps for the architecture were done across each of the following languages - Gondi, Assamesse and Odia as they covered a wide range of training data.

Prior 2: Optimal Training Hyperparameters We sweeped across a set of hyper-parameter sets for Bribri, Gondi, Assamesse and Gujarati to identify the optimal set for the distilled student models. Our goal here was to specifically study the transferability of a hyperparameter set which performed competitively for one or more languages, to all the languages in our target set.

Prior 3: Amount of Training Data for the Student We sweeped across 3 candidate sizes of our synthetic dataset: 100K, 250K and 500K pseudo-labels. Since this decision could also be greatly dependent on the quality of the labels generated per language - we ran this sweep for Bribri, Gondi, Odia and Gujarati, as the quality of the labels generated by the teachers for these languages would be expected to demonstrate significant variation.

Prior 4: Optimal Teacher Architecture To do a preliminary quantification of the effect of the choice of a teacher architecture and the quantity of data that a teacher is trained for on the compressibility of the model - we decided to evaluate the confidence of our teacher models on the predictions they generated. For this, we sampled 100 instances from each of our testsets and monitored the logit distribution of our teacher models. Specifically, we calculated the average of the softmax entropy of the token-level softmax distributions for a sequence. Taking inspiration from the unsupervised estimation of quality of machine translation outputs (Fomicheva et al., 2020) through similar methods, we hypothesised that the lower the entropy of our model, the more confident it would be in its predictions for a given sample. The intuition here was that if a model is confident about its prediction, its logit distribution would be highly-skewed, and not resemble a uniform distribution (which would indicate its indecisiveness in being able to predict the right token - and therefore, the right sequence). Eventually, this could be used to gauge the quality of the pseudo labels that are student were being trained on.

2.4 Size Adaptation: Quantization

Quantization is a common way to reduce the computational time and memory consumption of neural networks (Wu et al., 2020). Here, a lower-bit representation of weights and activation functions is used to achieve a lower memory footprint. In this work, we perform post-training quantization, where after training the base model with full precision of floating point 32 bits (fp-32), we convert the weights and activations of the model to 8 bit integers (int-8). Note that during inference, we still preserve the precision of the input and output encoder-decoder distributions as fp-32. In theory, this brings down the memory consumption of the model by nearly 4x times, though we see an effective reduction of about 3x in practice. More details on the memory-reductions achieved are specified in the Appendix A.4

3 Experimental Setup

3.1 Data

(a) Bribri and Wixarica: We use the training data 7K and 8K sentences, respectively from Feldman and Coto-Solano (2020) and evaluate on test data from Mager et al. (2021). **(b) Gondi**: We use 26k sentences from the data opensourced by CGNET Swara (CGNET, 2019) and split it into training and test sets.[2] **(c) Mundari:** We use a dataset of 10K sentences provided by Indian Institute of Technology, Kharagpur[3], and split it into training and test sets.[1] **(d) Assamesse, Odia, Punjabi and Gujarati**: We use the training data from Ramesh et al. (2022) (with 0.14M, 1M, 2.4M and 3M sentences, respectively) and evaluate on test data from FLORES200 Goyal et al. (2022) for Assamese and WAT2021 Nakazawa et al. (2021) for the remaining languages. Additional details about datasets (sizes and splits) are mentioned in the Appendix A.1.

3.2 Training Setup

Hyperparameters: We use the transformer and mT5 as our model classes as described previously in Section 2. The hyperparameters for our transformer model was optimized for fine-tuning of Odia, trained on 1M sentence pairs. For fine-tuning, we use the Adafactor optimizer (Shazeer and Stern, 2018), with a linearly decaying learning rate of 1e-3. Since training with smaller batches is known to be more effective for extremely low-resource language training (Atrio and Popescu-Belis, 2022), we tuned the training batch size for every language - varying from 32 to 256 (with gradient accumulation as 2) though we did not see very significant variation in the performance on the basis of this tuning. For our stopping criteria: we fine-tuned all models for 60 epochs (which concluded with considerably overfit models) and then selected models by we picking the checkpoint which had the best validation performance on BLEU (with only the 13a tokenizer which mimics the mteval-v13a script from Moses) (Post, 2018).

We use the sentencepiece tokenizer to build tokenizers for training the baselines for each of the languages (Kudo and Richardson, 2018). We use the per-token cross-entropy loss for fine-tuning all our models. Following Xu et al. (2021), we opt for a relatively smaller vocabulary size with the intent of learning more meaningful subword representations for our extremely low-resource languages. Specifically, we use a vocabulary size of 8K for Gondi, Mundari, Bribri and Wixarica, compared to 32K used for Assamesse, Odia Punjabi and Gujarati.

Experimental Setup for Distillation For Mundari and Gondi we utilize 500K Hindi sentences sampled from the Samanantar corpus (Ramesh et al., 2022); We use the corresponding English corpus to sample English sentences for generating the pseudo labels for Assamesse, Odia,

[2] To avoid any test-set leaks, we deduplicate the data by removing tuples (S^i, T^i) where S^i is the i^{th} sentence in the source language and T^i is $i^{th}$the sentence in the target language, between the train and the test set.

[3] Data to be released soon;

Punjabi and Gujarati. For Bribri and Wixarica - We use Spanish data made available by the Tatoeba Challenge (Tiedemann, 2020). We use the per-token cross-entropy loss for training our distilled models.

Evaluation Metrics: We use BLEU (sacrebleu with spm pre-tokenization (version 2.2.0)) (Post, 2018) for all our evaluations (Goyal et al., 2020). In addition to this, we also report chrF2 (Popović, 2016) for all our experiments for a more comprehensive comparison between the models.

4 Results

In section 4.1, we present the performances of our base models in Table 2. In the following section 4.2, we report the performances of the distilled HM in Table 3. Using these empirical results we focus on answering the following questions (a) To what degree can scaling the student training data improve the performance of the student model? (4.3) (b) How sensitive is distillation to the choice of the architecture of the student model? (4.4) (c) How can we choose an optimal teacher that is most suitable for compression? (4.5) (d) To what degree does the hyperparameter set suitable for distilling a model for one language transfer to another language? (4.6)

While answering these questions, we also analyze in parallel the performance of the quantized variants of these models implicitly indicating the reduced sensitivity of these variants from most of the previously discussed priors in spite of their competitive performances.

Language	Data	Vanilla transformer		mT5	
		spBLEU	chrF2	spBLEU	chrF2
Bribri	7K	1.7	11.6	**6.4**	19.3
Wixarica	8K	2.2	14.1	**6.2**	28.0
Mundari	10k	0.1	5.6	**15.9**	33.7
Gondi	26K	1.2	7.9	**14.3**	32.5
Assamesse	140K	0.8	12.4	**10.7**	30.4
Odia	1M	23.7	43.6	**27.4**	47.6
Punjabi	2.4M	**38.4**	50.6	34.8	44.1
Gujarati	3.05M	**35.9**	53.4	35.7	49.8

Table 2: Performance of our base models (transformer and mT5) without quantization or distillation. Best performing models out of the two architectures are marked in bold.

4.1 Analyzing the Baseline Models

As expected, the transformer models for target languages start competing (and outperforming) once an adequate amount of data is available for training the vanilla transformers. In addition to the obvious gain for being only optimized for target languages, the performance gains of these baselines can also be attributed to the language-specific tokenizer that they utilize, in contrast to the pretrained mT5 tokenizer that might be sub-optimal for language-specific generation. For our low-resource languages though, the advantage of transfer learning is clearly evident: all languages achieve a minimum and maximum performance improvement of 4 and 16 BLEU points. Gondi and Mundari, despite having relatively low-amount of data, perform well - though we expect an overestimation of their performance due to the homogenity between the train and the test set. Additionally though, both languages share scripts with a dominant language script i.e., Devanagari and hence, can be expected to gain because of that.

4.2 Analyzing the Compressed Models

In Table 3, we briefly present the performances of our distilled and quantized models. As evident, especially for the lowest-resource models, both distillation and quantization give competitive performance in addition to providing a significant size reduction. Note that Table 3 does not report the performance of the quantization of the vanilla transformer models for Odia, Gujarati and Punjabi even though they had competed or outperformed the mT5 variants. This is because they suffered a significant drop in performance - Odia dropped in performance to 8.4 BLEU/30.5 chrF2 in contrast to its HM scores of 23.7 BLEU/ 43.6 chrF2 respectively. Gujarati and Punjabi also dropped to 16 BLEU/31.2 chrF2 and 19.1/36.0 , respectively. To explain this we note what distinguishes these two architectures: (a) mT5 is deeper than transformer having 2 extra layers on the encoder's side than the vanilla transformer and (b) leverages multilingual pretraining. These attributes become useful in interpreting mT5 robustness to compression. In agreement with prior work like Li et al. (2020), deeper models can be expected to be more immune to compression. In fact, these models can be expected to be regularized by a certain degree through quantization, and we posit that we might be adopting a sub-optimal fine-tuning hyperparameter set for the initial fine-tuning of these models, consequently generating potentially overfit models and this gets mitigated to some extent upon quantization. Taking into consideration the lack of prior work on fine-tuning large LMs on such extremely low-resource languages and the infeasibility of running intricate hyperparameter sweeps per language with such large models, this can also be expected to degrade the quality of the labels generated for training the distilled models - ultimately affecting the performance that the distilled models achieve.

Language	HM	Distilled HM		Quantized HM	
	spBLEU	spBLEU	chrF2	spBLEU	chrF2
Bribri	6.4	6.8	13.2	**7.4**	19.4
Wixarica	6.2	4.1	17.3	**7.2**	26.8
Mundari	15.9	**18.2**	32.7	15.7	29.3
Gondi	14.3	**14.2**	32.8	13.8	31.1
Assamesse	10.7	**9.6**	27.4	6.2	25.7
Odia	27.4	20.2	40.7	**21.0**	41.3
Punjabi	38.4	**32.8**	46.6	27.0	48.0
Gujarati	35.9	**29.8**	48.6	28.4	51.4

Table 3: Performance of the HM for all languages after applying Distillation and Quantization. Best performing models out of both of the size adaptations are marked in bold.

In the following sections we focus on presenting our analysis of distillation's sensitivity to certain priors. In each section, we also discuss an analysis of the same priors' effect on quantization. Note that since the mT5 outperformed the vanilla transformer variants for all languages up till Odia - we distilled and quantized them for these languages. Also note that the HM for these languages is hence, mT5. Additionally, for Odia, Gujarati and Punjabi, we quantized both the mT5 and the vanilla transformer variants of the models.

4.3 Sensitivity to Priors: Data

The quality, quantity and the domain of data that the teacher or uncompressed variant of the model is trained on, appears to impact both the mechanisms of compression: For distillation the gold training data as well as the monolingual data utilized for generating student labels is of relevance, and for quantization only the gold data that the teacher is fine-tuned for, is of relevance.

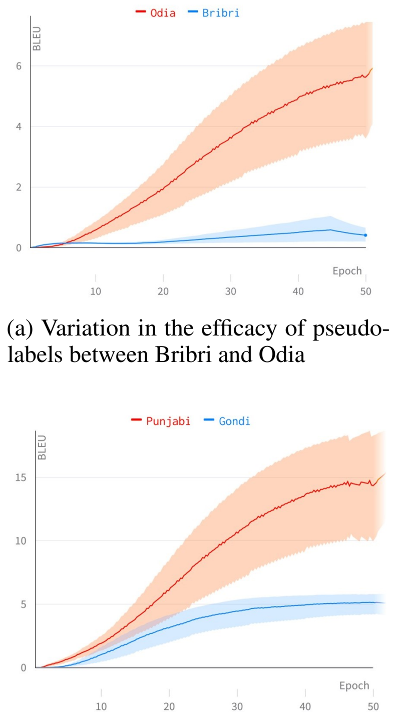
Quantity of Training Data Interestingly, quantization displayed consistent performance variations across the entire range of our low-resource language sets (all languages up till Odia), giving marginally close scores to the HM so at least within the data sparse languages we did not see any direct variation in the performance according to the amount of training data used. Both mechanisms show nearly equal degradation in performance for the HRL.

Quality of Training Data The quality of the data that the teacher is trained on affects the model's immunity to compression. This is best demonstrated by the post-compression performances of Gondi and Mundari in Table 3: In Gondi - the train set has nearly 26K sentences, which by the virtue of being collected via crowd-sourcing may be expected to be noisy. Mundari's training data, though also crowd-sourced, claims to have been validated manually after its collection by the providers to generate the final corpus of about 10K sentences. The observed difference where Gondi suffers a slight performance degradation post-compression and Mundari experiences a significant performance gain, may be attributed to the difference in the quality of their training data. Note that both languages are being translated from the same source language, share the same script and are being tested on a correlated test set - so the quality and quantity of training data are expected to be major contributors to the variations in their performance.[4]

Quantity of Pseudo-Labels used for Student's Training Results of our analysis of scaling student data between 100K to 500K are presented in Figure 1. More data seemed to help for the entire spectrum of languages - though it is evident that the gain in the performance diminished in proportion to the amount of added data as we approached the lowest-resource languages in our set. The gain in performance upon the addition to 250K samples to a HRL like Odia or Punjabi is significantly more pronounced than the gain in performance for Bribri or Gondi - where there is a very marginal improvement in the performance upon the addition of 250K samples. This could be indicative of the diminishing efficacy of the increasingly noisy data that was generated by the lowest-resource teachers. We explore this notion in more depth in Section 4.5.

Domain of Data While we do not perform any targeted experiments to evaluate the domain dependence of the two compression mechanisms - we posit that the distilled models' significantly better performance than its quantized variant in As-

[4] The two languages do belong to two different language families - Gondi belonging to the Dravidian language family which has a higher representation in the pretraining corpus for mT5, and Mundari being Austro-Asiatic



(a) Variation in the efficacy of pseudo-labels between Bribri and Odia

(b) Variation in the efficacy of pseudo-labels between Punjabi and Gondi

Figure 1: Min/Max range curves of the performance of the models trained on scaled data: The shaded range is considerably lower for the lowest-resource languages indicating reduced efficacy of scaling student data.

samesse could be attributed to the distilled model's exposure to the diverse-domain data during the student's training. Note that the testset used in Assamesse, FLORES 200 (Goyal et al., 2022), is claimed to be of a very diverse-domain origin. Given this, the process of training a student on monolingual data of a potentially more diverse origin to that of the native training set - would explain the gain that the language demonstrates on a domain-agnostic testset. Prior work like Mghabbar and Ratnamogan (2020) already shows distillation's efficacy in enabling students to adapt to out-of-domain data that the teacher may not have ever been exposed to. Quantization on the other hand, has no opportunity for exposure to any out-of-domain data - so its adaptation and performance across a domain-agnostic testset can be expected to only degrade.

4.4 Sensitivity to Priors: Student Architecture

We find that distilled student models could be adversely sub-optimal for a given language, despite being sub-optimal or even an optimal choice for a large subset of languages. To demonstrate this

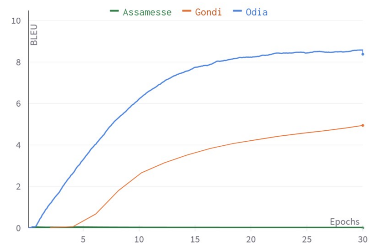


Figure 2: Variation in BLEU due to difference in the choice of a student architecture: An optimal architecture choice for Odia and Gondi gives adversely sub-optimal performance for Assamesse

in Figure 2, we show the performance of two distilled models on an identical hyperparameter set and student architecture. While the chosen student architecture gives competitive performances for Gondi and Odia, Assamesse performs significantly worse for this candidate architecture. We did attempt retraining the model with a different seed to negate the possibility of a randomly poor initialization though this did not improve the convergence. While we did not notice such a drastic performance variation across any other candidate set, this instance did indicate brittleness to the student-architecture for a given language. After these sweeps, we fixed a transformer-based encoder with 6 layers and a transformer-based decoder with 4 layers as the distilled model for our further experiments.

4.5 Sensitivity to Priors: Confidence of the Teacher Model

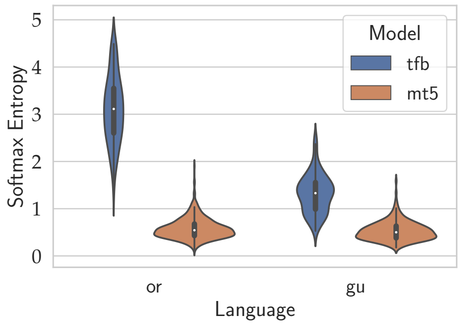

Figure 3: Entropy distributions of mT5 and transformer: lower-entropy indicates high-confidence and consequently suggest higher-quality of translations.

Estimating the confidence of our teacher models displayed manifold benefits: Within Distillation, it helped us get an indirect estimate of the quality of the training data that the student model was trained on. Within Quantization, it was useful in analyzing why the mT5-variants were more robust to quantization. Note that since the testsets for all the languages are of varying difficulty - doing a language-wise comparison on the basis of such metrics was non-trivial since the confidence predictions could also vary in accordance with the complexity of the testsets being evaluated upon. Hence, we majorly focused on analyzing languages which were either evaluated on the same test set (Gujarati, Punjabi, Odia with WAT21 testset (Nakazawa et al., 2021)) or the different architectures for each of our languages which could be evaluated for the same testset.

Figure 3 demonstrates the difference in the entropy of the softmax distributions of the mT5 and transformer teacher variants. Note that this is for Gujarati and Odia, our highest resource language, for which both architectures perform quite competitively and the vanilla transformer even outperforms the mT5.

As is evident, the mT5 variant has much lower entropy scores, with lower dispersion indicating high-confidence in the predictions it produces for each of the samples. Note that the inference pipeline for both architectures is identical - Greedy Search with no sampling so we don't expect any difference in the decoding mechanism to affect the quality or distribution of representations that we are monitoring. This is a very interesting observation, as both models appear to perform comparably according to our automatic metric evaluations - yet differ quite significantly in the stability with which they generate these predictions.

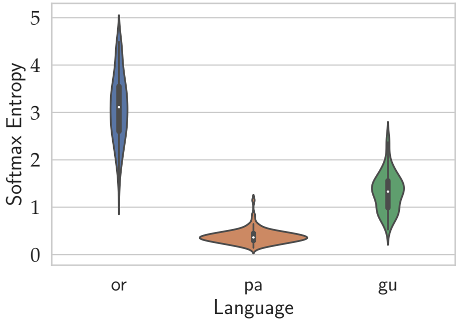

Figure 4: Entropy distributions for transformer across different languages: Models become increasingly more confident about their predictions with an increase in training data

Next, we attempt to establish if training with more data makes a model more confident in its prediction. Figure 4 demonstrates the entropy scores for Odia, Punjabi and Gujarati. Each of these have data increasing in the order of 1M, 2.4M and 3M respectively. Here we observe that indeed, models trained with more data achieved consistently lower entropy scores.

4.6 Sensitivity to Training Hyperparameters

In this section we present results of evaluating if an adequate hyperparameter set for a given language may be suitable for generating an optimal variant for another distilled language. Here too, we demonstrate using a subset of our hyperparameter sweep that there can be a marked degradation in the suitability of an averagely optimal hyperparameter set (that might be close to optimal to multiple languages with similar attributes) to an unseen language;

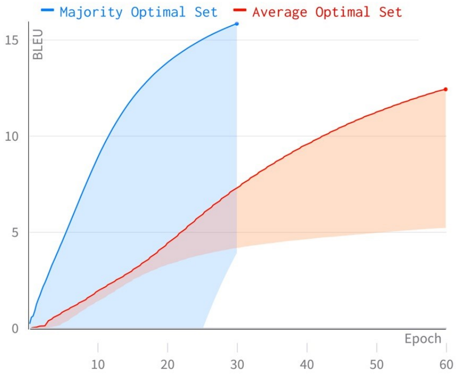

Figure 5: Min/Max range of performances of Gujarati, Bribri and Assamesse across a hyperparameter set that is optimal for these languages but adversely sub-optimal set for Gondi

In Figure 5, when tuned for the hyperparameter set that is optimal for a majority of languages in our set, Gondi does not even converge as a result of which the lower-bound of a teacher's performance for that hyperparameter set is 0. Note that this hyperparameter set transferability does not seem to show any specific data oriented trends as well. For instance, the same hyperparameter set that was optimal for Gujarati, our highest resource language with 3M data points, is only slightly sub-optimal for Bribri, our lowest resource language with 7000 data points, and Assamese, our mid-resourced language with 135K sentences. Also note that we were able to get acceptable performance for Gondi with almost an identical hyperparameter setup with a larger batch size (quadrupled to the one in this setup) indicating that a per-language sweep would be an ideal and acceptable solution even though this would imply that distilling models would mandate a significant hyperparameter tuning for achieving optimal performance. A detailed list of what hyperparameters we sweeped through can be found in the Appendix Table 5.

5 Takeaways

We encapsulate the learning from our analysis as the following takeaways:

1. ***Data Dependence of the Method of Compression:*** Training teacher models with lesser quantity, higher quality data is expected to improve a model's robustness against both quantization and distillation. The post-quantization performance suffers equally for models trained with varying degrees of data. This is not the case with distillation, where increasing the amount of training data for student distilled models starts providing diminishing returns as the amount of training data for the teacher reduces.

2. ***Cost of Compression:*** Distillation is quite sensitive to its training hyperparameters and the student's architecture. This choice doesn't necessarily follow any data-oriented trends as well i.e., languages having similar amount of data may perform very differently on similar hyperparameter and student architecture sets. Hence, Distillation mandates a significant hyperparameter tuning cost that Quantization does not incur.

3. ***Stability of Compression*:** Hard Distillation and Post-Training Quantization are both promising methods of quickly compressing massively multilingual models for machine translation for extremely low-resource languages. Post-Training Quantization should be preferred when the uncompressed variants is pretrained and/or deep, expected degree of compression is upto 4x the original model's size and the cost of compression is to be minimum. Distillation, on the other hand, should be preferred when domain-expansion, language-specific tokenization and more than 4x degree of compression needs to be achieved at the cost of a tuning for optimal architecture and training setup selection.

6 Related Work

Owing to the known benefits of compressing language models due to their lower-memory footprint, improved inference speed and even improved performance in some cases, compression techniques have been explored widely in NLP.

Quantization While the work on quantizing encoder-models is replete (Zafrir et al., 2019; Bondarenko et al., 2021; Kim et al., 2021; Zadeh et al., 2020) the focus on quantizing decoder-only models (Tao et al., 2022b), and specifically seq2seq models has been relatively much lower. Recent work like, EdgeFormer, (Ge and Wei, 2022), LLM.int8() (Dettmers et al., 2022) have recently demonstrated the generation of seq2seq quantized models which provide a high-compression ratios and competitive performances though this work has also been done with much higher resource languages.

Distillation Work within distillation is replete, even for the multilingual-type of models that we focus on. Work like Kaliamoorthi et al. (2021); Jiao et al. (2021); Yang et al. (2022) represent the major body of work in multi-lingual distillation - that is also centered across the encoder-only space. Relatively lesser work has been done in the space of mutli-lingual distillation (Soltan et al., 2021; Mukherjee et al., 2021) of seq2seq models and even though work like Zhang et al. (2020); He et al. (2019) extends this analysis to relatively low-resource languages, they rely on the use of monolingual data for the target language, a luxury that we cannot afford for half of the languages in our language set.

Note that since both processes are orthogonal, their conjunctive use has also been explored - Tao et al. (2022a) for instance, get competitive results by applying token level contrastive distillation and module-wise dynamic scaling while quantizing generative models. Note that we made the conscious decision of excluding pruning from our analysis because while it is known to demonstrate very effective parameter reduction, it is generally not as aggressive in it's memory footprint reduction as much as quantization and distillation (Behnke and Heafield, 2020; Mohammadshahi et al., 2022). As we'll discuss further in section 7, size-reduction was an implicit focus of this work that is one of the most fundamental bottlenecks of community deployment A.4.

7 Discussion

While this work explicitly focuses on only the performance comparison between distillation and post-training quantization, it's efficacy can also be viewed in demonstrating the development of lightweight, machine translation models for extremely low-resource languages. This is a very critical outcome as Performance-oriented Machine translation (MT) models for low-resource languages are often not suited for the immediate consumption of the community. The access bottleneck introduced by these bloated models, can especially affect those communities which haven't traditionally enjoyed access to a digital ecosystem, often widening the gap between those who can and cannot access these tools. Towards this direction, the exploration of compression strategies for these models - especially when tied to end-user centric NLP services such as translation is imperative. In this work, the size of all models being evaluated after compression was less than 400MB - the quantized models are at least 3x lighter the size of the native HM and the distilled models give even more impressive gains of upto 8x smaller than their uncompressed counterparts. This size reduction, coupled with the increased speed of inference associated with this reduction in most cases can enable a suite of accessible translation models for these languages[5]. This establishes a very promising potential in achieving deployment-constraint aware models: For instance, in areas where users do not enjoy a sustained access to the internet - these lightweight models may be adapted to operate on edge in an offline fashion.

8 Conclusion and Future Work

In this work we established that hard-distillation is sensitive to several priors which makes it a brittle mechanism of compression, especially for languages with extremely low-resources. In relative comparison, post-training quantizaton provides a competitive, stable and cost-effective compression mechanism that works effectively for extremely low-resource languages as well. Moving forward, we wish to explore the effect of using additional data (augmented or natively available) on the compressed variants of these models and extend distillation's analysis to utilizing logit distributions of the teacher (soft-distillation). Having observed the poor confidence measures of the transformer - and it's relatively random distributions we expect to get more interpretable evidence towards the suitability of these models for soft distillation through such an analysis.

[5] A more detailed description of the sizes of these models and the associated inference patterns is provided in the Appendix A.4

Acknowledgements

We sincerely thank the reviewers for their detailed feedback on the work which greatly helped us improve the quality of this work. Additionally, we thank Indian Institute of Technology, Kharagpur for giving us access to the Mundari data. Finally, we also thank Anurag Shukla for helping formalize the quantization pipeline and Kabir Ahuja, Sumanth Doddapaneni and Naman Jain for all the helpful discussions.

A Appendix

A.1 Details of Data Sources

For all the languages in Table 1 we now describe the training and evaluation corpora used. Note that for languages like Assamesse, Odia, Punjabi, etc. we could have accessed a monolingual corpus to supplement our training as well but since we wouldn't have been able to leverage data at a similar scale and quality for the entire language set, we abstained from using methods that leveraged monolingual corpora in these languages.

Bribri Training data from Feldman and Coto-Solano (2020) containing about 7K parallel sentences. Test data from Mager et al. (2021) with 1003 sentences.

Wixarica Training data from Feldman and Coto-Solano (2020) containing about 8k parallel sentences. Test data from Mager et al. (2021) with 1K sentences.

Mundari We requested Indian Institute of Kharagpur for Data on Mundari. This corpus contained 10K parallel sentences. We partition train and test sets from this and generate a test set of 980 sentences [6]

Gondi Data obtained from CGNET (2019) containing 26K sentences. We partition train and test sets from this and generate a test set of 730 sentences6.

Assamesse Train data obtained from Ramesh et al. (2022) containing 0.14 parallel sentences. Test data from (Goyal et al., 2022) containing 1012 sentences

[6] To avoid any test-set leaks, we deduplicate the data by removing tuples (S^i, T^i) where S^i is the i^{th} sentence in the source language and T^i is $i^{th}$the sentence in the target language, between the train and the test set.

Odia Train data obtained from Ramesh et al. (2022) containing 1M parallel sentences. Test set from WAT2021 (Nakazawa et al., 2021) containing 2390 sentences

Punjabi Train data obtained from Ramesh et al. (2022) containing 2.42M parallel sentences. Test set from WAT2021 (Nakazawa et al., 2021) containing 2390 sentences

Gujarati Train data obtained from Ramesh et al. (2022) containing 3.05M parallel sentences. Test set from WAT2021 (Nakazawa et al., 2021) containing 2390 sentences

A.2 Evaluating Continued Pretaining with Synthetically Augmented or Lexicon Adapted Monolingual Data for improving the HM

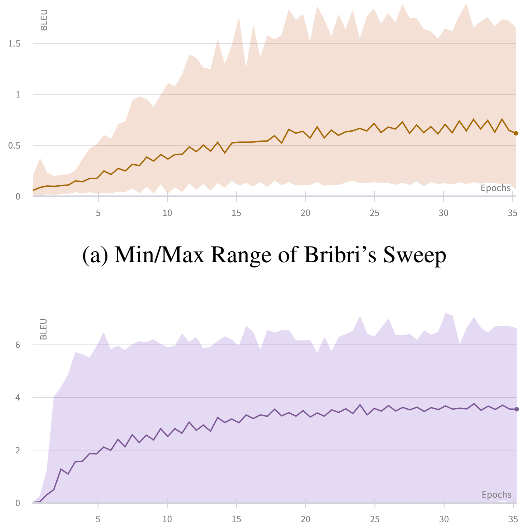
The use of continual pretraining with monolingual data has been shown to be very useful in improving the transfer for low-resource languages. In our cases, our lowest resource languages, i.e, Bribri, Wixarica, Gondi and Mundari, did not have any monolingual data available natively so we explored the augmentation of the same using lexicons (Wang et al., 2022). We also generated forward translated data using the HM that we developed to fuse with the lexicon-adapted data. For continued pretraining we use a fixed learning rate of 0.001. Results of our experiments are logged in Table 5.We use the following notations to report our results GMD- *Gold Monolingual Data,* LA- *Lexicon Adapted Monolingual Data,* KDD- *Knowledge Distilled Monolingual Data* where GMD indicates the target-side monolingual data available within the parallel corpus of the language, KDD indicates the forward-translated data that we generate via our best-performing model for Gondi i.e., mt5-base. We generated 100K labels using mt5-base teacher, and also experimented adding 100K sentences from a weaker teacher, i.e., mt5-small in hopes of leveraging a more diverse class of labels to train the student on.

We did observe a small gain in performance upon the addition of LA data during pretraining - though the post-quantization performance and the distilled model' significant performance degradation called for a deeper investigation on the effects of continued pretraining for this language.

A.3 Hyperparameter Trial Configurations

We ran Hyperparameter sweeps with the configurations specified in Table 5.

Note that in congruence with the observations of subsection 4.6, we also provide the min-max range of performance for Gondi and Bribri in Figure 6.



(a) Min/Max Range of Bribri's Sweep

(b) Min/Max Range of Gondi's Sweep

Figure 6: Variation of performance across languages

As can be observed, for a set of hyperparameters, at least one of which is optimal for some other language in the set, both languages fail to converge. Similarly, in extension to subsection 4.4, we also checked if for the same hyperparameter set, the variation in student architecture produced significant performance variations.

The results demonstrated in Figure 7 did not show any significant variation except for the case of Gondi, i.e., altering the student architecture - while keeping all other priors the same: adversely affected the performance in that one case.

A.4 Comparing Size-Reduction Affinity of Quantization and Distillation

This exploration is extremely useful as the size of a model significantly impacts several factors associated with the consumption of any service, impacting it's adoption by community members through several ways including *(a) Accessibility on Edge:* Since mobile devices are constrained in their RAM and Memory Usage - users with edge devices of low-capabilities are naturally inhibited to is services that drain their device's resources. *Inadequate Connectivity Requirement for Inference, One-time download and Service Updates:* Users

may often avoid downloading apps that seem too large, particularly in emerging markets where devices connect to often-spotty 2G and 3G networks or work on pay-by-the-byte plans [7]. *Large Rendering Time:* Finally, a bloated size may often be associated with a larger rendering response period which might hinder the usability experience of a user engaging with the MT service.

Note on Inference Times In theory, compression through both distillation and quantization is expected to be conducive to faster inference for the models: The distilled models are not bounded to use a pretrained embedding and hence can gain in inference by using smaller, target-language specific embeddings. The quantized models can also benefit due to the reduced precision in which the inference operations are carried out, though this optimization is heavily dependent on if the hardware running the model can leverage these operations in

their expected precision (Bondarenko et al., 2021). Especially in the case of quantization, the scope of this analysis would be quite vast, which is why we also excluded it from our current analysis.

Data Augmentation for Inline Tag-Aware Neural Machine Translation

Yonghyun Ryu, Yoonjung Choi, Sangha Kim
Samsung Research
Seoul, Republic of Korea
{yonghyun.ryu, yj0807.choi, sangha01.kim}@samsung.com

Abstract

Despite the wide use of inline formatting, not much has been studied on translating sentences with inline formatted tags. The detag-and-project approach using word alignments is one solution to translating a tagged sentence. However, the method has a limitation: tag reinsertion is not considered in the translation process. Another solution is to use an end-to-end model which takes text with inline tags as inputs and translates them into a tagged sentence. This approach can alleviate the problems of the aforementioned method, but there is no sufficient parallel corpus dedicated to such a task. To solve this problem, an automatic data augmentation method by tag injection is suggested, but it is computationally expensive and augmentation is limited since the model is based on isolated translation for all fragments. In this paper, we propose an efficient and effective tag augmentation method based on word alignment. Our experiments show that our approach outperforms the detag-and-project methods. We also introduce a metric to evaluate the placement of tags and show that the suggested metric is reasonable for our task. We further analyze the effectiveness of each implementation detail.

1 Introduction

While most machine translation studies are focused on plain text, the textual information that we encounter every day on the internet contains words with different styles and links within the sentence. Various styling of any part of the text is called inline formatting and is represented by markup and markdown tags. The inline formatting not only improves the readability of documents but also provides additional information with tags; so it is important to correctly translate sentences including tag information. In addition, the widespread use of formatting tags in the computer-based document system makes it inevitable to increase the demand for translating web text or structured documents containing inline tags.

There are two main approaches to translating segments with inline tags. One solution is the detag-and project method (Hanneman and Dinu, 2020). It first strips tags from the source sentence and translates only the plain text. Then, the removed tags are reinserted into the translation results using word alignments, which can be induced from attention weight in the model or an external aligner such as SimAlign (Jalili Sabet et al., 2020). This method does not take into account the re-insertion of tags in the translation process, making it difficult to restore tags at the proper positions.

Another way is to use an end-to-end model which takes sentences including tags as inputs and generates translation results with tags. Since tag information is considered, the translation can be performed with more context, thus this method potentially improves the quality of translation and the placement of tags. To train end-to-end models, a parallel corpus, where both source target sentences contain aligned tags, is required. Even though a parallel corpus with markup tags was released by Hashimoto et al. (2019), their data is limited to the domain of online help and there is still not many of such data available to train a high-quality model.

To address this lack of tagged parallel corpus, Hanneman and Dinu (2020) introduces a data augmentation approach using tag injection. Their method is to insert tags into corresponding fragments in the source and the target. In their approach, the aligned phrases are identified by an exhaustive search by matching all translated source fragments with all target fragments. This method has two drawbacks by its nature. The first is that their approach requires a high computational cost because it requires computing translation for all possible phrases for at least millions of parallel sentences to train a model. Secondly, only constrained tags can be augmented because they find corresponding pairs with out-of-context translation.

In this paper, we propose an efficient and effec-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 886 - 894
December 7-8, 2022 ©2022 Association for Computational Linguistics

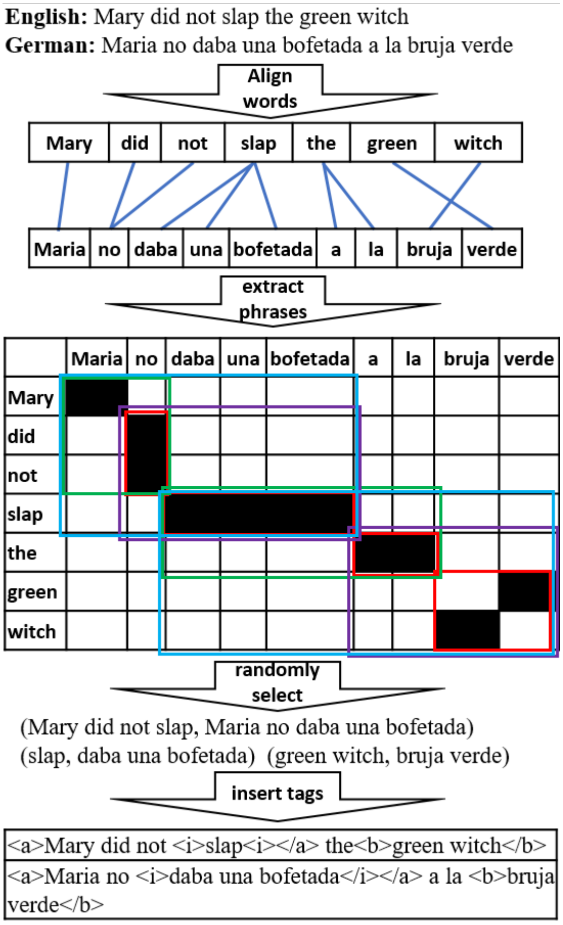
tive tag augmentation method using word alignments (Brown et al., 1993) to overcome the above shortcomings. Our method uses an external word aligner to compute correspondence between the source and target words, and find aligned fragments by phrase extraction algorithm (Och et al., 1999). Then tags are inserted according to the phrasal alignments. The tag-augmented parallel corpus by this method can train a model that translates sentence containing tags in an end-to-end way.

For comparisons, we implement competitive baselines and propose a metric to automatically evaluate the placement of tags. Through experiments, we show that our approach is superior to the detag-and-project methods and demonstrate the effectiveness of each implementation detail.

2 Method

In this section, we propose an efficient and effective method to insert inline tags into an existing parallel corpus. In augmented data, the position of tags in the source segment must be preserved in the target segment. The word "*preserved*" means that tags in the target sentence must surround spans with the same role and meaning as the corresponding source spans. In other words, the source and target fragment in the same tag has to correspond with each other. Moreover, inline tags can contain not only a word but also a phrase or even any consecutive words. Therefore, how to find corresponding phrase[1] pairs for each parallel sentence is the key to synthesizing tag-aligned parallel data. This makes our method focus on finding aligned phrase pairs.

Our proposed augmentation method consists of three steps. We first generate word alignments for the parallel corpus using external word aligners (Section 2.1). Then we extract aligned phrase pairs for each sentence pair with the word alignments (Section 2.2). Lastly, for each parallel sentence and the aligned phrase pairs, since each sentence usually has a lot more aligned pairs than the number of words in the sentence, we randomly select some of the pairs and insert tags to surround the phrases (Section 2.3). Figure 1 presents the whole process of our methods. The example is from Philipp Koehn's lecture[2].



English: Mary did not slap the green witch

<a>Maria no <i>daba una bofetada</i></a> a la <b>bruja verde</b>

Figure 1: The process of our methods.

2.1 Word Alignment

Word alignment represents word-level correspondence in a parallel sentence. In statistical machine translation, implementation of IBM models (Brown et al., 1993) such as FastAlign (Dyer et al., 2013) and GIZA++ (Och and Ney, 2003) are famous to compute word alignment from parallel corpus. As deep neural network-based aligners, there are SimAlign (Jalili Sabet et al., 2020) and AwesomeAlign (Dou and Neubig, 2021). These neural methods use the similarity of contextual embeddings based on pretrained multilingual models to compute the correspondence between source and target words.

Our approach starts by using one of the above external word aligners to compute forward (source-to-target) and backward (target-to-source) word alignment, and then apply symmetrizing heuristics (Koehn et al., 2005) such as `grow-diag` and `grow-diag-final-and` for better alignment.

[1] In this paper, the word "*phrase*" indicates consecutive words of any length. The length can be 1 and more.

[2] https://wiki.eecs.yorku.ca/course_archive/2014-15/W/6339/_media/esslli-slides-day3.pdf

2.2 Phrase Extraction

The phrase level alignment has been proposed in Och et al. (1999) to improve statistical machine translation.

We find aligned phrase pairs depending on word alignments with phrase extraction algorithms. The phrase extraction algorithm finds phrasal alignments by exhaustively searching all phrase pairs that are consistent with word alignment. For the detailed algorithm description, please see the NLTK implementation (Loper and Bird, 2002)[3].

We do not use phrase probability tables (Koehn et al., 2003) to refine aligned pairs since it prevents the collection of diverse kinds of phrases. Instead, we do not allow phrases with unaligned words for more accurate phrase extraction[4].

2.3 Tag Insertion

In this step, we insert tags that surround aligned phrase pairs. The number of tags is randomly selected to less than 30% of the number of words. Then the aligned phrase pairs are randomly chosen as many as the number of tags, and tags are inserted according to the pairs. In this process, we can insert tags following the HTML syntax, and the tags can be nested.

2.4 Augmentation Cost Analysis

The cost of augmentation is crucial since machine translation models typically are trained on more than millions of parallel sentences. For this reason, we roughly analyze the amount of computation to show that our method is cost-efficient over the previous approach.

The previous tag augmentation method suggested in Hanneman and Dinu (2020) uses a machine translation model to find corresponding fragments with exhaustive search. Their method needs at least $O(n * m)$ translation model inferences for each parallel sentence, where n is the size of the maximum corresponding phrase length and m is the number of tokens in the source.

Assume that our method use SimAlign (Jalili Sabet et al., 2020) for a word aligner. Our approach requires one XLM-R (Conneau et al., 2020) inference to compute contextual word embeddings and single matrix multiplication to get cosine similarities between tokens. Since single XLM-R inference cost much to single matrix multiplication, we can count single XLM-R inference as the amount of computation. Alignment symmetrizing heuristic algorithms and phrase extraction are also required for our approach, but we do not count it to time comparison since these algorithms also take much less time than neural model inference.

Because the translation model uses beam search, both XLM-R and a translation model have almost the same computation cost, but the translation has more latency because it is autoregressive. In short, the previous method needs $O(n * m)$ translation model inference but our approach only requires a single XLM-R inference for each sentence pair. Therefore, our model is more efficient than translation-based augmentation.

3 Experimental Setup

3.1 Data

3.1.1 Training Data

Our data augmentation goal is to train an end-to-end model to translate inline tagged text with competitive translation quality. For a fair comparison of translation performance, we use the same training and test sets as Edunov et al. (2018) and Garg et al. (2019). The tagged parallel corpus released by Hashimoto et al. (2019) is also used to evaluate the placement of tags.

WMT'18 This dataset is a set of parallel corpora for the WMT'18 English-German news translation task (Bojar et al., 2018) and consists of the Europarl v7, common crawl, news commentary v13, and rapid corpus of EU press releases. Parallel sentences with either a sentence longer than 250 tokens or a source/target token length ratio exceeding 1.5 are removed[5].

LXM In this paper, we call the dataset released by Hashimoto et al. (2019) **LXM** which is their GitHub repository name's initials[6]. The data have parallel sentences with aligned inline tags. For German-to-English, there are about 100,000 train pairs and 2,000 development pairs. Only about a quarter of them contain tags.

[3] https://www.nltk.org/_modules/nltk/translate/phrase_based.html

[4] The original phrase extraction implemented in the NLTK includes unaligned words in the aligned phrase since it is still considered to be consistent with word alignment.

[5] We use the XLM-R tokenizer to filter the parallel corpus.

[6] https://github.com/salesforce/localization-xml-mt

LXM-plain This data is the **LXM** training data without tagged pairs. Since the domain of LXM is online help and WMT'18 corpora do not cover them, thus we add this data to training data. In this paper, we prove the effectiveness of the tag augmentation approach, thus we only use plain sentences from the training set.

3.1.2 Test Data

For comparison of our approach to the previous works, we use newstest2014 (**WMT'14**) to evaluate translation quality and LXM development set (**LXM-dev**) for the accuracy of tag placement.

3.2 Naive End-to-end Baseline

This baseline takes text with markup tags as inputs and handles them like plain text but uses a model which has been trained without tagged parallel corpus.

3.3 Detag-and-project Baselines

The detag-and-project approach (Hanneman and Dinu, 2020) first strips tags from the source sentence, translates the plain one, and then places the removed tags in the corresponding positions according to the word alignments. During the projection stage, one tag can be projected into separated parts, in this case, we insert one minimum-sized tag that surrounds all of the parts, which is also called the Min-Max Tag Pair Projection in Zenkel et al. (2021).

We establish three detag-and-project baselines according to the way to get word alignment.

Layer Average Baseline The layer average baseline is to extract word alignments from the attention. There are two methods to induce word alignments from the attention (Chen et al., 2020): NAIVE-ATT and SHIFT-ATT. Word alignments are induced from attention scores between the encoder and decoder. NAIVE-ATT (Garg et al., 2019) relates the maximum attention scores with the decoder's output token and uses attention weight of the penultimate layer of the decoder. SHIFT-ATT (Chen et al., 2020) associates the maximum attention scores with the decoder's input token and uses attention weight of the third layer of the decoder.

Garg et al. (2019) This baseline can be simply called attention enhanced approach. Like the layer average baseline, this method also extracts word alignments from attention scores, but it uses the trained attention head by multi-task learning. Specifically, one attention head of the fifth layer of the decode is jointly trained with translation by word alignments from GIZA++ (Och and Ney, 2003). Furthermore, full target context is used when the attention weight learns word alignments and predicts alignments from cross-attention. We re-implement the model by the author's Fairseq (Ott et al., 2019) implementation[7] to reproduce their results. In this paper, we do not apply any pre-tokenizer, and only use an unigram language model tokenizer (Kudo, 2018) with a vocabulary size of 35,000. All other hyperparameters are the same as Garg et al. (2019).

SimAlign This method uses SimAlign (Jalili Sabet et al., 2020) as an external aligner to restore tags on the translation results. For this model, the layer average baseline model is used to generate translated sentences. We take **argmax**[8] function to extract each direction of word alignment and apply `grow-diag-final-and` heuristics (Koehn et al., 2005) to symmetrize the bidirectional alignments for better word alignments.

3.4 Implementation Details

Reversible Tokenization The previous works use Moses tokenizer (Koehn et al., 2007) as a pre-tokenizer before applying Byte-Pair-Encoding (Sennrich et al., 2016). However, we don't use any pre-tokenizers like Moses because it is impossible to detokenize tokenized results to the original sentence completely even if a well-designed rule-based detokenizer is applied. We only apply SentencePiece (Kudo and Richardson, 2018) for tokenization, because it is a reversible tokenizer and makes a purely end-to-end system possible. A unigram language model tokenizer (Kudo, 2018) is trained from the WMT'18 corpus only without applying subword regularization.

Whitespace Shift As SentencePiece (Kudo and Richardson, 2018) tokenizer adds dummy whitespace at the beginning of a sentence, we move the whitespace before the tag to the back of the tag since the whitespace at the beginning of a word plays an important role in tokenization because the whitespace is also considered a target to tokenize by the subword tokenizer. A word without whitespace at the beginning is often tokenized differently from a word with a whitespace. For example, "World" is

[7] `https://github.com/facebookresearch/fairseq/tree/main/examples/joint_alignment_translation`

[8] Argmax aligns words to the most similar word.

Tag Shift	29.1	53.37	52.07	100	99.35	53.75

Table 1: Evaluation results on the WMT'14 and LXM-dev. Models are trained with WMT'18 and LXM-plain by default. In *Tag Shift*, all tags are moved to one word to the left in the translation hypothesis.

tokenized into "Wo", "r", "ld", however, "_World" is tokenized into "_Wor", "ld". This inconsistency affects adversely translation quality. For this reason, we move the space and put it back in the pre- and post-processing step.

Tag Replacement Markup tags often have attributes and the attributes generally don't need to be translated and just copied to the translation. Like other approaches (Müller, 2017) and (Hanneman and Dinu, 2020), we replace the real tags with indexed special tags. We insert at most 9 tags per each parallel pair in tag augmentation. In our implementation, we use "<a_0>,<a_1>,...<a_9>,</a_0>,</a_1>,...</a_9>" as special tokens. In the training step, the index of special tokens is shuffled for training efficiency. In the inference, we convert real tags to the special tokens and the convert table in the pre-processing step. After translation, we revert them to the original tags in post-processing.

Tag Augmentation Hyperparmeters We use subword alignments instead of word alignments since according to recent studies (Garg et al., 2019) (Jalili Sabet et al., 2020), and (Dou and Neubig, 2021); subword-based alignments outperform word alignments on AER (Alignment Error Rate). Since our SimAlign baseline uses the XLM-R model (Conneau et al., 2020), for a fair comparsion, parallel corpus is tokenized by the XLM-R tokenizer[9] before computing word alignment with statistical models.

Like Garg et al. (2019), for our augmentation, Giza++ with 5 iterations of IBM1, HMM, IBM3 and IBM4 are used as a word aligner. However, for training an end-to-end model, we use a different tokenizer as explained in 3.4. For end-to-end training, we use the combination of tagged data and plain data in a 1:1 ratio.

Model Training Hyperparameters Basically for all experiments, we follow the same hyperparameters as the Align and Translate Task of Garg et al. (2019). We use the fairseq toolkit (Ott et al., 2019) for all of our experiments. The big transformer architecture[10] with the post layer normalization is used for all experiments. The difference is that we use learning rate of 5e-4, learning rate warmup over the first 8000 steps, and a batch size of 32768 tokens[11] on 8 A100 GPUs for 120k updates. We use the checkpoint which averages the last 10 checkpoints, and a beam size of 5 for inference.

4 Evaluation

In this section, we describe several metrics to evaluate our methods and present experimental results.

4.1 Evaluation Metrics

For comparison of translation quality to Garg et al. (2019) and Edunov et al. (2018), we use

[9] They use SentencePiece tokenizer and the model can download in `https://github.com/facebookresearch/XLM`.

[10] The architecture name we used in faisreq is `trasnformer_wmt_en_de_big`.

[11] Actually, we use 16384 tokens with accumulating 2 update gradients.

	WMT'14	LXM-dev			
Variation	**BLEU**	**BLEU**	**XML BLEU**	**XML Match (Acc.)**	**F1**
Baseline	29.1	53.37	52.8	99.35	74.31
w/o Tag Replacement					
trained on plain corpus	28.8	51.05	49.9	98.2 (98.6)	58.93
trained on tagged corpus	28.7	52.44	51.62	99.05 (99.85)	71.14
Symmetric Heuristics					
`intersection`	29.2	53.13	52.4	99.2	60.13
`grow`	28.9	53.21	52.52	99.2	74.73
`grow-diag-final-and`	29.0	53.11	52.39	99.2	75.35
Phrase Length					
8	28.8	53.33	51.9	99.05	72.07
16	28.9	53.17	52.86	99.45	73.61
32	29.1	52.85	52.25	99.25	73.12
128	28.9	52.92	52.55	99.45	72.84
Word Aligner					
Fast-Align	29.0	52.89	52.14	99.2	72.99
SimAlign	28.9	52.99	52.41	99.15	73.5
w/o whitespace shift	28.6	52.88	52.26	99.4	71.77
NLTK phrase extraction	28.9	52.85	51.96	99.3	72.48
Violating HTML syntax	29.1	53.09	52.29	99.2	72.58
Tagged data only	28.5	52.59	51.66	99.35	72.27

Table 2: Variations on tag augmentation. The baseline uses `grow-diag` heuristics, phrase length of 64, GIZA++ as a word aligner, and improved phrase extraction. The score on XML Accuracy is not mentioned because all scores are 100. *w/o whitespace shift* do not apply whitespace shift in the training and inference.

sacreBLEU (Post, 2018) with **WMT'14**. Like Hashimoto et al. (2019)'s work, we use BLEU, XML BLEU, XML Accuracy, and XML Match as metrics in the evaluation of LXM-dev. We also use the same evaluation scripts as they do[12]. For accurate evaluation of the tag placement, we introduce an F1 score-based metric to evaluate the position of tags by focusing on the words that tags surround.

BLEU and XML BLEU The BLEU score here is the same as the existing BLEU score measured in plain text. For that, all tags first are removed if exist, and then the BLEU is measured using the same tokenizer as Hashimoto et al. (2019). The XML BLEU uses the same metric, but if there are tags, the BLEU score is measured with text containing XML tags. The XML tags are also considered to compute the score.

XML Accuracy and Match The XML accuracy is the ratio of the valid XML outputs in all translation results. The XML match is the ratio of the outputs that have the same XML structure as the reference.

F1 score This metric is introduced to evaluate the placement of tags. Since the goal of tag transfer is to surround the corresponding words accurately, we introduce a metric to focus on evaluating words surrounded by tags. In this sense, we make use of the metric from SQuAD (Rajpurkar et al., 2016), since it evaluates the words in the span. SQuAD's answers consist of a span of consecutive words in a paragraph and they evaluate how accurately the span contains the correct answer. Since what we really want to evaluate is not the position of tags but the content of the span surrounded by tags, the goal of their evaluation is similar to ours in that they aim to assess a range of words.

We apply this metric to evaluate the accuracy of tag placement. The score measures the overlap between the ground truth and the prediction to calculate a score. More precisely, they treat the hypothesis and the reference as bags of words, and calculate F1. Unlike SQuAD dataset, LXM-dev can have more than one tag for each sentence, thus

[12] `https://github.com/salesforce/localization-xml-mt`

Model	Alignment Error Rate (AER)					
Method	**SHIFT-ATT**			**NAIVE-ATT**		
Layer	**1**	**2**	**3**	**4**	**5**	**6**
Layer Average Baseline	**29.1**	31.8	36.1	41.9	42.8	51.2
Tag Augmentation (ours)	27.9	**26.4**	49.6	37.8	35.7	44.7
Garg et al. (2019) (all heads)	32.0	26.0	22.7	35.3	29.1 (**20.5**)*	72.2

Table 3: Results on Vilar et al. (2006). * uses the first head trained by word alignments. Others use the average. While we apply SHIFT-ATT for the half bottom layers, we apply NAIVE-ATT on the top 3 layers for better performance on AER (Chen et al., 2020).

we use the average score per tag[13].

4.2 Results

Firstly, in order to show the relevance of the proposed F1 metric, we shift all tags to the left by one word, which must cause performance degradation in tag placement. In the results of *Tag Shift* in Table 1, compared to *Tag Augmentation*, there is only a slight drop on XML BLEU, however, the F1 score shows a significant decrease. This implies that the proposed metric is reasonable to evaluate the placement of tags.

In Table 1, there are the results of the baselines and our tag augmentation method. The experimental results show that our augmentation method achieves the best performance for all metrics. Furthermore, according to the XML Accuracy, the tag augmentation model is able to generate all XML tags grammatically correctly in the source without XML-constrained beam search.

4.3 Augmentation Variation

We conduct various experiments to figure out what greatly affects the performance. Firstly, we note that tag augmentation with intersection heuristics causes considerable degradation on the f1 score. We also note that according to (Dou and Neubig, 2021), the performance of word alignments between Fast-Align and Giza++ is considerable, but the models trained on each data show relatively similar performance compared to the AER scores.

Even though there is a little gap in performance, the result indicates that all of our proposed implementation details have a positive influence on both translation quality and tag placement. As a result, performance improvement is achieved by all factors combined.

4.4 Indirect Learning Alignment

We further investigate the effect of the aligned tagged corpus. Table 3 shows that the AER score from all layers is improved than the *Layer Average Baseline*, but does not reach the score of multi-task training model (Garg et al., 2019) where word alignments are trained directly. This result indicates that the tag-augmented data help models' attention to learn the correspondence between source and target words indirectly.

5 Conclusion

In this paper, we have presented an efficient and effective inline tag augmentation method to insert tags into existing parallel corpora using a word aligner and the phrase extraction algorithm. Our approach injects inline tags economically and accurately.

We also introduced a reasonable metric for the automatic and accurate evaluation of the placement of tags and analyzed the effectiveness of the detailed methods used in our approach. The experiment results show that the model trained on data augmented by our method outperforms the previous detag-and-project methods.

Abstract

This paper describes the SPECTRANS submission for the WMT 2022 biomedical shared task. We present the results of our experiments using the training corpora and the JoeyNMT (Kreutzer et al., 2019) and SYSTRAN Pure Neural Server/ Advanced Model Studio toolkits for the language directions English to French and French to English. We compare the predictions of the different toolkits. We also use JoeyNMT to fine-tune the model with a selection of texts from WMT, Khresmoi and UFAL data sets. We report our results and assess the respective merits of the different translated texts.

1 Introduction

For this WMT22 Biomedical workshop, we focused on the selection of texts used for fine-tuning. We selected what we believe to be the two best models we produced for the EN-FR track with two different neural toolkits but we mostly took the opportunity to discuss the translated texts. The rest of the paper is organised as follows: Section 2 summarises our approaches to the task, Section 3 details the training data of our experiments, Section 4 presents the results. Section 5 discusses them.

2 Our Approaches to the Task

This section presents our various strategies for this task and our four submissions. We compared the predictions of two toolkits but our comparison is very partial as the training data differs. We trained several systems with JoeyNMT (Kreutzer et al., 2019) training and fine-tuning with UFAL, WMT and Khresmoi data. We used the SYSTRAN Pure Neural® Server generic system and tried to fine-tune with specialised terminology. We used SYSTRAN Advanced Model Studio® to fine-tune a generic model with in-house data based on 2,700 aligned segments collected during the translation of the French federation for diabetes.[1] Table 1 summarises our submissions.

With JoeyNMT, we selected the training data, comparing the performance with and without the added data and applied fine-tuning to the model based on UFAL medical corpora The following section details the model selection and fine-tuning.

3 Data and Tools Used

In this section, we present different approaches that we adopted to train baseline models and proceed to fine-tuning. We have built two baseline models : one trained with generic data set fine-tuned with in-domain data, and the other trained directly with in-domain data, in order to compare their performances and to better understand functioning of in-domain NMT training.

3.1 Data for baseline models training

We used two baseline models : the first one is built based on our model submitted for WMT 2021. It took the Europarl 7 parallel corpus as data set trained with 341,554 sentences in two directions (EN⇔FR)(Ballier et al., 2021); the second one has been built by using bilingual (EN-FR) in-domain parallel corpora data set UFAL provided by WMT 2022 (with 2,693,509 sentences). The corpora have been normalized and sentences longer that 50 words have been removed. Thus we have retained 2,159,307 sentences. These sentences are split in the ratio of 6-2-2 : 60% for training, 20% for development and the last 20% for evaluation. Two tokenizations are applied to all the data sets : standard tokenization (`Spacy`) segments data into words and BPE tokenization into sub-words with `SentencePiece` (Kudo, 2018).

[1] https://www.federationdesdiabetiques.org. Diabetes terminology proved to be not so useful for the actual test set.

3.2 Data for fine-tuning

We used two data sets to fine-tune the generic baseline model. For the first data set, we have compiled the WMT Medline parallel corpus since 2016 [2] as well as Khresmoi dev and test data (EN-FR) [3]. The whole data set contains 109,912 sentences. For the second one, we used the normalized and sub-tokenized UFAL data set mentioned above.

4 Experiments and Results

In our experiments, we aimed to compare the different JoeyNMT models (baseline and fine-tuning) that we have trained with SYSTRAN model. JoeyNMT, which is based on TRANSFORMER (Vaswani et al., 2017), requires lighter implementations than OpenNMT (Klein et al., 2017).

4.1 Baseline with JoeyNMT

We have trained a baseline model with in-domain data set UFAL. For FR→EN model, the best checkpoint is recorded at step 60,000 with a BLEU score of 61.01 (PPL: 1.53); as for EN→FR model, the best checkpoint is recorded at step 40,000 with a BLEU score of 59.23 (PPL: 1.45, see Figure 1) [4].

4.2 Fine-tuning with JoeyNMT

The generic baseline model was fine-tuned with the following parameters: vocabulary size: 32,000, maximum sentence length: 50, maximum output length: 100, training initializer: XAVIER, number of layers: 6, number of heads: 8 normalization: tokens, encoder embedding dimension: 512, decoder embedding dimension: 512, hidden size: 512. It was fine-tuned with two data sets. The first one with Medline-Khresmoi data set got the best BLEU score from French to English 54.8, 38.4 as from English to French (see Figure 2).

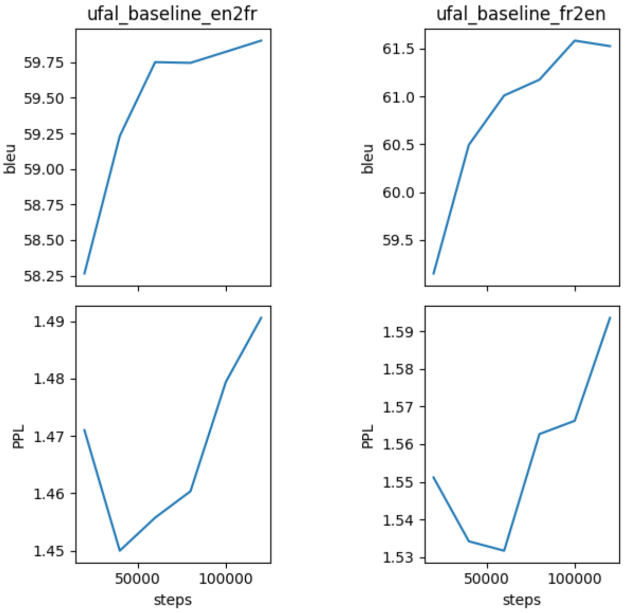

Figure 1: Baseline trained with UFAL data set FR⇔EN

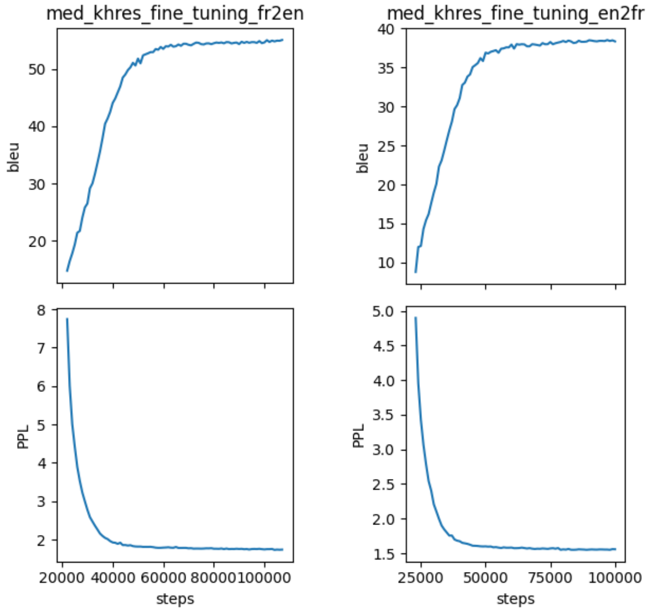

Figure 2: Fine-tuning with Medline and Khresmoi data set FR⇔EN

[2] https://github.com/biomedical-translation-corpora/corpora

[3] http://hdl.handle.net/11234/1-2122

[4] We noticed that the validation processes were extremely long. Every validation after 20,000 steps took about 28 hours.

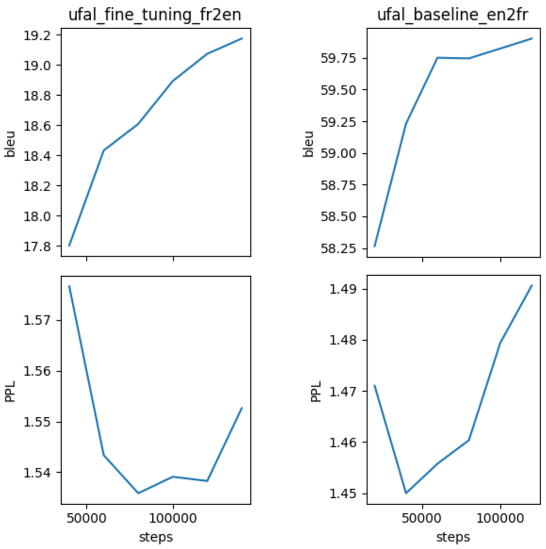

Figure 3: Fine-tuning with UFAL data set FR⇔EN

With the same parameters, the model fine-tuned with UFAL data set had, surprisingly, relatively low scores : we obtained a BLEU score of 18.60 for French→English model and 21.13 as for English→French model (see Figure 3).

4.3 Training and Fine-tuning with Systran Model Studio

SYSTRAN Pure Neural® Server is a multilingual translation platform that offers website translation and localisation features. [5] The server uses Pure Neural® Machine Translation (PNMT®), a commercial engine based on AI and deep learning, launched in 2016. This technology enables neural engines to learn language rules from a given translated text and to produce a translation achieving the current state of the art. An open source neural machine translation system OpenNMT developed by the Harvard NLP group and Systran is available online: http://opennmt.net.

For our work, we used SYSTRAN Pure Neural® Server installed on PAPTAN [6].

We used *characteristic elements* computation (Lebart et al., 1997) implemented in *iTrameur*[7] to compare the results of run2 (generated by SYSTRAN Pure Neural® Server) and run1 (generated by JoeyNMT), using characteristic elements computation (Lebart et al., 1997). In this paper, we discuss the results of FR→EN translation (Table 2). As one can see in Table 2, in the SYSTRAN translation, a sentence always starts with capitalization (“The”, “This”, “In”). Capital letters are also used for acronyms and abbreviations (“BMI”, “VCE”). This can be explained by the default detokenization function of JoeyNMT in detokenizing translation in sub-tokenized form.

The modal verb “must” is overused in the SYSTRAN translation (IndSP = +5) and is never used in the JoeyNMT translation, which tends to prefer the use of the modal verb “should” (Figure 4). The absence of "must" produced by the JoeyNMT system might be due to the large difference of frequencies of both words in training data : 18,462 occurrences of "should" and 4,061 occurrences of "must". The preponderance of "should" in the training corpus has seemingly induced the system to systematically produce the word whenever the system needs to produce a modal verb before a base verb.

We also note that JoeyNMT translation under-

Figure 4: Comparison occurrences of "must" and "should" in SYSTRAN and JoeyNMT translations

SYSTRAN translation	JoeyNMT translation
We take stock of knowledge about this addiction and its management.	knowledge about this dependency and the management thereof is a pending state.

Table 3: "we" in SYSTRAN and JoeyNMT translations

uses “we” (IndSP = -4). This finding is interesting because it makes sometimes possible to identify substantial differences between both translations in Table 3.

These results show how training data affects translation results. To our knowledge, SYSTRAN NMT relies upon a broad selection of general texts that do not belong to any single text type, subject field, or register (many of them are translated texts from the web available on https://opus.nlpl.eu). The WMT corpus consists of randomly selected sentences from abstracts and main texts of scientific articles published in medical journals. The articles follow the so-called introduction, methods, results and discussion structure (IMRAD) (Heßler et al., 2020). The selection is not necessarily balanced in terms of represented discourse functions. Thus, we noticed the overuse of “should be” that definitely constrained our translation output (see Figure 4 “should be given”, “should be reached”, “should be considered”, etc.).

5 Discussion

5.1 Degrees of Specialisation

If the Biomedical terminology was indeed present in the testing set (eg "hypertension artérielle pulmonaire","nutriments", "supplémentation en vitamine D"), some sentences were not particularly specialised. For instance, "Le but de cet article est de les résumer de manière relativement exhaustive." is representative of Scientific French for specific purposes but not really of biomedical specialised language. The same holds for the test set from English into French. In view of these observations, it is easy to understand why models trained on more generic data perform so well in this task.

5.2 The performance of gigamodels

We have not submitted translations produced on mBART-50 (Tang et al., 2021), but we compared the translations of our best system (PNS for Pure Neural Server) with those of mBART. [8]. The translation based on mBART produces fluent grammatical sentences but seems to be less specific in the terminology. For instance "vapotage" (*vaping testing*) was translated as *poultry testing* and instead of *vaping frequency* the system produced *pooping frequency*. The terminology is not always consistent or accurate : *hyperthyroïdie frustre* was translated as *rough* (SYSTRAN) or *fruity* (MBART). Oddly enough, with mBART, percentages were literally translated as "per cent" instead of the % symbol.

Figure 5 plots the vocabulary growth curves (VGCs) of the two translated texts. The y axis corresponds to the number of new types and the x axis corresponds to the number of tokens in the translated texts. As can be seen, the two systems have remarkably similar patterns of VGCs, with SYSTRAN PNS slightly above MBART, in spite of the variants we noticed. For the French translation of "keloids", mBART varies between "céloïdes" and "keloïdes", whereas SYSTRAN PNS only produces "chéloïdes".

Measuring specificity indices (Lebart et al., 1997) allowed us to spot differences in the translation. One of the most striking ones was the choice of feminine determiner *la* for *la COVID* in the PNS translations, as evidenced by the specificity of *la COVID* in the two translations (Figure 6). A somewhat belated and debated ruling of the Académie

[8] We used mBART1 through the HuggingFace API (Wolf et al., 2020).https://huggingface.co/facebook/mbart-large-50-many-to-many-mmt

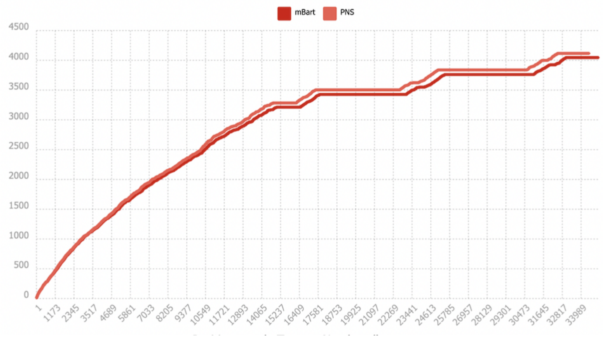

Figure 5: Comparison of Vocabulary Growth Curves in SYSTRAN PNS and mBART translations

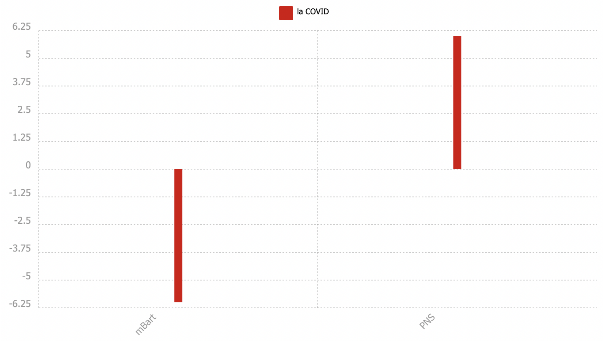

Figure 6: Comparison of Specificity Vocabulary Growth Curves in Systran PNS and mBART translations

française endorsed and imposed "*la*" for the gender of COVID in French. This benign detail probably can be used as a chronological landmark for the training data collection of the two systems: it seems that PNS was trained with more recent French texts. It may also be the case that SYSTRAN has used rule-based normalisation to regularise the output for *la COVID*.

6 Conclusion

This paper presents the SPECTRANS system description for the WMT 2022 biomedical Shared Task. We participated in the English-to-French and French-to-English tasks. We only used the data provided by the organisers but also analysed the translations produced with mBART. We obviously concur with previous research that training data is key. For the MT system, we applied a variety of strategies, toolkit comparison and fine-tuning to compare outcomes of different NMT systems in biomedical translation.

Our contribution mostly lies in the textometric analysis of the output. This allowed us to raise the issue of the role of the variability observed for the gender of COVID in French or for technical terms like "keloids".

Acknowledgements

The SPECTRANS project is funded under the 2020 émergence research project and this publication has emanated from research supported in part by a 2021 research equipment grant from the Scientific Platforms and Equipment Committee (PAPTAN project), both under the ANR grant (ANR-18-IDEX-0001, Financement IdEx Université de Paris).

We gratefully acknowledge support from the CNRS/TGIR HUMA-NUM and IN2P3 Computing Center (Lyon - France) for providing some of the computing and data-processing resources needed for this work.

Abstract

This paper describes the Samsung Research's Translation system (SRT) submitted to the WMT22 biomedical translation task in two language directions: English to Spanish and Spanish to English. To improve the overall quality, we adopt the deep transformer architecture and employ the back-translation strategy for monolingual corpus. One of the issues in the domain translation is to translate domain-specific terminologies well. To address this issue, we apply the soft-constrained terminology translation based on biomedical terminology dictionaries. In this paper, we provide the performance of our system with WMT20 and WMT21 biomedical testsets. Compared to the best model in WMT20 and WMT21, our system shows equal or better performance. According to the official evaluation results in terms of BLEU scores, our systems get the highest scores in both directions.

1 Introduction

Neural Machine Translation (NMT) has shown rapid growth with an encoder-decoder framework, especially Transformer (Vaswani et al., 2017), in recent years. Most of the research focuses on general-purpose translation models since there are a lot of parallel data available. On the other hand, domain-specific translation, which lacks relatively high-quality parallel corpus available, is one of the challenges that need to be solved in the NMT task. To address this issue, there have been several approaches such as finetuning general-purpose models with in-domain data and utilizing in-domain monolingual corpus through back-translation (Yeganova et al., 2021).

In the domain translation, one of the issues is the terminology translation. In the case of domain-specific terms, translation results are often poor because they are relatively infrequent. Yeganova et al. (2021) also mentioned that some domain-specific terms including abbreviations were not translated correctly in previous shared tasks. Moreover, when new terms are introduced such as COVID-19, it is difficult to obtain the correct translation results as they are not in the training data. To handle this issue, we adopt the soft-constrained terminology translation proposed by Molchanov et al. (2021), which provides the terminology constraints of the target language as input to our system with source sentences like a *hint*. These terminology constraints can be obtained from in-domain dictionaries.

In addition, as many domain translation studies, the back-translation strategy (Sennrich et al., 2016) is applied to generate synthetic parallel data from in-domain monolingual corpus. To improve the overall performance of our system, we also employ the Deep Transformer architecture (Bapna et al., 2018) and the ensemble strategy (Sutskever et al., 2014). Moreover, to find better translation results, noisy channel modeling (Yee et al., 2019) and discriminative reranking (Lee et al., 2021) are attempted. Our experiment shows that deep transformer and data augmentation by the back-translation strategy improve the overall performance while the performance is not improved with reranking methods.

The rest of this paper is organized as follows. Section 2 describes the training and test data used in our system, and Section 3 explains our systems including deep transformer and soft-constrained terminology translation. Section 4 describes the details of our training and experimental results of our system; Section 5 presents the official evaluation results. Section 6 is the conclusion of our work.

2 Data

In this section, we present general-domain (out-of-domain) corpus, in-domain corpus, and in-domain terminology dictionaries used as the training data

in our system. For training, all data are tokenized by SentencePiece (Kudo and Richardson, 2018); the vocab size is 32K for each lanaugage. The validation and test data are also described in this section. The statistics of our data are listed in Table 1.

2.1 General-Domain Parallel Corpus

We collect general-domain parallel corpus for English-Spanish from several sources. Some are from WMT News translation task. The data list is as follows: ParaCrawl[1], CommonCrawl[2], Europarl[3], News Commentary[4], and Tatoeba[5].

We also consider two datasets that are provided by organizers: United Nations (UN) Parallel Corpus[6] and UFAL Medical Corpus[7]. The UN Corpus consists of official records and other parliamentary documents of the UN that are in the public domain. In UFAL Medical corpus, it contains not only medical-domain data but also general-domain data; we consider the general-domain data of UFAL as a general-domain parallel corpus in our system.

2.2 In-Domain Parallel Corpus

We use the in-domain data provided by the WMT22 biomedical task organizers.

- Medline Corpus: It contains titles and abstracts of scientific publications. They provide three groups of English-Spanish parallel data: WMT16, WMT19, and WMT22. In WMT16 and WMT19 data, all sentence pairs are already aligned, so we use them without preprocessing process. However, in WMT22 data, all sentences of one abstract are written in one line; thus, after splitting sentences with the sentence splitter provided by Moses[8], only data that matched the number of sentences in both languages are considered as in-domain parallel corpus.

- UFAL Medical Corpus: As we mentioned in Section 2.1, it consists of a general-domain and medical-domain data. The parallel data tagged as the medical-domain are considered in-domain parallel data.

- MeSpEn Corpus: It is the resource for English-Spanish Medical Machine Translation and Terminologies (Villegas et al., 2018). It provides several biomedical and clinical literature data such as IBECS, SciELO, and Pubmed. This corpus contains titles and abstracts from several records. Since all sentences of each abstract are written in one line such as WMT22 Medline corpus, we conduct the same process to extract the parallel corpus.

2.3 In-Domain Monolingual Corpus

In the in-domain parallel corpus, some data are excluded because the number of sentences is not matched between two languages as we menteiond in Section 2.2. In this paper, we use this excluded data as in-domain monolingual data.

Moreover, for the English monolingual corpus, we extract only English data from other language pairs' dataset in Medline corpus and UFAL Medical corpus.

2.4 In-Domain Terminology Dictionary

As we mentioned in Section 1, it is important to translate domain-specific terminologies well in the domain translation. So, we also collect in-domain

terminology dictionaries from MeSpEn Glossaries[9] and ClinSpEn-CT[10]. Both are translated by professional medical translators. MeSpEn glossaries contain 125,645 English-Spanish term pairs and CinSpEn-CT sample set includes 7,000 term pairs. We not only utilize in-domain terminology dictionaries as the training data but also use them in the soft-constrained terminology translation.

When the dictionary data is used as the training data, all data in dictionaries is used as it is. However, for the soft-constrained terminology translation, data refinement is required since there are redundant data. It will be described in detail in Section 3.3.

2.5 Vadlidation data

For the validation data, we use the Khresmoi development data. WMT17, WMT18, and WMT19 testset are also used as the validation data.

2.6 Test data

We consider WMT20 and WMT21 "OK" aligned testset as the test data in our system to evaluate the translation quality for the final submission.

3 System Overview

In this section, we describe our system which is based on Transformer architecture (Vaswani et al., 2017). The training details are described in Section 4.1.

3.1 Deep Transformer

Peters et al. (2018) have shown that deeper layers could efficiently extract syntactic and semantic information that could improve the overall performance. Bapna et al. (2018) also have explored deeper encoders for Transformer to improve the translation quality. Several teams that participated in the biomedical shared task last year (Yang et al., 2021; Wang et al., 2021b) have adopted the deep transformer, especially deeper encoders. In this paper, we also adopt the deep transformer architecture which contains 30 encoder layers and 6 decoder layers based on TRANSFORMER-BIG setting (Vaswani et al., 2017).

3.2 Data Augmentation

To augment the in-domain parallel corpus, we adopt back-translation (Sennrich et al., 2016), where the synthetic parallel corpus is generated by translating target-side monolingual data into the source language. Back-translation is one of the effective methods to utilize monolingual data.

In this paper, we first train base models of each direction with the combination of general-domain and in-domain parallel corpus; then, we utilize these trained models to generate source-side sentences from target-side monolingual data.

Moreover, Wang et al. (2021a) present that the overall performance is improved when the in-domain dictionaries are appended to the training corpus. We also consider in-domain terminology dictionaries as the training data.

3.3 Soft-Constrained Terminology Translation

The common approach for the terminology translation is constrained decoding (Hokamp and Liu, 2017), where the translation results are forced to contain pre-specified subsequences, such as the terminology, at decoding time. Since it is the hard-constrained method, it can aggravate the translation quality. Moreover, constrained decoding methods increase the complexity of the decoding process. To address these problems, Dinu et al. (2019) and Molchanov et al. (2021) propose the soft-constrained methods, where pre-specified terminologies are given as input with the source sentence. Although there is no guarantee that translation results always contain these pre-specified terminologies, it can learn a copy behavior at training time without compromising the overall performance.

In this paper, we adopt the soft-constrained strategy of Molchanov et al. (2021) for the terminology translation; that is, we add the desired translation result of the terminology as input with special tokens such as <*term_start*>, <*term_end*>, and <*term_trans*>. Figure 1 presents the example of the revised source sentence including the desired translation result with special tokens. For this, the training corpus should be revised to reflect this input format. First, $N\%$[11] sentence pairs of the training data are randomly extracted and both source and target sentences are tokenized by SpaCy[12] which not only supports tokenization but also provides neural network models for part-of-speech tagging. To obtain the word alignment information between

[9] https://github.com/PlanTL-GOB-ES/MeSpEn_Glossaries

[10] https://zenodo.org/record/6497373#.YxHGtXZBz-j

[11] This is a heuristic value. In this paper, we set it to 15.

Source sentence: Patient had a MI or CVA in last year, or has unstable cardiovascular disease.
Terminology in the source sentence: MI
Desired translation result: IM

New source sentence: Patient had a *<term_start> MI <term_end> IM <term_trans>* or CVA in last year, or has unstable cardiovascular disease.

Figure 1: Example of the revised source sentence for the soft-constrained terminology translation

source and target sentences, the word-aligner[13] is applied. Among aligned words, we only consider *Nouns* as candidates of pre-specified terminologies. In each sentence pair, up to three[14] candidates are randomly selected to provide the desired translation result. Finally, the source sentence is revised by adding a subsequence of the target sentence that is aligned to the selected candidate of the source sentence with special tokens.

For the inference of test data, the biomedical terminology dictionaries described in Section 2.4 are utilized to provide pre-specified terminology information. As we mentioned, terminology dictionaries should be refined. We first remove duplicate terminologies; for instance, if one terminology in the source language is matched with multiple terminologies in the target language, it should be removed since we don't know which of them is the desired translation result. Moreover, if the frequency of the terminology is high in general-domain data, we don't need to consider it. Thus, dictionaries are filtered based on the frequency in general-domain data. For test data, the desired translation results which are from refined dictionaries are added to each source sentence for up to three terminologies, such as the training corpus. If the source sentence in test data doesn't contain any term which is in refined dictionaries, we just input the original source sentence.

3.4 Ensemble

From several NMT studies (Sutskever et al., 2014; Garmash and Monz, 2016; Firat et al., 2016), it has been already shown that ensembling methods can improve the overall performance. In this paper, we conduct the ensemble strategy with the top three models based on our testset for the final submission.

3.5 Reranker

The current NMT system utilizes the beam search approach to generate the final translation result. However, since it is the auto-regressive model, it considers only a limited target context to get the probability of a target token. To address this issue, there are several reranking methods that generate several different hypotheses from the NMT model and rerank them. Since reranking models can consider the entire target context, it can improve the overall performance over the beam search (Lee et al., 2021).

In this paper, we adopt two reranking methods: noisy channel modeling (Yee et al., 2019) and discriminative reranking (Lee et al., 2021). Noisy channel modeling is based on Bayes' rule; it generates translation results based on a backward model and a pre-trained target-side language model. We use a translation model in the opposite direction as a backward model and train transformer language models for the target-side language model. The discriminative reranking model is a transformer architecture that takes the source sentence and the n-best list of output hypotheses as input. It also includes position embeddings and language embeddings for representing two different languages' inputs. As in Lee et al. (2021)'s work, we use XLM-R (Conneau et al., 2020) which is a transformer-based multilingual masked language model as the pre-trained model.

4 Experiments

In this section, we present training details and experimental results of our systems.

4.1 Training details

The baseline models are trained based on TRANSFORMER-BIG setting (Vaswani et al., 2017) which contains 6 encoder layers. We first train baseline models with only general-domain corpus and incrementally train them using in-domain parallel corpus to confirm the effectiveness of in-domain

Table 2: BLEU scores on the WMT20 and WMT21 OK aligned test set.

corpus. The deep transformer models which contain 30 encoder layers are trained with the combination of the general-domain and in-domain parallel corpus; based on them, the synthetic data are generated from in-domain monolingual data. Finally, we train the deep transformer models on all corpus: general-domain (GD) and in-domain (IN) parallel corpus, synthetic data (BT), and in-domain dictionary (IND) information. The soft-constrained (SC) terminology translation models are also trained based on deep transformer models with revised training corpus described in Section 3.3. In addition, the ensemble strategy and reranking methods explained in Section 3.5 are applied. For the implementation, we use Fairseq[15], and all models are trained using 8 A100 GPUs. Adam optimizer is used. The batch size is 4K tokens, and the frequency of parameter update is 20. The learning rate, the dropout, and the label smoothing are set to 0.0007, 0.1, and 0.1, respectively. For the inference, the beam size is set to 8. The BLEU scores are calculated using the mt-eval script from Moses (Koehn et al., 2007).

4.2 Experimental results

The experimental results of English to Spanish (En2Es) and Spanish to English (Es2En) directions are shown in Table 2. The baseline models show that the in-domain corpus improves the overall performance in the domain translation. We then apply the deep transformer with the general-domain and in-domain data and it achieves a significant improvement over baseline models. With data augmentation by back-translation of monolingual in-domain data and in-domain dictionaries, there is a slight improvement on average; even though the performance drops slightly in the WMT20 testset of En2Es and WMT21 testset of Es2En, it improves more in other testset of each direction.

En2Es	WMT20	WMT21
Plain Testset	0.5158	0.5450
Revised Testset	**0.5325**	**0.5505**
Es2En	**WMT20**	**WMT21**
Plain Testset	0.5216	0.5362
Revised Testset	**0.5294**	**0.5472**

Table 3: BLEU scores of soft-constrained terminology translation models on plain testsets and revised testsets with soft-constrained terminologies.

The ensemble models show better performance than a single model in general.

In the soft-constrained terminology translation, the performance is slightly improved in one testset while the performance is decreased in the other testset in each direction. Since the soft-constrained terminology translation models are trained with revised corpus, the testset also should be revised by adding desired translation results with special tokens in order to evaluate the performance accurately. Table 3 shows BLEU scores of soft-constrained terminology translation models on plain testsets and revised testsets which contain desired translation results. We observe that soft-constrained terminology translation models are more effective when the desired translation results of some terminologies are given such as training corpus.

As we mentioned in Section 3.5, two reranking methods are adopted, but as a result, the overall

performance is not improved. (The discriminative reranking is experimented only on En2Es.)

Since there is no improvement with two reranking methods, we exclude their results in our final submissions. Our final submissions are results of data augmentation, ensembling models, and soft-constrained terminology translation.

5 Official Evaluation Results

The official evaluation results of our submissions (SRT) for WMT 2022 biomedical translation task are shown in Table 4. All our submissions show the best BLEU scores.

6 Conclusion

This paper presents the Samsung Research's Translation system (SRT) for the WMT22 biomedical translation shared task in two language directions: English to Spanish and Spanish to English. We perform experiments with several strategies such as deep transformer, data augmentation, soft-constrained terminology translation, ensembling models, and reranking methods. Our experiments show the effectiveness of each strategy. The deep transformer, data augmentation, and ensemble strategies improve effectively the overall performance in the domain translation. Moreover, we present that the soft-constrained terminology translation is a reasonable method to achieve good performance in the domain translation. Our systems show the best BLEU scores in the official evaluation results.

Abstract

Pre-trained language models (PLMs) often take advantage of the monolingual and multilingual dataset that is freely available online to acquire general or mixed domain knowledge before deployment into specific tasks. Extra-large PLMs (xLPLMs) are proposed very recently to claim supreme performances over smaller-sized PLMs such as in machine translation (MT) tasks. These xLPLMs include Meta-AI's wmt21-dense-24-wide-en-X (2021) and NLLB (2022). *In this work, we examine if xLPLMs are absolutely superior to smaller-sized PLMs in fine-tuning toward domain-specific MTs.* We use two different in-domain data of different sizes: commercial automotive in-house data and **clinical** shared task data from the ClinSpEn2022 challenge at WMT2022. We choose popular Marian Helsinki as smaller sized PLM and two massive-sized Mega-Transformers from Meta-AI as xLPLMs.

Our experimental investigation shows that 1) on smaller sized in-domain commercial automotive data, xLPLM wmt21-dense-24-wide-en-X indeed shows much better evaluation scores using SACREBLEU and hLEPOR metrics than smaller-sized Marian, even though its score increase rate is lower than Marian after fine-tuning; 2) on relatively larger-size well prepared clinical data fine-tuning, the xLPLM NLLB **tends to lose** its advantage over smaller-sized Marian on two sub-tasks (clinical terms and ontology concepts) using *ClinSpEn offered metrics* METEOR, COMET, and ROUGE-L, and totally lost to Marian on Task-1 (clinical cases) on *all official metrics* including SACREBLEU and BLEU; 3) **metrics do not always agree** with each other on the same tasks using the same model outputs; 4) clinic-Marian ranked No.2 on Task-1 (via SACREBLEU/BLEU) and Task-3 (via METEOR and ROUGE) among all submissions.

1 Introduction

Owing to the recent development of neural machine translations (NMTs) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Bahdanau et al., 2014; Akhbardeh et al., 2021; Han, 2022a), especially the self-attention based Transformer learning structures (Devlin et al., 2019; Vaswani et al., 2017), pre-trained language models (PLMs) have been dominant in natural language understanding (NLU) and natural language processing (NLP) tasks. These applications include Long-Short Term Memory (LSTM) and BERT (Pre-training of Deep Bidirectional Transformers) based models to text mining (Dernoncourt et al., 2017; Wu et al., 2022), question-answering (Dong et al., 2021), reading comprehension (Schlegel, 2021), and summarisation (Perez-Beltrachini and Lapata, 2021), etc., in addition to MT (Han et al., 2021a; Han, 2022b; Han and Gladkoff, 2022).

PLMs often have a large amount of trainable parameters for downstream applications. For instance, in translation task, the popular Marian NMT (Junczys-Dowmunt et al., 2018) pre-trained by Microsoft Translator team [1] on OPUS [2] (Tiedemann, 2012) multilingual corpus has 7.6 million parameters, which can still be fine-tuned on Google's Colab or AWS at virtually no cost. However, very recent work has shown much larger PLMs that have much more parameters than smaller models, e.g. the multi-lingual Transformer model submitted to WMT2021 shared task by Meta-AI research group "wmt21-dense-24-wide-en-x"(WMT21fb) (Tran et al., 2021), which has 4.7 billion parameters, i.e. 618 times bigger than Marian, and does not fit into regular GPUs. In this year, Meta-AI published another model NLLB (NLLB Team et al., 2022) that has 54.5 billion parameters and covers 200 languages in the full model. From now on, we name

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 908 - 919
December 7-8, 2022 ©2022 Association for Computational Linguistics

both “wmt21-dense-24-wide-en-x” and NLLB as Meta-AI’s *Mega-Transformer* models. Meta-AI’s Mega-Transformer (WMT21fb) has claimed the best performing system on 10 out of 14 language pairs in WMT2021 shared task including winning bilingual-trained models.

In this work, we raise the question whether extra-large PLMs (xLPLMs) such as Meta-AI’s Mega-Transformers have absolute superiority in NMT tasks on domain-specific fine-tuning. We prepare experimental investigation on two different data set to answer this question. One is our specific automotive domain in-house commercial data and the other is clinical domain data from ClinSpEn2022 challenge task we attended which is affiliated with WMT2022 [3].

We set up the following *hypothesis* and *research questions*. Our ***hypothesis*** is: xLPLMs do not absolutely demonstrate superiority over smaller sized PLMs in NMT fine-tuning and it shall depends on specific tasks deployed including domain topic, size of available in-domain data, and performance-cost trad-off.

From this hypothesis we derive two *research questions (**RQs**)*: 1) Do xLPLMs always demonstrate better performances in NMT over smaller sized PLMs for domain fine-tuning? 2) if not, in what situations?

To the best of our knowledge, this is the first published work that has been carried out in the field on fine-tuning Meta-AI’s extra-large multilingual PLM Maga-Transformers, and in translating specialised automotive and clinical data.

The rest of the paper is organised as below: Section 2 introduces more details on related work to ours including PLMs and fine-tuning in automotive and clinical domains, Section 3 describes our initial model settings including deployed baseline models, Section 4 presents our experimental evaluation carried out on our in-house commercial automotive domain data, Section 5 describes our system submission to ClinSpEn Biomedical-MT challenge task at WMT2022 on clinical data, and Section 6 gives our conclusion and future work plan.

2 Related Work

Fine-tuning PLMs has been in practice towards different domain applications in recent years. For instance, Wang et al. (2021) carried out experimental investigation on fine-tuning PLMs for conversational recommendation system, Chakraborty et al. (2020); Gu et al. (2021); Lee et al. (2019); Alsentzer et al. (2019) built biomedical and clinical domain pre-trained models using BERT structure and PubMed data on scientific publications, and then Wu et al. (2022); Han et al. (2022a) developed new machine learning structures using PLM Transformer and BERT as encoders in concatenation with statistical graph-based conditional random fields (CRFs) as decoders for clinical text mining.

However, aforementioned work did not deploy extra-large PLMs in a scale as Meta-AI’s multilingual Mega-Transformers. For example, the PLMs (Transformer-CRFs) deployed by Wu et al. (2022) as baseline have around 42 million of trainable parameters, which set is already relatively large, even though it is still far from Mega-Transformers’ 4.7 billion and 54.5 billion parameters.

Regarding PLM applications in automotive domain, the only recent work we found is from Romell and Curman (2022), who tested the DistilBERT and XLM-RoBERTa PLMs for text classification task using Swedish truck manufacturer data, instead of MT.

There are also researchers working on the overview of model comparability, bench-marking, and fine-tuning methodologies regarding larger scale PLMs, e.g., from Aßenmacher (2021); Ruder (2021).

Overall, none of the work mentioned before has investigated into extra-large Mega-Transformer level PLMs (xLPLMs) for NMT in automotive and clinical domains, especially their comparisons to smaller sized PLMs.

3 Initial Model Settings

To investigate into PLMs with fine-tuning for specialised domain NMT from different scales, we firstly deploy two of such models in different sizes from a multilingual setting. The first one is the popular Marian NMT model developed in C++ since 2018 using deep RNN and Transformer (Junczys-Dowmunt et al., 2018). It is mostly maintained by the Microsoft Translator team and features with efficiency, fast training, and state-of-the-art NMT architectures [4]. This PLM has a smaller sized 7.6 million trainable parameters.

[3] The 7th Conference on MT https://www.statmt.org/wmt22/

[4] available at https://marian-nmt.github.io

The second one we use for fine-tuning is one of the extra-large PLMs (*xLPLMs*) Meta-AI's Mega-Transformer "wmt21.dense-24-wide.En-X" (Tran et al., 2021) developed for WMT2021 shared task on multilingual MT, which was submitted to 14 language pairs and claimed the best on 10 of them [5]. It has 4.7 billion trainable parameters, which is super large in comparison to Marian model. In the later section (5), we will explain another Mega-Transformer Model NLLB developed in this year by Meta-AI and deploy it for our ClinSpEn2022 shared task submission on clinical domain.

4 Model Fine-Tuning and Comparison on Commercial Automotive Data

4.1 In-house Corpus and Hardware

At the development stage, we use our in-house prepared domain-specific commercial corpus from automotive field. We split our data set into 90% vs 10% for fine-tuning and testing respectively and make sure that the test data is not seen during the fine-tuning / development stage [6]. We use a larger GPU from NVIDIA A100 with 80GB VRAM for our experiments because of the much higher computational powers the Mega-Transformer model requires.

4.2 Our Evaluation Setup

BLEU (Papineni et al., 2002) has always been criticised by researchers on its reliability. This includes very recent work by Freitag et al. (2021), which demonstrates that BLEU has closer correlation to lower quality crowd sourced human evaluation then to expert based human evaluation, and by Han et al. (2021a), which investigation on Chinese-English NMT shows that BLEU score fails to reflect the real quality differences between NMT systems especially on translating multi-word expressions (MWEs) and terms (Han et al., 2020).

Furthermore, BLEU scores can be very different caused by configurations, such as tokenisation and normalisation strategies applied to the reference text which can lead to 1.8 margin of difference reported by (Post, 2018). In light of these findings, we adopt two alternative evaluation metrics, i.e. SACREBLEU (Post, 2018) and hLEPOR (Han et al., 2013b; Erofeev et al., 2021; Han et al., 2021b) that we will give further details about.

4.2.1 Revisiting SACREBLEU

SACREBLEU is developed by the work from Post (2018) and is maintained online in its Python version [7]. The author discussed the uncertainty regarding reporting BLEU scores by MT researchers. This is involved in many parameter settings when using BLEU metric including number of references, length penalty computation on multi-references, maximum n-gram, and smoothing applied to 0-count n-grams. Because of such variations, when MT researchers report the BLEU scores from their system, "the BLEU" score actually cannot be reproduced in many cases due to lack of detailed technical description of encoder, etc. .

To address these issues, SACREBLEU added some constrains while using BLEU metric. These include the applying of its own metric-internal pre-processing for detokenised system outputs, the avoiding of user handling reference set via automatically downloading from WMT, and the export of a summary on settings used.

4.2.2 Revisiting hLEPOR

hLEPOR is an augmented metric for automatic MT evaluation which was firstly proposed in WMT2013 Metrics shared task (Han et al., 2013a,b) and was reported as one of the best performing metrics at both system level (Macháček and Bojar, 2013) and segment level (Graham et al., 2015) [8]. It is calculated via a weighted harmonic mean of several main factors including sentence length penalty, position difference penalty, precision, and recall. Furthermore, there are more weighting parameters among all the sub-factors. Let's see the brief formulas below:

$$
h\text{LEPOR} = Harmonic(w_{LP}LP, \\ w_{NPosPenal}NPosPenal, w_{HPR}HPR)
$$

where *LP* is the sentence length penalty factor and is calculated as:

[5] package "wmt21.dense-24-wide.En-X" available at https://github.com/facebookresearch/fairseq/tree/main/examples/wmt21

[6] Because this is a commercial corpus, we do not give much details on it but this does not affect the experimental findings we achieved

[7] available at https://github.com/mjpost/sacrebleu

[8] The python version is available at https://pypi.org/project/hLepor/ and the original Perl code at https://github.com/poethan/LEPOR

$$\text{LP} = \begin{cases} e^{1-\frac{Length_{ref}}{Length_{hyp}}} \; if \; Length_{hyp} < Length_{ref} \\ 1 \; if \; Length_{hyp} = Length_{ref} \\ e^{1-\frac{Length_{hyp}}{Length_{ref}}} \; if \; Length_{hyp} > Length_{ref} \end{cases}$$

Then, n-gram based position difference penalty (NPD) is used to measure the word position and order difference among matched words between system output and reference translation ($MatchN_{hyp}$ and $MatchN_{ref}$).

$$NPosPenal = e^{-NPD}$$

$$NPD = \frac{1}{Length_{hyp}} \sum_{i=1}^{Length_{hyp}} |PD_i|$$

$$|PD_i| = |MatchN_{hyp} - MatchN_{ref}|$$

Finally, the weighted harmonic mean of precision and recall is calculated using this formula.

$$HPR = \frac{(\alpha + \beta) Precision x Recall}{\alpha Precision + \beta Recall}$$

$$Precision = \frac{Aligned_{num}}{Length_{hypothesis}}$$

$$Recall = \frac{Aligned_{num}}{Length_{reference}}$$

hLEPOR is an extended version of the original LEPOR metric (Han et al., 2012; Han, 2014). hLEPOR also has a latest customised version named cushLEPOR which uses automatic hyper-parameter optimisation framework Optuna (Akiba et al., 2019) to achieve better and easier feature weights fine-tuning towards specific language pairs and domains in practice. It was reported as one of the best performing metrics in WMT2021 (Erofeev et al., 2021; Han et al., 2021b) on the officially-ranked language pairs English-German and Chinese-English on News domain, and English-Russian on TED talk data (Freitag et al., 2021) where human expert level evaluations were available. hLEPOR is also gaining popularity in other NLP task evaluations, e.g. language generation (NLG) (Novikova et al., 2017; Gehrmann et al., 2021; Marzouk, 2021), language understanding (NLU) (Ruder et al., 2021), text summarization (ATS) (Bhandari et al., 2020), and searching (Liu et al., 2021).

4.3 Evaluation Results

The evaluation scores using SACREBLEU and hLEPOR are shown in Table 1 and 2 respectively. From Table 1, we can see that the fine-tuning has successfully improved each single n-gram precision score in SACREBLEU for both Marian and Mega-Transformer models, leading to an overall 150.14% and 75.81% score increasing. Similarly, Table 2 shows that our in-domain fine-tuning improved hLEPOR scores on Marian and Mega-Transformer models via 32.16% and 26.01%.

Like BLEU, SACREBLEU is precision based metric. The very large margin evaluation score increases in SACREBLEU (150.14% and 75.81%) indicates that according to reference translation, our fine-tuned models produce more fluent output than the baseline in this domain specific test set. Unlike SACREBLEU, hLEPOR is an augmented metric with comprehensive factors, including recall and positional difference penalty, in addition to precision. The large margins of hLEPOR score increase, i.e. 32.16% and 26.01% tell that the fine-tuned models can also have more adequate translation towards this domain, in addition to maintaining higher fluency.

In summary, the fine-tuning of these two PLMs has demonstrated evaluation score improvement with large margins in commercial domain data. xLPLM Mega-Transformer has much higher SACREBLEU evaluation score than Marian before fine-tuning, 39.12 vs 19.64, which indicates its larger amount of knowledge acquired. However, after fine-tuning, the SACREBLEU scores of them are much closer, 50.33 vs 45.20. This means that fine-tuning of smaller sized PLM for this commercial data is far more effective than the xLPLM Mega-Transformer from computation and time cost point of view, as well as the cost of computational power itself, since supercomputer time is much more expensive.

This partially verifies our assumption that xLPLMs do not always win smaller sized PLMs in practical applications when computational cost is in place and when time is constrained.

To further investigate our research questions, we carry out another experimental evaluation on clinical domain data via attending the ClinSpEn2022 shared task challenge which will be detailed in the next section.

	Marian					
	uni-gram	bi-gram	tri-gram	4-gram	BP	Overall
Before fine-tuning	19.64	10.96	4.56	2.00	1.0	7.38
After fine-tuning	45.20	24.54	14.44	8.69	0.96	18.46 (↑150.14%)
	Mega-Transformer (wmt21fb)					
	uni-gram	bi-gram	tri-gram	4-gram	BP	Overall
Before fine-tuning	39.12	18.81	9.78	5.23	1.0	13.93
After fine-tuning	50.33	30.14	19.47	12.85	0.99	24.49 (↑75.81%)

Table 1: SACREBLEU score comparisons on the MT test set: before vs after fine-tuning

	Marian	Mega-Transformer
Before fine-tuning	36.91	47.55

Rate(↑)	32.16%	26.01%

Table 2: hLEPOR score comparisons on the MT test set: before vs after fine-tuning

5 Submission to ClinSpEn at WMT22

In this section, we introduce our system submissions to Biomedical-MT task in WMT2022. In this task, we attended the affiliated clinical domain machine translation on Spanish-English language pair (ClinSpEn) task [9], which is hosted in CodaLab (Pavao et al., 2022) [10].

The aim of this task is to promote the development of MT models on medical domain via three sub-tasks: 1) Clinical Cases (CC): on 202 COVID-19 clinical case reports; 2) Clinical Terms (CT): using more than 19K parallel terms extracted from biomedical literature and electric health records (EHRs); 3) Ontology Concepts (OC): using more than 2K parallel concepts from biomedical ontology. The translation direction on these three sub-tasks are EN→ES, EN←ES, and EN→ES respectively.

5.1 Corpus Used

In addition to the official corpora prepared by the ClinSpEn organisers, we used some external corpora for our model fine-tuning. This is because that neural-network based machine learning models are data dependent while the officially offered parallel sample sentences are very limited. We found useful biomedical Spanish-English corpora described in (Névéol et al., 2018) from WMT[11], and MeSpEn corpora from (Villegas et al., 2018)[12], which include Spanish Bibliographical Index in Health Sciences (IBECS), Scientific Electronic Library Online (SciELO), and U.S. National Library of Medicine (PubMed and MedlinePlus). However, due to the time restriction for this shared task, we only managed to get 250,000 aligned pairs from IBECS after careful preparation, which is a bibliographical data collecting scientific articles from different fields of health sciences, maintained by the Spanish National Health Sciences Library.

5.2 Adaptations on xLPLM: NLLB

Two systems we submitted to ClinSpEn2022 are clinic-Marian and clinic-NLLB (NLLB Team et al., 2022). We reported our clinic-WMT21fb model outputs in a followup work (Han et al., 2022b) (also due to the time restriction). Some training parameters and training logs for clinic-Marian are listed below:

- batch size = 64
- gradient accumulation steps = 1
- weight decay = 0.01
- learning rate = 2e-5
- number of training epochs = 1
- number of examples = 225,000

NLLB (No Language Left Behind) is another extra-large PLM model built by Meta-AI freshly in

[9] https://temu.bsc.es/clinspen/

[10] https://codalab.lisn.upsaclay.fr/competitions/6696

[11] https://github.com/biomedical-translation-corpora

[12] https://zenodo.org/record/3562536

this year [13], which was targeting low-resource languages via knowledge transfer from high-resource ones, and Spanish is among the high-resource languages covered by NLLB [14]. NLLB-200 has a total of 54.5 billion parameters in its full model as the authors mentioned. In this shared task, we applied the distilled version of NLLB, i.e. the "NLLB-200-distilled-1.3B" which still has 1.3 billion trainable parameters [15]. As Meta-AI's "wmt21.dense-24-wide.en-X" model we used in the earlier section, we call NLLB-distilled as one of their *Mega-Transformers*.

Some fine-tuning parameters for NLLB-distilled are listed below:

- batch size = 24
- gradient accumulation steps = 8
- weight decay = 0.01
- learning rate = 2e-5
- number of training epochs = 1
- encoder-decoder layers = 24+24

The fine-tuned clinic-NLLB model has relatively apparent evaluation score increase using SacreBLEU in comparison to baseline model on both translation directions, as shown in Table 3, for EN→ES and ES→EN in the upper and middle parts of the table with increasing rate 11.74% and 9.70% respectively. This demonstrates that that fine-tuning was successful.

Interestingly, if we fine-tune the model in one direction and carry out the inference translation in the opposite direction, the model performance will have a big drop even though it is the same language pair. This tells that pre-trained LMs lose their generalisation after fine-tuning. For instance, in the bottom of Table 3, we demonstrate that if the model is fine-tuned in English-to-Spanish direction and the inference test is carried out in Spanish-to-English direction, the overall SacreBLEU score has a 14.37% drop in comparison to without fine-tuning. So, we carried out fine-tuning on both translation directions for the system submission to three sub-tasks at ClinSpEn2022.

5.3 Official Evaluation Metrics

The official evaluation metrics used by ClinSpEn2022 shared task are METEOR (Banerjee and Lavie, 2005), SacreBLEU (Post, 2018), COMET (Rei et al., 2020), BLEU-HF (HuggingFace) (Papineni et al., 2002), and ROUGE-L-F1 (Lin, 2004). Among these, METEOR is a metric using both precision and recall not only on word surface level but also introducing paraphrasing features. COMET was proposed recently by taking advantage of cross-lingual PLMs using knowledge from both source and target languages. ROUGE was originally designed for text summarisation evaluation using n-gram co-occurrences, while ROUGE-L added the Longest Common Sub-sequence (LCS) feature from translation study.

5.4 Evaluation Scores on Three Tasks

We present the MT evaluation scores using five official metrics through CodaLab platform on the three sub-tasks in Table 4, for translating clinical cases, clinical terms, and ontology concepts. The two fine-tuned models are clinic-Marian and clinic-NLLB (one of the Mega-Transformers). From this shared task evaluation outcomes, the xLPLM clinic-NLLB starts to lose its comparisons to far smaller-sized clinic-Marian in Task-2 (CT) and 3 (OC), especially on METEOR and ROUGE-L scores but also on COMET (OC). What is very noticing is that clinic-Marian has an overall win on Task-1 (CC) via all evaluation metrics.

From the evaluation results on Task 2 and 3, i.e. CT and OC, we can see that the evaluation metrics do not agree with each other always. For instance, clinic-Marian wins METEOR and ROUGE-L on Task 2 but loses on other metrics, while clinic-NLLB wins SacreBLEU and BLEU-HF on Task 3 but loses on other metrics. This phenomenon is very interesting which tells that variation metrics from BLEU including BLEU-HF and SacreBLEU tend to not agree with other metric families including METEOR, COMET, and ROUGE-L. Furthermore, the same metric does not always agree with itself on different tasks, or the two MT models perform differently across tasks. For instance, COMET score says clinic-Marian and clinic-NLLB wins Task 3 (0.9495) and 2 (1.0290) respectively. Due to the time restriction from this shared task and the limited computational resource we have, our second model (clinic-NLLB) was submitted after the official deadline.

	English-to-Spanish (tune) & Spanish-to-English (test)					
	uni-gram	bi-gram	tri-gram	4-gram	BP	Overall
Before fine-tuning (es2en)	65.36	42.54	30.58	22.60	1	37.23
After *Reverse* fine-tuning	58.17	36.48	25.85	18.84	1.0	31.88 (↓14.37%)

Table 3: SACREBLEU score comparisons using NLLB: baseline vs fine-tuned in clinical domain.

This experimental investigation shows that with carefully prepared and larger amount of domain specific data for fine-tuning, the xLPLMs tend to lose its advantage over smaller sized PLMs using several automatic metrics. Thus it further verifies our hypothesis and research questions.

5.5 Comparisons to Other Teams

In the officially valid submissions (before the shared task deadline ended) for three tasks, there are four teams for Task-1 and Task-3 including Avellana Translation, DtranX, Optum and ours [16]. In addition to these four teams, Task-2 has another team Huawei, making it in-total five teams. Optum and Huawei have both multiple submissions/runs while other teams submitted one run. Our submission clinic-Marian ranked number 2 in both Task-1 and Task-3 via SACREBLEU/BLEU and METEOR/ROUGE respectively, as in Table 5 underlined. There are four runs from Optum team for both Task-1/3 and single submission by other teams. Table 5 includes the best submission from Optum. There is a little difference in the last digit of the evaluation scores between our own record (Table 4) and the official record (Table 5), which is because that we rounded the last digit scores while the official ones did not. This result shows that metrics tend to not agree with each others in many cases. For instance, on Task-3, our clinic-Marian has very similar score to DtranX on METEOR (0.6261 vs 0.6275) only from the third digit which is a metric using paraphrase and semantic similarity features; however, the score difference on BLEU is so large (39.10 vs 58.24) via SACREBLEU which rises the issue again on the credibility of BLEU metric. There are not many teams submitting their results into this clinical domain machine translation task in comparison to the traditional news domain MT task, which indicates that it is still a relatively new domain and calls for more attentions from MT researchers in the future.

6 Discussion and Future Work

In this work, we carried out experimental investigations on if extra-large pre-trained language models (PLMs) always demonstrate superiority over much smaller-sized PLMs using two domain specific data. The first experimental results using Marian vs "wmt21.dense-24-wide.En-X" shows that even though xLPLM still perform better evaluation scores in comparison to much smaller sized Marian, their score difference is much smaller after fine-tuning and the xLPLM costs more than smaller PLM from performance-cost trade-off point of view in practical applications, e.g. for language service providers (LSPs). The second experimental results using clinical data show that with carefully prepared certain amount of fine-tuning data (250k sentence pairs), the xLPLM NLLB even loses with its evaluation score in comparison to smaller PLM Marian in Task 1 "clinical cases" over all automatic metrics used, and in Task 2 "clinical terms" and 3 "ontology concepts" on partial of the automatic evaluation metrics officially used by ClinSpEn2022. Finally, our system submission clinic-Marian ranked the second place using SACREBLEU/BLEU for

Table 5: Comparisons on Task 1 and 3 across teams (ranked via SACREBLEU chosen by the organisers).

Task-1, and using METEOR/ROUGE for Task-3 among all teams who submitted on-time before the shared task deadline.

We looked into the translation outputs from clinic-NLLB for error analysis, and it shows that some of the translation errors come from very literal translation, and others come from gender related mistakes. In conclusion, *our two stage experimental investigations verify our hypothesis and RQs from different aspects*.

We also doubt if the official automatic metrics used for ClinSpEn challenge can correctly distinguish the NMT systems because mostly they do not really measure the translation output quality but the similarity to the gold standard single reference. Therefore, domain specific automatic evaluation metrics or metrics better measuring semantic similarities might be needed.

In the future work, we plan to carry out more experimental investigations from qualitative aspects looking into translation errors using human experts and classifying them into possible categories with examples and statistics, especially from clinical domain. This will allow us to validate automatic metrics with professional human judgements for this domain.

We will continue to fine-tune our models towards different domains and languages and use more of the available corpus for current clinical domain challenge task. We also plan to try different state-of-the-art pre-trained language models for evaluation.

Acknowledgements

The authors thank the ClinSpEn2022 shared task organisers for preparing the data set and evaluation platforms, thank Darryl Estrada for in communication with us during the competition. The authors thank the project support from HIPS (R126035 task A05) and from JigSaw (R124782 task A07) at The University of Manchester. We thank the open research projects Marian Helsinki NMT and Meta-AI's wmt21.dense-24-wide.En-X (2021) and NLLB (2022) we used.

Abstract

This paper introduces WeChat's participation in WMT 2022 shared biomedical translation task on Chinese→English. Our systems are based on the Transformer(Vaswani et al., 2017), and use several different Transformer structures to improve the quality of translation. In our experiments, we employ data filtering, data generation, several variants of Transformer, fine-tuning and model ensemble. Our Chinese→English system, named Summer, achieves the highest BLEU score among all submissions.

1 Introduction

This article describes the WeChat's participation in WMT 2022 shared biomedical translation task on Chinese→English. We improve the translation quality of the system by increasing the diversity of model structure and data, fine-tuning the model with in-domain data, inserting tags at the beginning of each source sentence and selecting models with high diversity and good performance for ensemble.

For model architectures, our system adopt BIG and DEEP Transformer models which contain 10-layer and 20-layer encoders, 10240 and 4096 filter sizes, respectively, with TRANSFORMER-BIG setting (Vaswani et al., 2017). In order to increase the diversity of the model, we use structures such as Average Attention Transformer (AAN) (Zhang et al., 2018) and Mixed-AAN Transformer architecture (Zeng et al., 2021) in the decoder part.

For data generation, we use back-translation (Sennrich et al., 2016a), knowledge distillation (Kim and Rush, 2016), and forward-translation (Zeng et al., 2021) to improve data quality. And we use some data augmentation methods to improve the model robustness, such as adding synthetic noise and dynamic top-p sampling (Zeng et al., 2021). Furthermore, according to the different sources of the corpora, we add tags at the beginning of the source sentence to perform domain adaptation.

For fine-tuning, we use in-domain bilingual corpus to fine-tune models from the general domain to the biomedical domain, and use target denoising (Meng et al., 2020) to improve the diversity of models and mitigate training-generation discrepancy.

For model ensemble, we use Self-BLEU (Zhu et al., 2018) to evaluate the similarity between models. We take the prediction of one model as the reference and use the prediction of the other model to calculate the BLEU score. The higher the Self-BLEU score, the lower the diversity of the models.

In the remainder of this paper, we start with presenting the data strategy in Section 2. Then we describe our system details in Section 3. Section 4 presents the experimental results. Finally, we conclude our work in Section 5.

2 Data

In this section, we introduce the details of bilingual and monolingual data used in this shared task.

2.1 Bilingual Corpus

Our baseline model is trained with out-of-domain (OOD) data from WMT 2022 shared task on general machine translation[1]. Additionally, we use in-house data (depicted in Table 1 as OOD-IN-HOUSE) to improve performance of baseline model. With regard to in-domain data, firstly, we use the in-domain bilingual corpus provided by the WMT 2022 shared biomedical translation task[2] (depicted in Table 1 as IND-BIO). And we use the Champollion[3] tool to align the sentences in the corpus. Then, we collect in-domain Chinese→English

December 7-8, 2022 ©2022 Association for Computational Linguistics

(depicted in Table 1 as IND-TAUS) sentence pairs from TAUS[4].

2.2 Monolingual Corpus

The out-of-domain monolingual corpora are collected from WMT 2022 shared task on general machine translation and the in-house monolingual data. With regard to in-domain data, the English part of the bilingual corpus in other languages provided by the WMT 2022 shared biomedical translation task is used as in-domain monolingual data.

3 System overview

In this section, we introduce the details of our system used in the WMT 2022 shared biomedical translation task. Our system adopts data filtering, data generation, model architectures, fine-tuning and ensemble.

3.1 Data Filtering

For data filtering, we use the following rules for bilingual corpus:

- Normalize punctuation with Moses scripts on both English and Chinese.
- Filter out sentence pairs that are the same at the source and target.
- Filter out sentence pairs whose source sentence's language recognition result is different from the original language.
- Filter out sentence pairs with a source-to-target length ratio greater than 1:3.
- Filter out the sentences longer than 150 words or exceed 40 characters in a single word.

Besides these rules, we use fast-align[5] to filter out the sentence pairs with low alignment scores. We also filter out sentence pairs in which English sentences contain Chinese characters.

3.2 Data Generation

In this section, we introduce the approaches of data generation in our system, including back-translation, knowledge distillation, forward-translation, synthetic noise and tagging.

3.2.1 Back-Translation

Back-translation (Hoang et al., 2018) is the most commonly used data augmentation method in neural machine translation. Following the previous work (Edunov et al., 2018), we use following strategies to generate back translations to improve the diversity the training data:

- Beam search: We use beam search to generate the pseudo corpus with beam size setting to 4.
- Dynamic top-p sampling: Following the work (Zeng et al., 2021), at each decoding step, we select a word from the smallest set whose cumulative probability exceeds p, with p varying from 0.9 to 0.95 during the data generation process.

3.2.2 Knowledge Distillation

For knowledge distillation (Kim and Rush, 2016; Wang et al., 2021), we use the corpus generated from the teacher models to train the student models.

3.2.3 Forward-Translation

For forward-translation, we use an ensemble model to generate forward translations with the source-language monolingual corpus as input.

3.2.4 Synthetic Noise

For synthetic noise, we add different noises at the source side of the pseudo corpus to improve the diversity of the data and improve the robustness of the model:

- Randomly replace some source tokens with $< unk >$.
- Randomly delete some tokens from the source sentence.
- Randomly swap the two tokens in the source sentence in the specify window.

3.2.5 Tagging

For tagging, inspired by (Johnson et al., 2017), we insert a tag at the beginning of each source sentence to denote its type: $< BT >$ for the back-translation data, $< NOISE >$ for the synthetic noise data, $< REAL >$ for the ground-truth bilingual corpus and $< FT >$ for the forward-translation data. Furthermore, we insert a tag at the second position of each sentence to denote its domain: $< BIO >$ for the in-domain data, $< NEWS >$ for the data from WMT22 general

LANGUAGE	OOD-NEWS	OOD-IN-HOUSE	IND-BIO	IND-TAUS
bilingual corpus	30.6M	90M	89K	0.4M
monolingual corpus	220M	50M	6.9M	–

Table 1: Data used for training the system, where *OOD-NEWS* is the out-of-domain data provided by WMT22 general translation task. *OOD-IN-HOUSE* is the out-of-domain data collected from in-house corpus. *IND-BIO* is the in-domain data provided by WMT22 shared biomedical translation task. And *IND-TAUS* is the in-domain data collected manually (not from MEDLINE, as depicted in 2.1). *M* denotes *million* and *K* denotes *thousand*.

translation task and $< INHOUSE >$ for the data from our in-house corpus. At inference time, we always use the $< REAL >$ and $< BIO >$ tag.

3.3 Model Architectures

In this section, we introduce the model architectures used by our system, including Transformer (Big/Deep), Average Attention Transformer (AAN) and Mixed Average Attention Transformer (Mixed-AAN) (Zeng et al., 2021).

3.3.1 Transformer

Our baseline models are Big- and Deep-Transformer (Vaswani et al., 2017) models. In our experiments, we use multiple model configurations with 20-layer and 30-layer encoders for deep models and 10-layers encoders for big models, and use 6-layers decoders for all models. The hidden size is set to 1024 and the filtering size is set from 4096 to 10240.

3.3.2 Average Attention Transformer

To increase the diversity between models, we adopt Average Attention Transformer (Zhang et al., 2018), where the average attention is used to replace self-attention in the decoder. AAN summarizes the historical information of previous positions by means of cumulative average, which increases diversity with almost no harm to the quality of the model.

3.3.3 Mixed-AAN Transformers

Following the previous work (Zeng et al., 2021), we adopt the Mixed-AAN Transformers to further improve the diversity and quality of models. In this experiment, we only use two architectures of Mixed-AAN:

- Self-first: In the decoder part, we use self-attention as the first layer, and then use average attention and self-attention alternately.

- AAN-first: In the decoder part, we use average attention as the first layer, and then use self-attention and average attention alternately.

3.4 Fine-tuning

For fine-tuning, we mainly use the in-domain data provided by WMT22 shared biomedical translation task for domain adaption (Luong and Manning, 2015; Li et al., 2019). In order to prevent the model from overfitting, as well as to improve the diversity of the model after domain transfer, we adopt target denoising (Meng et al., 2020). We add synthetic noise at the decoder inputs during fine-tuning. Therefore, with target denoising, the model becomes more robust. The method of adding synthetic noise is described in Section 3.2.4.

3.5 Ensemble

After obtaining a variety of different models through the above methods, we need to find the best model combination to get the best result. In general, the better the model performance and the greater the diversity between models, the better the performance for the model ensemble. To measure diversity, we use Self-BLEU (Zhu et al., 2018) to evaluate the similarity between models. Overall, we select 6 models from 52 candidate models for ensemble. All the candidate models are generated by different combinations of data and different training strategies as described earlier.

4 Experiments

4.1 Settings

Our experiment is based on Fairseq [6]. The single models are carried out on 8 NVIDIA V100 / A100 GPUs. We adopt the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.998$. The batch-size is set to 4096 tokens, and the “update-freq" is set to 4, and the warmup step is set to 4000 and the learning rate is set to 0.0005.

4.2 Pre-processing and Post-processing

The Chinese sentences are segmented by a in-house segmentation tool and English sentences are seg-

mented by the tokenizer toolkit in Moses[7]. We normalize punctuation using Moses scripts on both English and Chinese. For handling uppercase and lowercase of the English letters, we add a special token at the beginning of a word to denote uppercase (_UU_) and title case (_U_). By this way to reduce the size of the word list and reduce the difficulty of model training. For instance, *"We are together NOW."* → *"_U_ we are together _UU_ now."*. We use BPE (Sennrich et al., 2016b) with 32K operations for all the languages.

With the regard of post-processing, we use *detokenizer.perl* on the English translations provided in Moses.

4.3 Results

The experimental results of Chinese→English on WMT21 OK-aligned biomedical test set are shown in Table 2.

Compared with the baseline model (Baseline_TAG), the in-domain bilingual data (+IND-BIO) provided by WMT22 shared biomedical translation task brings a huge improvement, with 6.5 point increase in BLEU score. After adding the in-house out-of-domain corpus (+OOD-IN-HOUSE), we further gain +1.1 BLEU. We further obtain +1.8 BLEU by applying back-translation (+Back-Translat), and +0.23 BLEU by using knowledge distillation (+Knowledge Distillation), and +0.25 BLEU by using forward-translation (+ Forward-Transla). After using iterative back-translation (Hoang et al., 2018) (+Multi BT) described in Table 2, we further achieve improvement of +0.84 BLEU.

Additionally, we can find that the model with TAG was similar to the model without TAG in early stage experiments. As the number of data categories and data domains increases, the model with tags gradually demonstrates its advantages. Our best single model (+Target denoise fine) achieves 45.54 BLEU score, and we finally achieve 46.91 BLEU score by model ensemble (+Ensemble).

[7] http://www.statmt.org/moses/

5 Conclusion

We introduce WeChat's participation in WMT 2022 shared biomedical translation task on Chinese→English. Our system is based on the Transformer (Vaswani et al., 2017), and uses several different Transformer structures such as Average Attention and Mixed-AAN to improve the performance. We use several data augmentation methods such as iterative back-translation, knowledge distillation, forward-translation and synthetic noise. We use tags to assist the model in domain learning and use in-domain fine-tuning with target denoising to domain transfer. Finally a Self-BLEU based ensemble method is used for model ensemble. Overall, our system achieves 46.91 BLEU score on WMT21 OK-aligned biomedical test set, and we achieve the highest BLEU score among all submissions.

Optum's Submission to WMT22 Biomedical translation tasks

Sahil Manchanda
sahil_manchanda@optum.com

Saurabh Bhagwat
saurabh_bhagwat@optum.com

Abstract

This paper describes Optum's submission to the Biomedical Translation task of the seventh conference on Machine Translation (WMT22). The task aims at promoting the development and evaluation of machine translation systems in their ability to handle challenging domain-specific biomedical data. We made submissions to two sub-tracks of ClinSpEn 2022, namely, ClinSpEn-CC (clinical cases) and ClinSpEn-OC (ontology concepts). These sub-tasks aim to test translation from English to Spanish. Our approach involves fine-tuning a pre-trained transformer model using in-house clinical domain data and the biomedical data provided by WMT. The fine-tuned model results in a test BLEU score of 38.12 in the ClinSpEn-CC (clinical cases) subtask, which is a gain of 1.23 BLEU compared to the pre-trained model.

1 Introduction

The quality of Neural Machine Translation (NMT) was boosted by the use of Recurrent Neural Networks (RNN) for machine translation. In this approach, the source sentence is fed to an encoder which outputs a context vector. This context vector is fed to the decoder to output the target language text (Cho et al., 2014). Some approaches also use Long Short Term Memory (Hochreiter and Schmidhuber, 1997) for this task (Sutskever et al., 2014).

Machine Translation (MT) systems after seeing great progress in recent years have been found to be sensitive to synthetic and natural noise in input, distributional shift, and adversarial examples (Koehn and Knowles, 2017; Belinkov and Bisk, 2017; Durrani et al., 2019; Anastasopoulos et al., 2019; Michel et al., 2019). Fine-tuning has proven to be a successful technique to carry out this task. One of the most prominent variations is described in (Chu and Wang, 2018), which trains an NMT model on out-of-domain corpora until model convergence and then resumes training from step 1 on a mix of in-domain and out-of-domain data.

A fine-grained human evaluation research of the transformer based systems and state-of-the-art recurrent systems was carried out on the translation from English to Chinese. The evalution results shows reduction in errors by 31 percent and significantly less errors in 10 out of 22 error categories when using Transformer based MT systems. (Ye and Toral, 2020). Another research has shown that improved efficiency and accuracy can be obtained by converting a pre-trained transformer into its efficient recurrent counterpart. A swap procedure is implemented which replaces softmax attention of a pertained transformer with its linear-complexity recurrent alternative followed by fine-tuning. Fine-tuning has proven to help reduce the training cost and improve efficiency and accuracy (Kasai et al., 2021).

We took part in WMT 2022 Biomedical translation task from English to Spanish using the fine-tuning approach on the Transformer based models and we describe our efforts in this paper. The paper is structured as follows. The data sets and their preparation is outlined in Section 3 and Section 4, followed by details of the experiments carried out and their results in Section 5. We then present the summary of our findings and conclusion in Section 6.

2 Related Work

Machine translation systems out of domain performance has been negatively impacted to the extent that they completely sacrifice adequacy for the sake of fluency. Hence, the presence of domain inconsistency is considered a key challenge in machine translation (Koehn and Knowles, 2017). The common approach to tackle this challenge is firstly to train an MT system on a (generic) source domain and secondly to fine-tune it on a (specific) target domain (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016; Servan et al., 2016; Chu et al., 2017), followed by continuous fine-tuning of data

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 925 - 929
December 7-8, 2022 ©2022 Association for Computational Linguistics

sets which are similar to the target domain (Sajjad et al., 2017), or to dynamically change the balance of data towards the target domain (van der Wees et al., 2017). An alternative approach is to train systems on multiple domains simultaneously, while adding domain-specific tags to the input examples (Kobus et al., 2016).

Other methods include the works around Dual Contextual (DC) module, which is an extension of the conventional self-attention unit, to effectively make use of both, local and global contextual information. This work aims to further improve the sentence representation ability of the encoder and decoder sub-networks, thus enhancing the overall performance of the translation model (Ampomah et al., 2021). Domain adaptation methods include instance weighing, data selection (Wang et al., 2017) and incorporating a domain classifier (Chen et al., 2017; Britz et al., 2017).

Some language pairs do not have enough parallel text for training. Hence, to counter the data sparsity problem of the NMT training some have used various strategies like augmenting training data, exploiting training data from other languages, alternative learning strategies that use only monolingual data (Haque et al., 2021). Some of the researchers have made use of monolingual data available either in the target domain, for example, by training the decoder on these data sets (Domhan and Hieber, 2017), or by back-translating (Sennrich et al., 2016), or in the source domain, using similar techniques (Zhang and Zong, 2016).

3 Data

In the experiments described in this paper, we use data sets from both the general and clinical domains. ParaCrawl, EMEA, and WMT are available in the public domain, while, M&R Letters is a data set internal to Optum. The M&R in-domain data set comprises of medical claim correspondence letters sent to the insurance customers which have been manually translated to Spanish. Among the public data sets, ParaCrawl is the largest publicly available parallel corpora for European languages. EMEA is a multi-lingual parallel corpus made out of PDF documents from the European Medicines Agency. We have used data from all three subtracks namely, clinical cases, clinical terminology, and ontology concepts of the ClinSpEn data set provided by WMT. Table 1 summarizes the data sets used and their size. It is important to note that we generate train and test splits on ParaCrawl (general domain), EMEA, and M&R data sets (clinical domain) and evaluate on these. For WMT, we use all 8K sentence pairs as training data and share evaluation BLEU scores computed by WMT submission system on their hidden test set.

Data Fragment	Sentences	Domain
ParaCrawl	38M	General
M&R Letters	492K	Medical
EMEA	15K	Clinical
WMT	8K	Clinical

Table 1: Data sets used in this work and corresponding source and number of sentences in each.

4 Data Preparation

The Data preparation very closely follows the steps outlined in (Manchanda and Grunin, 2020). The additional steps are listed below.

1. **Language Check Elimination**
   Sentences not from the intended language were eliminated.

2. **Length difference check**
   The internal data that we used comprised of correspondence letters to our customers anonymized and their manual translations. It was found upon a close observation that manual translations differ depending on the translator. Sometimes, the same phrase can be translated multiple ways or some additional information can be added unintentionally to the translation which can confuse the learning algorithm leading to under-fitting. We eliminated any translation that differs from the source sentence in length by more than 40 percent.

5 Experiments and Results

As described in the Data Section (3), We are using data sets from both the General domain and Medical/Clinical domain. To fine-tune the model, we have a 2-GPU setup with a docker container deployed on on-premise machines containing all the required packages to fine-tune the OPUS en-es translation model [1]. We use HuggingFace transformers library (Wolf et al., 2020) for all our experiments.

[1] https://huggingface.co/Helsinki-NLP/opus-mt-en-es

The following fine-tuning experiments are done on the transformer model used by the Helsinki-NLP opus-mt-en-es model. As evident from its model card, this model was trained on general-purpose English to Spanish training corpus and in these experiments, we will try to fine-tune the model to the clinical domain.

Since the data provided by the sub-task was limited, we used the entire WMT 2022 data as training data and used train-test splits on other clinical domain data sets to test the success of fine-tuning.

One of our key observation while doing the experiments and serving these models on production systems were that they regularly need to be checked for over-fitting and hallucination errors. In addition to evaluation by BLEU scores, We do a "**Sanity check**" by running an inference with source language strings of various lengths to mimic handwritten text and check if the translation is not adding extra tokens.

1. **Experiment 0: Reference Baseline**
   We use the model already pre-trained without any fine-tuning as our reference baseline and compare our fine-tuning results against this to determine the better models.

2. **Experiment 1: Mix of General and In-domain data**
   First, we fine-tune the general purpose model on a mix of in-domain and public data set. Our in-domain data sets are M&R correspondence letters, EMEA clinical data set and WMT 2022. We mix these with 2 million sentences randomly selected from the ParaCrawl corpus to keep the model from over-fitting to only one domain. We keep the learning rate on the higher side (1e-5) for this experiment and train for 1 epoch only. We do not add length difference check (2) in this experiment on the in-domain data.

3. **Experiment 2: Fine-tuning on only In-domain data**
   Our next experiment was to fine-tune the public model on only the in-domain data sets. This experiment contains all the data preparation steps. The learning rate for this experiment was kept lower as compared to the previous experiment (1e-6) as the data was purely in-domain.

Figure 1 shows a graph of the BLEU scores at evaluation time for all the above-mentioned experiments. Along with the BLEU scores on the test splits of general and Clinical (EMEA/M&R) datasets, this figure also shows the test BLEU scores provided by WMT on their hidden test sets. We observe that the model trained on only general-purpose data (Experiment 0) performs decently on both in-domain and general-purpose data sets. Experiments 1 and 2 yield better results on the EMEA/M&R data sets, and degrade a little on the general-purpose data sets. It can be noted that both experiments have the same scores on general and EMEA/M&R datasets. This indicates that the approach of fine-tuning with a high learning rate with some general domain data present (experiment 1) and fine-tuning with a low learning rate only on the in-domain data (experiment 2) yields very similar results.

However, Experiment 2 yields the best results on the WMT test data set and hence is our primary submission to the task. It is interesting to note that the gain on the BLEU scores of EMEA and M&R datasets is more significant as compared to the gain in WMT BLEU scores. One of the major reasons for that could be the amount of data available for this particular domain.

6 Conclusion

We fine-tuned a publicly available model in multiple ways using different combinations of data from various sources. We showed how fine-tuning is sensitive to new domains and can show promising results if done diligently. This paper shows the results of fine-tuning on a single domain but we think that fine-tuning on any new domain would provide gains in the translation quality. The scale of this gain, however, can depend on the amount of training data available in that particular domain.

7 Limitation

As evident from our experiments and results, in-domain machine translation involves some trade-off in translation quality amongst domains. When we tried to fine-tune a translation model to a new domain, the BLEU scores on the general domain drop. The users of the fine-tuned model need to be cognizant of the fact that while these models are the best for the domain they were fine-tuned for, they might not be the best to translate general handwritten text which lacks the structure of the fine-tuning data. We recommend separate specialized models for different use cases.

Huawei BabelTar NMT at WMT22 Biomedical Translation Task: How we further improve domain-specific NMT

Weixuan Wang , Xupeng Meng, Suqing Yan, Ye Tian, Wei Peng[*]
Artificial Intelligence Application Research Center, Huawei Technologies
peng.wei1@huawei.com

Abstract

This paper describes Huawei Artificial Intelligence Application Research Center's neural machine translation system ("BabelTar"). Our submission to the WMT22 biomedical translation shared task covers language directions between English and the other seven languages (French, German, Italian, Spanish, Portuguese, Russian, and Chinese). During the past four years, our participation in this domain-specific track has witnessed a paradigm shift of methodology from a purely data-driven focus to embracing diversified techniques, including pre-trained multilingual NMT models, homograph disambiguation, ensemble learning, and preprocessing methods. We illustrate practical insights and measured performance improvements relating to how we further improve our domain-specific NMT system.

1 Introduction

The existing mainstream neural machine translation (NMT) system is predominantly data-driven. Our participation in WMT biomedical tasks traced back from 2019 has witnessed pursuits extending beyond this modality. In our WMT20 and WMT21 submissions, various domain adaption technologies (Bawden et al., 2020; Akhbardeh et al., 2021) have been applied including practical approaches fine-tuning on general-purpose models, back-translation (Sennrich et al., 2016a) and leveraging in-domain dictionaries (Peng et al., 2020; Wang et al., 2021). Despite achieving state-of-the-art (SOTA) BLEU scores for most of our submissions in the last two years, under-translation occurred in the "English ↔ Chinese" due to the models' incapability to handle long sentences (Wang et al., 2021). It was rectified by ensembling the affected model with the baseline, resulting in a decrease in BLEU scores. In addition, the models trained predominately with the general domain data still face challenges associated with domain adaptation.

In this paper, we present practical insights into how we further improve Huawei Artificial Intelligence Application Research Center's neural machine translation system ("BabelTar") in domain-specific machine translation. This year, our participation in the WMT22 biomedical translation task covers language directions between "English (EN)" and the other seven languages "German (DE)", "Spanish (ES)", "French (FR)", "Italian (IT)", "Portuguese (PT)", "Russian (RU)" and "Chinese (ZH)". More specifically, we adopt in-house general-purposed bilingual NMT models built upon the transformer-big architecture (Vaswani et al., 2017) and a pre-trained multilingual NMT model (M2M100) (Fan et al., 2021) with an M2M100-418M configuration as baseline models. Finetuned with the in-domain data provided by the organizer, the back-translated monolingual Medline data in English dating before July 2018, the in-domain dictionaries enhanced with terminologies, the models can be improved significantly over the last year's submissions, for example, +1.18 BLEU on "EN → IT" and +1.24 BLEU on "EN → DE". Leveraging the knowledge learned in addressing the ambiguities caused by homographs, we can further boost +0.65 BLEU in the language direction of "EN → ZH". By optimizing the sequence length during decoding, we successfully solve the issue of under-translation in the language pair of "EN ↔ ZH".

2 The Data

In this section we detail the bilingual and monolingual corpora used in this shared task (Table 1).

- **OOD**: The general domain data (OOD) are in-house data used to train the baseline models.
- **IND**: In all directions, we use the in-domain

Table 1: Data used for training and evaluating the system. “M” is the acronym for “million”, and K stands for “thousand”, indicating the records of sentences, lexicon pairs or vocabularies. The Dev. datasets are extracted from the training datasets, and we use WMT21 shared task test data to evaluate our submission this year.

data (IND) provided by the shared task organizers to finetune the baseline models. [1] The IND data consists of WMT-released bitexts from Pubmed, UFAL, [2] Medline, [3] MeSpEn, [4] Scielo [5] and Brazilian Thesis and Dissertations.[6]

- **IND-dict.**: The lexicon pairs are collected from SNOMED-CT, [7] DOPPS[8] and WFOT.[9] Other terminologies are from Babel linguistics, [10] with COVID-19 related terms obtained from Neulab. [11]

- **IND-Aug.**: We augment the in-domain data using parallel corpora collected from TAUS [12] for the English ↔ Spanish, English ↔ French, English ↔ Italian, and English ↔ Chinese language pairs.

- **IND-BT.**: A batch of monolingual Medline data in English (IND-BT.) dated before July 2018 has been collected and back-translated for data augmentation. The official released IND data from WMT is also back-translated. The models used for back-translation are from our last year’s shared task (Wang et al., 2021).

It is noted that OOD, IND, IND-dict. and IND-Aug. are combined and subsequently partitioned for training and evaluation.

3 The Approaches

The proposed systems are finetuned using the following methods. It is noted that bilingual models are trained on one Tesla V100 GPU, taking approximately 8-20 hours. All multilingual models are trained on eight Tesla V100 GPUs, taking 6-50 hours, depending on the volumes of data involved.

3.1 Multilingual NMT Models

Unlike our previous submissions focusing merely on bilingual NMT models, we leverage pre-trained multilingual NMT models (M2M-100) in the shared task this year.

Table 3: Effects of applying different finetuning order to train English⇔Italian, English⇔Portuguese, English⇔Russian M2M-100 models on WMT21.

3.2 Domain-specific Dictionaries

Leveraging domain-specific dictionaries is proved a viable solution for domain adaptation in NMT (Peng et al., 2020; Wang et al., 2021) to enhance IND data coverage. A terminology dictionary is generated from the collected lexicons and attached to the end of the parallel corpus for each language direction to train the models.

3.3 Ensemble Learning

Ensemble learning is a representative method aggregating several models' predictions to obtain more accurate predictions. We average the probabilities of NMT output layers at each time step as depicted in Garmash and Monz (2016). In these experiments, we choose the top 3 best bilingual NMT models to participate in ensemble learning.

3.4 Homograph Disambiguation

Homographs may confuse an NMT model in selecting an inaccurate prediction due to conflicting word sense meanings in different domains. We design a novel approach to tackle homographic issues of NMT in the latent space to handle cross-domain ambiguities. The method is under review and will appear in another venue.

3.5 Preprocessing and Postprocessing

The under-translation problem presented in Wang et al. (2021) is associated with the inability of an NMT model to handle long sentences. The presence of noisy training data may cause under-translation. We optimize the preprocessing pipeline to include techniques like sentence segmentation, punctuation normalization, special tokens replacement, etc., leading to a resolution of the under-

Models	EN→DE	DE→EN	EN→FR	FR→EN	EN→IT	IT→EN	EN→ZH	ZH→EN
Model-1	31.25	40.46	**47.27**	48.82	43.92	**44.73**	**42.23**	**39.62**
Model-2	31.65	40.42	47.21	48.34	43.92	44.22	41.58	39.14
Model-3	31.01	40.17	47.25	48.55	45.04	44.05	41.29	38.92
Ensemble	**32.49**	**41.57**	46.79	**48.86**	**45.10**	44.71	41.36	38.50

Table 4: Results from the ensemble learning of the top three models on WMT21.

translation problem. More specifically, we first perform punctuation normalization to standardize data formats using Moses library (Koehn et al., 2007). Sentencepiece approach (Sennrich et al., 2016b) is subsequently used to tokenize the sentences into a series of subwords. Sentences with a length longer than a threshold (i.e., 80 subwords) are segmented to handle issues wrt under-translation. Preprocessing also replaces some unique tokens with placeholders, such as roman numbers, to avoid the out-of-vocabulary (OOV) problem. Postprocessing strategies are used to recover the previously segmented sentences. The detokenization is performed to convert subwords into words. Finally, we apply specific rules to handle punctuations and remove undesirable spaces.

4 Experimental Results and Analysis

As OOD data also contribute to the domain-specific NMT (Wang et al., 2021), both OOD data and IND data are used to finetune the NMT bilingual and multilingual NMT models. OK-aligned WMT21 test data are used for evaluation in the experiments. The BLEU scores are evaluated using the MTEVAL script from Moses (Koehn et al., 2007) with results shown in Table 2.

4.1 Multilingual NMT

It is challenging to finetune a pre-trained multilingual NMT model with hundreds of millions of parameters (i.e., 418 millions parameters for M2M-100-418M) with limited numbers of in-domain data. We design a two-stage training procedure in which a multilingual baseline initially finetuned on IND data of all available language pairs (“IND-all”) is subsequently trained on data from a specific language pair (“IND”). As depicted in Table 3, such a two-stage training method (“IND-all + IND”) is more effective than a simple finetuning step, achieving a significant improvement to the BLEU score (up to +3.86). Multilingual NMT models outperform bilingual NMT models, particularly for low-resource language pairs, such as EN ↔ RU and IT → EN (shown in Table 2).

4.2 Ensemble Decoding

We choose the three best models to ensemble in all experiments, including our best model submitted in the WMT21 shared task and the other two models trained following the methods depicted in this paper. Unlike the way mentioned in Wang et al. (2021) in averaging the logarithmic probabilities of a decoded token, we average the outputs of the output layer. This proves to be a more effective approach than the one used in previous years’ submissions. The results are shown in Table 4. We have not investigated means to ensemble a pre-trained multilingual NMT model with our SOTA bilingual NMT models due to time and resource constraints in this year’s shared task.

4.3 The Effect of Homograph Disambiguation

Table 6 demonstrates the effectiveness of applying a method designated for homographic disambiguation. It can be observed that resolving homographic issues in domain-specific NMT can significantly improve the BLEU score to up to +0.65.

4.4 Preprocessing to Solve Under-translation

To handle issues relating to under-translation, we design a segmentation strategy to break sentences longer than 80 subwords. Combined with other preprocessing techniques, we can further improve the performance of our domain-specific NMT system. Table 7 shows a +0.89 BLEU enhancement. A comparison of translated examples is shown in Table 5 to aid our understanding.

5 Discussion

It is the fourth year we have participated in this shared task, and we have made significant progress in our submissions measured against officially released test data from previous years. But the improvements for some language directions are not always accompanied by a consistent uplift of BLEU

Sentence	Example
Input	The disease duration ranged from 2 weeks to 60 months (median, 4 months), and the affected segment was C All the patients were followed up 3 to 42 months (median, 12 months).
Wang et al. (2021)	病程2周
This year	病程2周-60个月（中位，4个月），累及节段为C。随访3-42个月（中位，12个月）。

for the contest year. The learned NMT models still suffer from "out of distribution" issues many deep learning models have encountered. Apart from maintaining the NMT models with a large amount of the latest IND data, we need to design deep learning systems to adapt to changes in distributions (Bengio et al., 2021).

On another point, we realized that the reference data sometimes do not reflect the ground truth of the translation during our manual evaluation process. It raises a related question about the rationale of using BLEU as an exclusive automatic evaluation criterion. Although BLEU may remain the default metric for evaluating machine translation quality, we strongly suggest the community investigate complementary metrics capable of accommodating good translation results with semantics variations in this shared task.

6 Conclusion

This paper depicts Huawei's neural machine translation system ("BebelTar") and the submission to the WMT22 biomedical shared task. The submission consists of fourteen models covering language directions between English and all seven other languages available in this track. We can improve the domain-specific NMT significantly by leveraging a broad range of techniques, which includes pretrained multilingual NMT models, lexicon-based enhancement, homograph disambiguation, ensemble learning, preprocessing and postprocessing, etc. In the meantime, we share practical insights on achieving the measured performance, hoping to contribute to the machine translation community in this shared task. Our future work will focus on investigating mechanisms to adapt a domain-specific NMT model to different distributions.

Acknowledgements

We express our gratitude to colleagues from HUAWEI Artificial Intelligence Application Center for their continuous support. We also appreciate the WMT22 organizers for hosting this shared task and anonymous reviewers' insightful comments, which enable us to further improve domain-specific NMT.

Abstract

This paper describes the translation systems trained by Huawei translation services center (HW-TSC) for the WMT22 biomedical translation task in five language pairs: English↔German (en↔de), English↔French (en↔fr), English↔Chinese (en↔zh), English↔Russian (en↔ru) and Spanish→English (es→en). Our primary systems are built on deep Transformer with a large filter size. We also utilize R-Drop, data diversification, forward translation, back translation, data selection, finetuning and ensemble to improve the system performance. According to the official evaluation results in OCELoT[1] or CodaLab[2], our unconstrained systems in en→de, de→en, en→fr, fr→en, en→zh and es→en (clinical terminology sub-track) get the highest BLEU scores among all submissions for the WMT22 biomedical translation task.

1 Introduction

Machine translation (MT) refers to the automatic translation of text from one language to another, and the biomedical translation task aims to evaluate the performance of MT systems in the biomedical domain. In this year's biomedical translation task, our team (HW-TSC) participates in five language pairs, including en↔de, en↔fr, en↔zh, en↔ru and es→en (clinical terminology sub-track).

Since the size of in-domain (ID) data is limited, we first use a large amount of out-of-domain (OOD) data to train our baseline neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) system, which is a deep transformer model (Dou et al., 2018; Li et al., 2019) leveraging R-Drop (Wu et al., 2021) training strategy. We then use the collected ID data (except the data from medical database) to further train the NMT model for domain transfer. To better use the limited ID training data, we employ data selection to extract ID data from OOD data, in addition to basic data augmentation strategies including data diversity, forward translation and back translation. Finally, we use finetuning (Dakwale and Monz, 2017) and model ensemble (Wang et al., 2020b) to further improve model performance in the biomedical domain.

This paper is structured as follows: we describe data size and data pre-processing methods in section 2; the model structure and training methods in section 3; final results in section 4; and conclusion in section 5.

2 Dataset

2.1 Data volume

The data size for each language pair for the WMT22 biomedical translation task is shown in Table 1. The OOD bilingual data, used to train our baseline model, comes from the WMT general MT task and our internal corpus; while the ID bilingual and monolingual data, used for transferring the domain (Yang et al., 2021), come from Biomedical Translation, UFAL Medical Corpus and our internal corpus. As there is no ID monolingual data, we use the OOD monolingual instead.

2.2 Data Pre-processing

The data pre-processing process is as follows:

- Remove duplicate sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Remove sentences with mismatched parentheses and quotation marks.
- Filter out sentences of which punctuation percentage exceeds 0.4.
- Filter out sentences with the character-to-word ratio greater than 12 or less than 1.5.

[2] https://codalab.lisn.upsaclay.fr/competitions/6696#results

	bilingual					monolingual				
	en↔de	en↔fr	en↔zh	en↔ru	es→en	en	de	fr	zh	ru
OOD	200M	600M	200M	200M	200M	-	10M	-	-	40M
ID	2.75M	6.05M	10.87M	0.24M	8.1M	46M	-	2M	92M	-

Table 1: The data size for each language pair in the WMT22 Biomedical Translation Task

- Filter out sentences with more than 150 words.
- Apply langid (Joulin et al., 2017, 2016) to filter sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter out sentence pairs that are poorly aligned.

It should be noted that for en↔de, en↔fr, en↔ru and es→en translation task, we adopt joint SentencePiece model (SPM) (Kudo and Richardson, 2018; Kudo, 2018) for word segmentation, with a vocabulary of 32k. As for en↔zh translation task, we use Jieba tokenizer[3] to pre-segment Chinese sentences, and Moses tokenizer (Koehn et al., 2007) to pre-segment English sentences. Then we use joint Byte Pair Encoding (BPE) (Sennrich et al., 2016) to perform subword segmentation on Chinese and English sentences. The vocabulary size of BPE is also set to 32k.

3 System Overview

3.1 Model

Transformer (Vaswani et al., 2017), as the current mainstream architecture for NMT, adopts a fully self-attention mechanism, which can realize algorithm parallelism, speed up model training, and improve model performance. Deep Transformer, as an improvement of Transformer, increases the number of encoder layers and uses pre-layer-normalization to further improve model performance. Therefore, for all four language pairs, we adopt the Deep Transformer (Wei et al., 2021) model architecture: Based on the Transformer-big model architecture, our Deep Transformer model features pre-layer-normalization, 25-layer encoder, 6-layer decoder, 16-head self-attention, 1024-dimension word embedding and 4096-dimension hidden state.

3.2 R-Drop

Dropout (Srivastava et al., 2014) is a powerful and widely used technique for regularizing deep neural networks. Though it can help improve training effectiveness, the randomness introduced by dropouts may lead to inconsistencies between training and inference. R-Drop (Wu et al., 2021) forces the output distributions of different sub-models generated by dropout be consistent with each other. Therefore, we use R-Drop to augment the baseline model for each task and reduce inconsistencies between training and inference.

3.3 Data Diversification

Data diversification (Nguyen et al., 2020) is a simple and effective strategy to improve the performance of NMT. It uses predictions from multiple forward and backward models, and combines the results with the original data to train the final NMT model. The method does not require additional monolingual data and is applicable to all NMT models. It is more efficient than knowledge distillation (Wang et al., 2021) and dual learning (He et al., 2016). In our en↔de, en↔fr, en↔zh and en↔ru translation tasks, we use only a forward model and a backward model to generate synthetic data, and then mix the synthetic data with the bilingual data for NMT model training.

3.4 Forward Translation

Forward translation (Wu et al., 2019), also known as self-training (Imamura and Sumita, 2018), refers to using a forward NMT model to translate source-side monolingual data to generate synthetic bilingual data, which is then used to expand the training data size. Forward translation usually relies on beam search (Freitag and Al-Onaizan, 2017) decoding to generate synthetic data. Therefore, we adopt the forward translation method based on beam search decoding.

3.5 Back Translation

Back translation (Sennrich et al., 2015; Edunov et al., 2018) refers to translating the target monolingual data back to the source language, and then using the synthetic data to increase the training data size. This method has been proven effective in improving the NMT model performance. There are many back translation methods, among which sampling (Graça et al., 2019), noise (Edunov et al.,

[3] https://github.com/fxsjy/jieba

2018) or tagged (Caswell et al.) back-translation methods work better. In the scenario where forward translation and back translation are used in combination (Wu et al., 2019), the improvement effect brought by sampling back translation is more significant. In our translation task, we adopt sampling back translation method.

3.6 Data Selection

Data selection (van der Wees et al., 2017) is a data augmentation method that we use to select ID bilingual data from OOD bilingual data. Inspired by the domain feature calculation in curriculum learning (Wang et al., 2020a), we use an ID NMT model and an OOD NMT model to calculate the decoding probability of OOD bilingual data. The bilingual data of which ID decoding probability is higher than OOD decoding probability can be selected as additional ID data. The data selection process is also shown in Algorithm 1:

Algorithm 1: Data selection process

```
Input  : ID NMT model $\theta_I$, OOD NMT model $\theta_O$ and OOD bilingual data set $D_O$.
Output : ID bilingual data set $D_I$.
for each sentence pair $(x, y) \in D_O$ do
    // $x$ is the source sentence, $y$ is the target sentence.
    $score = \frac{\log P(y|x;\theta_I) - \log P(y|x;\theta_O)}{|y|}$
    if $score > 0$ then
        add $(x, y)$ to $D_I$
    end
end
```

3.7 Finetuning

Finetuning (Dakwale and Monz, 2017) is a way to achieve domain transfer. In our translation task, we adopt a two-stage finetuning strategy. In the first stage, we use ID bilingual data to continue training the OOD NMT model, and then use the data augmentation strategy mentioned above to improve the model performance. In the second stage, we use the development set and synthetic data generated from the source-side text in the test set to finetune the ID model for more fine-grained domain transfer.

3.8 Ensemble

Ensemble (Wang et al., 2020b) is a widely used method to integrate different models for better performance. It is worth noting that when using ensemble, increasing the number of models does not always lead to better performance, and sometimes even causes performance deterioration. Therefore, for each track, we train four models on the same data, and go through all combinations of models to choose the one that performs best on the development set. This is also the model selection strategy (Yang et al., 2021) we use in the WMT21 biomedical translation task.

4 Experimental Result

During the training phase, we use Pytorch-based Fairseq[4] (Ott et al., 2019) open-source framework, and use deep Transformer model architecture as our benchmark system. Each model is trained using 8 GPUs with a batch size of 2048. The update frequency is 4 and the learning rate is 5e-4, the label smoothing rate (Szegedy et al., 2016) is 0.1, the warm-up steps is 4000, and the dropout is 0.3. Adam optimizer (Kingma and Ba, 2015) with β1=0.9 and β2=0.98 is also used. Furthermore, we use reg_label_smoothed_cross_entropy as the loss function and set reg-alpha to 5 when applying R-Drop (Wu et al., 2021) training strategy. In the evaluation phase, we use Marian[5] (Junczys-Dowmunt et al., 2018) for decoding and then calculate the sacrebleu[6] (Post, 2018) on the WMT21 OK-aligned biomedical test set to measure the performance of each model.

4.1 en↔de

For en↔de track, Table 2 shows the results of using the methods mentioned above to improve the model performance. The results show that continuing training with ID bilingual data on the basis of an OOD baseline improves en→de translation performance by 1.6 BLEU, but has little effect on the de→en track, with an increase of only 0.1 BLEU. Data selection significantly improves en↔de translation performance by 0.9-1.2 BLEU. In addition, other training strategies also bring small performance improvements.

4.2 en↔fr

Table 3 shows the results of en↔fr model. The results show that data diversity brings the greatest improvement to translation of both directions

+ dev set & synthetic test set finetuning	46.8	48.4
+ ensemble	**46.9**	**48.6**

Table 3: BLEU scores of en↔fr on the WMT21 OK-aligned biomedical test set.

(0.7 BLEU and 1.3 BLEU respectively). However, data selection has little impact on fr→en translation, and even no impact on en→fr translation. We assume this is because not much ID bilingual data is selected from the OOD data.

4.3 en↔zh

For en↔zh track, continuing training with ID bilingual data on the basis of an ODD baseline, as well as data diversity, bring the greatest impact on the model performance, while data selection has the least impact. In addition, the methods such as forward translation & back translation, dev set & synthetic test set finetuning and ensemble have little improvement on en→zh translation, but have a great improvement on zh→en translation. The detailed results of en↔zh translation are shown in Table 4.

4.4 en↔ru

As shown in Table 5, for the en↔ru track, the results are similar to en↔zh translation task. Continuing training with ID bilingual data and data diversity have the greatest impact on model performance, while data selection does not lead to performance improvement. In addition, the performance improvements brought by other methods are also relatively limited.

4.5 es→en

We also participate in the es→en clinical terminology sub-track (ClinSpEn-CT) this year. The sample set contains 7,000 terms that are extracted from medical literature and clinical records, with a particular focus on diseases, symptoms, findings, etc. The translations are generated and revised by professional medical translators. We extract 1000 sentences from the sample set as the dev set.

The results are shown in Table 6. All chrF and BLEU scores are calculated on this dev set. Unlike other experiments above, for es→en clinical terminology sub-task, we abandon forward translation method for the sake of maintaining terminology accuracy. Instead, we perform two rounds of back translation using monolingual English ID data. Finally, we finetune the model with 6000 bilingual terms, which results in a significant improvement on the dev set.

System	en→zh	zh→en
OOD R-Drop baseline	38.5	32.1

	en→de	de→en	en→fr	fr→en	en→zh	zh→en	en→ru	ru→en	es→en
our submission system	**38.7**	**45.6**	**38.8**	**48.6**	**49.9**	43.0	43.3	50.3	**41.57**

Table 7: BLEU scores of our submission systems on WMT22 Biomedical Translation Task on OCELoT or CodaLab, where the highest BLEU scores among all submissions are bolded.

7, where our submitted systems achieve the highest BLEU scores in six language directions of the WMT22 biomedical translation task. In conclusion, from the results on the WMT21 OK-aligned biomedical test set, continuing training with ID bilingual data, data diversity, forward translation and back translation have great impacts on the NMT model performance. When the OOD bilingual data contains a certain amount of ID bilingual, the data selection method can also achieve a good boost effect. In addition, dev set & synthetic test set finetuning and ensemble can lead to further performance gains.

5 Conclusion

This paper presents our translation system for the WMT22 en↔de, en↔fr, en↔zh, en↔ru and es →en biomedical translation task. During the experiment, we use R-Drop and ID bilingual data finetuning methods to build our ID translation system, and then use data diversity, forward translation, back translation and data selection methods to expand the size of training data for training a better system. We also adopt finetuning and ensemble to further improve the system performance. According to the official evaluation results in OCELoT or CodaLab, our submitted systems achieve the highest BLEU scores in six language directions of the WMT22 biomedical translation task.

Abstract

We present the joint contribution of IST and Unbabel to the WMT 2022 Chat Translation Shared Task. We participated in all six language directions (English ↔ German, English ↔ French, English ↔ Brazilian Portuguese). We addressed the lack of domain-specific data with a lightweight adaptation approach, using mBART50, a large pretrained language model trained on millions of sentence-pairs, as our base model. We fine-tune it using a two-step fine-tuning process. In the first step, we fine-tune the model on publicly available data. In the second step, we use the validation set. After having a domain-specific model, we explore the use of kNN-MT as a way of incorporating domain-specific data at decoding time.[1]

1 Introduction

In recent years, neural machine translation (NMT) has seen remarkable advances due to the increasingly powerful models (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017). The translation of conversational text is an important and challenging application for machine translation, specially in the customer support domain, since international companies have an increasing need to offer customer support in various languages. However, this domain has not been substantially explored in machine translation research.

In the Chat Translation shared task, the goal is to understand the context's impact in conversational text translation, and to study the feasibility of multilingual systems for customer support translation. This year, the focus was on the case in which we have a centralizing costumer support with English speaking agents and a translation layer between agent and costumer, allowing the communication with customers which speak different languages.

In this paper we discuss our submission to this task. Our submitted system covers all 3 language pairs: English-German, English-Brazilian Portuguese, and English-French, in both directions: we translate the agent utterance from English to the other language and the customer utterances from the other language to English. As no training data is provided for this task, we recur to the use of the pre-trained multilingual machine translation model mBART50 (§2.1; Tang et al. (2020)) and perform domain adaptation through fine-tuning (§2.2) with domain-specific data and by retrieving similar examples from domain-specific datastores (§2.3). To increase the size of training examples that can be used to fine-tune the model and to create the domain-specific datastore we search for similar examples on publicly available datasets (§3.1) and perform back-translation of the provided monolingual data (§3.2).

2 Models

In this section, we describe the model that we used to tackle this shared task. We start by describing the base model. Then, we describe the techniques used to adapt the base model to customer support chat translation.

2.1 Base Model

As our base model, we use the mBART50 (Tang et al., 2020) "one-to-many" (English to 49 other languages) or "many-to-one" (49 languages to English), depending on the language direction. mBART50 can translate sentences between English and 49 different languages, which include the languages present in this shared task (German, French and Brazilian Portuguese). It consists of a pre-trained encoder-decoder transformer that is first pretrained on a auto-denoising task with monolingual data from 25 languages (mBART; Liu et al. (2020)) and then further pre-trained on an extended set of monolingual data that comprises

[*] Equal contribution.

50 languages. Then, to adapt the model to perform machine translation, Tang et al. (2020) performed multilingual fine-tuning on machine translation, using data from the 50 supported languages. For this, they used three different configurations: "one-to-many", "many-to-one", and "many-to-many". The first two are obtained by fine-tuning the model with the bilingual data, having English as the source or target language, respectively. The latter is obtained by fine-tuning the model with all the language pairs combinations (using English as the pivot language to obtain the bilingual data).

2.2 Fine-tuning

We performed a two-step fine-tuning process. First, we fine-tuned mBART50 on the domain-specific data that was obtained using data augmentation (§3.1). Then we performed a second step of fine-tuning using the validation sets provided by the shared task organization.

2.3 Nearest Neighbor Machine Translation

To further adapt mBART50, we use the nearest neighbor machine translation approach, kNN-MT, introduced by Khandelwal et al. (2021). kNN-MT consists of a semi-parametric model: besides having a parametric component (base model) that outputs a probability distribution over the vocabulary, $p_{\mathrm{NMT}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$, it also has a nearest neighbor retrieval mechanism, which allows direct access to a datastore of examples.

More specifically, we build a datastore $\mathcal{D}$ which consists of a key-value memory, where each entry key is the decoder's output representation, $\boldsymbol{f}(\boldsymbol{x}, \boldsymbol{y}_{<t}) \in \mathbb{R}^d$, and the value is the corresponding target token y_t:

$$\mathcal{D} = \{(\boldsymbol{f}(\boldsymbol{x}, \boldsymbol{y}_{<t}), y_t) \; \forall \, t \mid (\boldsymbol{x}, \boldsymbol{y}) \in \mathcal{S}\}, \quad (1)$$

where $\mathcal{S}$ denotes a set of parallel sentences.

Then, at inference time, the model searches the datastore to retrieve the set of k nearest neighbors $\mathcal{N}$. Using their distances $d(\cdot)$ to the current decoder's output representation, we can compute the retrieval distribution $p_{k\mathrm{NN}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$ by applying the softmax function:

$$p_{k\mathrm{NN}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) = \quad (2)$$
$$\frac{\sum_{(\boldsymbol{k}_j, v_j) \in \mathcal{N}} \mathbb{1}_{y_t = v_j} \exp\left(-d\left(\boldsymbol{k}_j, \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{y}_{<t})\right)/T\right)}{\sum_{(\boldsymbol{k}_j, v_j) \in \mathcal{N}} \exp\left(-d\left(\boldsymbol{k}_j, \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{y}_{<t})\right)/T\right)},$$

where T is the softmax temperature, k_j denotes the key of the j^{th} neighbor and v_j its value. Finally, the two probability distributions, $p_{\mathrm{NMT}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$ and $p_{k\mathrm{NN}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$, are combined to obtain the final distribution, which is used to generate the translation through beam search, by performing interpolation:

$$\begin{aligned} p(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) = {} & (1-\lambda)\, p_{\mathrm{NMT}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) \quad (3) \\ & + \lambda\, p_{k\mathrm{NN}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}), \end{aligned}$$

where $\lambda \in [0, 1]$ is a hyper-parameter that controls the weights given to the two distributions.

2.3.1 Using Two Datastores

As we use data from multiple sources (described in Section 3), we adapt kNN-MT to perform retrieval from two datastores which are composed of examples from different datasets. To do this, we simply need to perform retrieval from the two datastores obtaining two retrieval distributions, $p_{k\mathrm{NN}1}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$ and $p_{k\mathrm{NN}2}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x})$, computed using Eq. 2.

Then, we need to modify the distributions interpolation (Eq. 3) to account for three distributions:

$$\begin{aligned} p(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) = {} & (1-\lambda_1-\lambda_2)\, p_{\mathrm{NMT}}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) \quad (4) \\ & + \lambda_1\, p_{k\mathrm{NN}1}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}) \\ & + \lambda_2\, p_{k\mathrm{NN}2}(y_t \mid \boldsymbol{y}_{<t}, \boldsymbol{x}), \end{aligned}$$

where $\lambda_1 \in [0, 1]$ and $\lambda_2 \in [0, 1]$ are hyper-parameters that control the weights given to the three distributions.

3 Data

The data provided by the shared task organization is part of a corpus called MAIA corpus. It consists of parallel data of chats between an agent (English) and a customer (Brazilian Portuguese, German or French) across one domain: customer support conversation. Thus, there are a total of 6 translation directions. One of the main obstacles of this domain is the lack of parallel data publicly available. To make the task closer to a real case scenario, the shared task organization has only provided bilingual validation sets and monolingual data, for all languages.

As already mentioned, finding parallel data for this specific domain is challenging. The only exception is the dataset from WMT 2020 Shared Task on Chat Translation (Farajian et al., 2020). Unfortunately, it only contains two translation directions:

Language Direction	Original dev set	New training set	New dev set
en-de	1006	528	478
en-fr	1750	894	856
en-pt_br	1353	668	685
de-en	1103	519	584
fr-en	1003	466	537
pt_br-en	1006	469	537

Table 1: Statistics (number of sentences) of the development sets provided by the shared task organization, and of the new development and training sets after splitting it in two.

Language Direction	Number of Sentences
de-en	203,169,413
fr-en	471,885,306
pt_br-en	192,874,694

Table 2: Statistics (number of sentences) of the public available data in OPUS.

Language Direction	Number of Sentences
en-de	6494
en-fr	3311
en-pt_br	2010
de-en	6874
fr-en	1929
pt_br-en	1657

Table 3: Statistics (number of sentences) of the back-translated data.

English to German and German to English. Therefore, to circumvent the lack of domain-specific data available to fine-tune the model and to add to the datastores, we perform data augmentation (§3.1) and back-translate the monolingual data provided (§3.2).

3.1 Data Augmentation

As the domain-specific data available is limited to the provided bilingual development sets and monolingual sets, we perform data augmentation to create training sets. To do so, we use LaBSE (Language-Agnostic BERT Sentence Embedding) (Feng et al., 2020) multilingual sentence representations. In order to perform data augmentation we also use the k-nearest neighbours (kNN) implementation of the FAISS toolkit (Johnson et al., 2019).

We start by defining a seed corpus (which in our case is the validation set) and a pool corpus (generic data). Then, we use LaBSE to compute the sentence embeddings. After having the sentence embeddings, we built an in-house kNN implementation that relies on FAISS to compute the similarity among all sentences, obtaining a score between 0 (no similarity) and 1 (maximum similarity). Then, we keep the sentence-pairs with a score higher than 0.7.

3.1.1 Data Selection

Regarding data selection, we use all possible datasets publicly available in OPUS (Tiedemann, 2012) to create our pool of public data. Statistics can be find in Table 2.

3.1.2 Data Cleaning

After having downloaded all data, we perform data cleaning. To do so, we used a combination of heuristic filters and Bicleaner (Sánchez-Cartagena et al.; Ramírez-Sánchez et al., 2020). Bicleaner is a tool that detects noisy sentence-pair in a parallel corpus. It outputs the likelihood of two sentences being a mutual translation (in this case the value is near 1) or not (the value is near 0). We could have trained our own Bicleaner models but we decided to use the available ready-to-use language packages.

3.2 Back-translation

To increase the amount of domain-specific data, we also use the monolingual data provided by the shared task organizers. To do so, we performed back-translation of these datasets with best fine-tuned model using beam-search with 5 beams. The statistics are reported in Table 3. To perform back-translation we used ours models fine-tuned. We use the back-translated examples both for fine-tuning our models and as part of the datastores.

4 Experiments

In this section, we describe the experiments we made, to allow us to choose the best model to submit to the shared task.

4.1 Experimental Settings

The shared task organization provided two different baselines: one leveraging the conversation context

Model	Language Direction					
	en-de		en-fr		en-pt_br	
	SacreBLEU	COMET	SacreBLEU	COMET	SacreBLEU	COMET
Baseline (without context)	35.11	0.3989	54.23	0.8011	50.35	0.7897
Baseline (with context)	33.75	0.3755	53.95	0.8013	51.02	0.8721
kNN-MT	52.20	0.5873	61.20	0.9032	48.80	0.9398
Fine-tuned Model	62.50	0.7289	71.60	1.0485	67.80	1.1285
Fine-tuned Model + kNN-MT (1 datastore)	**62.70**	**0.7351**	71.60	1.0324	68.10	1.1330
Fine-tuned Model + kNN-MT (2 datastores)	61.30	0.7334	**72.00**	**1.0495**	**68.10**	**1.1356**

Table 4: Results obtained for the agent direction (en -> X).

Model	Language Direction					
	de-en		fr-en		pt_br-en	
	SacreBLEU	COMET	SacreBLEU	COMET	SacreBLEU	COMET
Baseline (without context)	45.75	0.5421	47.12	0.6413	44.52	0.5887
Baseline (with context)	47.13	0.6253	48.25	0.6855	47.29	0.6475
kNN-MT	57.70	0.8617	52.70	0.8390	50.90	0.7984
Fine-tuned Model	**59.40**	0.8811	**57.70**	**0.9250**	50.10	0.8117
Fine-tuned Model + kNN-MT (1 datastore)	59.20	0.8760	57.40	0.9277	50.90	0.7984
Fine-tuned Model + kNN-MT (2 datastores)	58.70	**0.8814**	57.20	0.9226	**51.80**	**0.8009**

Table 5: Results obtained for the customer direction (X -> en).

and another one that does not. Both of them use the M2M-100 (Fan et al., 2020) large pre-trained language model, which is originally a sentence-level model. Together with the baselines, the shared task organizers provided scripts to rerun the experiments using conversational context, which we did for our small test set.

As no training data was provided by the organization, we splitted the validation set into two. We used one of them as our validation set and the other was used to fine-tune the models and to perform kNN-MT. We report the data sets statistics in Table 1. We took into consideration the fact that we are dealing with conversations, and thus, we do not split conversations, i.e., we do not perform segment filtering that might break a conversation context.

We implemented all the models by the open-sourced toolkit *fairseq* (Ott et al., 2019).

Although mBART50 supports multilingual training, we trained each language direction separately. We started by fine-tuning mBART50 with the data obtained with the data augmentation process (§3.1), the data from WMT2020 Chat Translation shared task, and the back-translated monolingual data (§3.2). Then, we continued the fine-tuning step using the the training set of the shared task.

To perform retrieval we use 2 datastores having the first datastore the data from the validation sets and the second one the data obtained with the data augmentation process (§3.1) and the back-translated monolingual data (§3.2).

Hyper-Parameter	Value
Learning Rate	0.00003
Warmup updates	16000
Label Smoothing	0.2
Optimizer	Adam
β_1, β_2	0.9, 0.98
Weight Decay	0.1
Dropout	0.1
Clip Norm	5
Batch Size	256 (tokens)
Beam Size	5
kNN-MT k	8
kNN-MT temperature	10
kNN-MT λ_1	0.1
kNN-MT λ_2	0.1

Table 6: Fairseq Hyperparameters for our experiments. The first block gives the base settings used for fine-tuning mBART50 and the second block provides the details for the kNN-MT.

The selected values for hyperparameters are stated in Table 6. To evaluate the performance of our models we used SacreBLEU (Post, 2018) and COMET (Rei et al., 2020).

4.2 Results

We tested multiple configurations for kNN-MT: using only one datastore with the validation data or using two datastores with different values for the parameters that control the weight given to each distribution (λ_1 and λ_2), changing the number of neighbours retrieved, and the softmax temperature.

The results reported in Tables 4 and 5 show that performing fine-tuning of mBART50 on domain-specific data leads to large gains for all language pairs, for the two metrics. We can also see that, despite leading to worse scores than fine-tuning, simply retrieving examples from domain-specific datastores, using kNN-MT, leads to considerable gains when comparing with the baselines. Moreover, using kNN-MT with the fine-tuned model as the base model, leads to small gains on most language pairs, for the agent direction (English→X). For the customer direction (X→English), the results are very similar to the ones obtained without retrieval. When comparing with using 1 datastore (only with the validation data), using 2 datastores leads to small improvements, which suggests that the gains led by performing retrieval are due to the data coming from the validation sets.

In terms of speed, kNN-MT model requires retrieval for every single token, leading to a low decoding speed, around 8 times slower than a model that does not perform retrieval steps according to (Martins et al., 2022). Although, it is important to take into consideration that the time the model takes to add examples to the datastores is much shorter than the time needed to fine-tune the model.

Due to the repetitive nature of dialogues in customer service conversational content, we can see that by using only a few thousand domain-specific bilingual sentence-pairs together with out-of-domain sentence-pairs (selected using the data augmentation process), we are able to improve the performance of the baselines by a large margin. By analysing these experiments' results, we selected the model that combines fine-tuning and kNN-MT (with 2 datastores) as our primary submission. For the submission, we performed fine-tuning again using the complete development sets, and also added the entire development sets to the kNN-MT datastores.

5 Conclusions

We presented the joint contribution of IST and Unbabel to the WMT 2022 Chat Translation shared task. First, we perfomed fine-tuning of a large pretrained model, mBART50. Then we perfomed kNN-MT using multiple datastores to incorporate domain-specific data at decoding time. Through experiments we show that the combination of the proposed methods is a good way of performing domain adaptation when we have few domain-specific data available.

As we are dealing with conversational content it would be interesting to incorporate context information. Unfortunately the few experiments that we have performed using context did not improve the performance of our models. As future work, one interesting line of research is how to incorporate the context information together with augmented retrieval approaches. These can be complementary to each other leading to translation quality improvements.

Abstract

Multilingual chatbots are the need of the hour for modern business. There is increasing demand for such systems all over the world. A multilingual chatbot can help to connect distant parts of the world together, without sharing a common language. We participated in WMT22 Chat Translation Shared Task. In this paper, we report descriptions of methodologies used for participation. We submit outputs from multi-encoder based transformer model, where one encoder is for context and another for source utterance. We consider one previous utterance as context. We obtain COMET scores of 0.768 and 0.907 on English-to-German and German-to-English directions, respectively. We submitted outputs without using context at all, which generated worse results in English-to-German direction. While for German-to-English, the model achieved a lower COMET score but slightly higher chrF and BLEU scores. Further, to understand the effectiveness of the context encoder, we submitted a run after removing the context encoder during testing and we obtain similar results.

1 Introduction

Translation of Dialogues is a crucial part of building multilingual chatbots. With easier access to the internet than ever, we have the opportunity to connect with different people with different languages. However, language remains a barrier to smooth communication. Using automated machine translation systems can alleviate such issues. However, most of the general MT systems are not very suitable for conversations. This is due to additional challenges chat translation possesses that general domains do not have. This includes the presence of noisy utterances. Compared to other domains, chat is more prone to contain noisy sentences. This comes from multiple sources, as follows. a) Keyboard typos: Spelling mistakes that occurred due to quick typing. In this case, often, some characters are replaced by nearby characters on the keyboard. Further, the insertion of extra characters or the absence of some characters is also common. b) Intentional shortening of Words: Users often use short forms of words by removing certain characters (primarily vowels) while keeping the pronunciation similar to the correct word (For example, ‘hw’ instead of ‘how’). c) Grammatical Errors: Conversations usually occur in an informal setting, and grammar is mostly ignored as long as the meaning is understood correctly. However, this makes it difficult to translate. Further, there are other challenges, like context dependency. That is, the utterances can be ambiguous, and the correct meaning of an utterance can not be understood without referring to its dialogue history.

In this paper, we use a multi-encoder transformer to translate chat utterances. We use six encoder layers for source text and one encoder layer for context. For better comparison, we have submitted translations from two other models. To test the effectiveness of context, we did not provide context during the testing phase as described in section 3.3.2. Further, we train another model without using any context at all as described in 3.3.3. We achieved very competitive results for the Agent subset (English-to-German), where we obtained 0.551 BLEU, 0.730 chrF, and 0.768 COMET scores, where the best result among primary submissions of the participants are 0.555, 0.735, and 0.810 BLEU, chrF and COMET score respectively. For German-to-English, our method produced 0.907, 0.729, and 0.587 COMET, chrF, and BLEU scores, respectively.

2 Related Work

The area of chat translation mostly remained unexplored until recent years. This is in part due to the unavailability of suitable dialogue datasets. Farajian et al. (2020) introduced an German–English parallel conversational corpus. Berard et al. (2020) proposed a method that replaced rare characters

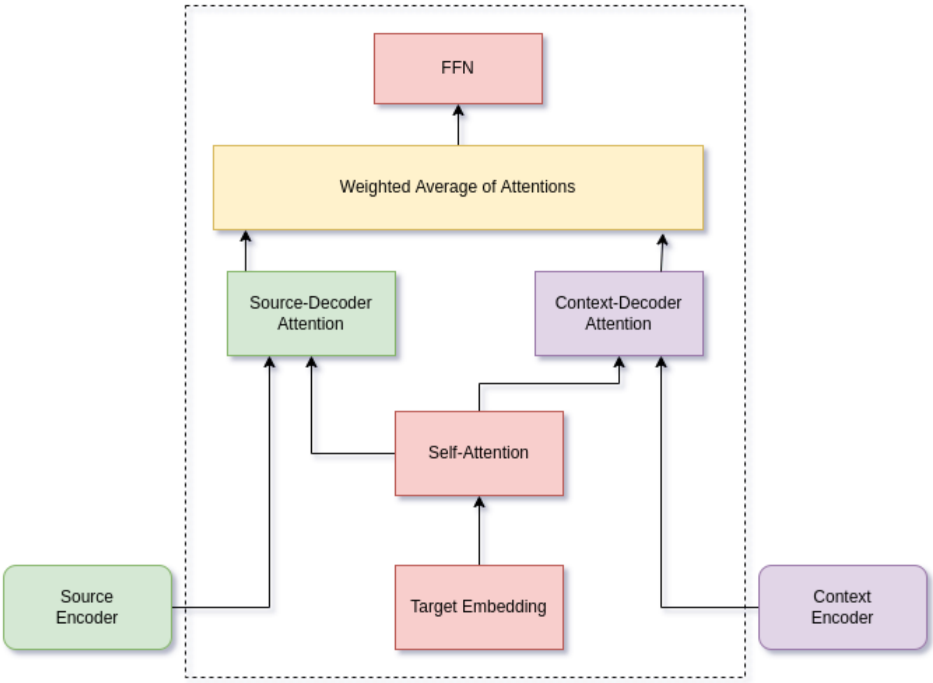

Figure 1: Diagram of our model; The weight is determined by a FFN from concatenated represenations of the attentions

with a special '<copy>' token, which helps the model to learn when to copy the tokens from source to target. Further, they used methods like inline casing, tagged back-translation (BT) (Caswell et al., 2019), Byte-Pair-Encoding (BPE) (Sennrich et al., 2016), and ensemble of models using domain-specific adaptive layers, etc. Ensemble model with a domain-specific adaptor layer generated the best translation on WMT20 Chat data. Moghe et al. (2020) used fine-tuned pre-trained models (Ng et al., 2019) on the pseudo-in-domain and in-domain data. Wang et al. (2020) used using three previous contexts along with the current sentence for adaptation of Cross-lingual Language Model Pre-training (Conneau and Lample, 2019) objectives into document-level NMT. Bao et al. (2020) used an additional encoder to process one previous context. However, adding an additional encoder did not result in consistent improvement in translation. Gain et al. (2021c) proposed a rule-based context selection technique where previous sentences by the same user are used to enhance the translation quality. This mainly helped to translate anaphoric pronouns correctly. Liang et al. (2021a) introduced a conditional variational auto-encoder (CVAE) model that captures role preference, dialogue coherence, and translation consistency. Liang et al. (2021b) proposed a multi-tasking system performing monolingual response generation, cross-lingual response generation, subsequent utterance discrimination, and speaker identification along with NMT objective. Here, the context-aware multi-tasking methods could generate better translation than context-agnostic models. Liang et al. (2022b) extended the same by introducing an additional objective, cross-lingual subsequent utterance discrimination. Further, they propose a multi-tasking algorithm that helped to generate better translation than traditional multi-tasking. Wang et al. (2021) proposed a multi-task learning-based model that identifies missing pronouns, typos and utilizes context to translate chat utterances. Liang et al. (2022a) observed visual features helps to generate better quality translation on multi-modal dialogue. Apart from chat translation, context is commonly used in other translation tasks as well. This include document translation (Kim et al., 2019; Zhang et al., 2018; Läubli et al., 2018) where other sentences from the document is used as context, multimodal translation (Yao and Wan, 2020; Gain et al., 2021a,b) where image features are used as context, etc. Gain et al. (2022) proposed a method where context is concatenated with source on both source and target side, requiring the model to translate context also, thus avoiding ignorance of context in Question-Answer translation.

3 Methodology

3.1 Pre-Training

Pre-training models with general domain data and transferring the knowledge to intended domain is standard practice in MT. We use Facebook AI's pre-trained models (Ng et al., 2019) from WMT19 [1]. The pre-training methodology consists of data processing techniques like normalize punctuation and tokenizing all data with the Moses tokenizer (Koehn et al., 2007) and byte-pair-encoding (Sennrich et al., 2016). Further, sentences with wrong language on either source or target side filtered out with language identification (Lui and Baldwin, 2012) filtering.

3.2 Model

We use a dual enocder-based transformer model. The components of the models are as follows:

- **Source Encoder:** Source Encoder consists of 6 standard transformer encoder layers. For all our models, the encoder weights are initialized from the pre-trained models. The input language of source encoder is the input language of the translation direction. That is, for English-to-German model, the language for Source Encoder is English.

- **Context Encoder:** Context Encoder of consists of 1 encoder layer. This is in part to keep model parameters lower. Further, context is supposed to assist the translation process. Thus has limited contribution compared to source. The language of the context encoder can be English or German, depending upon speaker of the previous utterance, irrespective of translation direction. We take one previous utterance from source side of previous speaker. That is, English if the speaker of previous utterance is *agent* or German if speaker of the previous utterance is *Customer*. For first utterance in a conversation, the context is empty.

- **Decoder:** Decoder consists of 6 layers of standard transformer decoder layers. We initialize the decoder from the pre-trained model. Further, in addition to encoder-decoder attention, we perform context-decoder attention. Then, we concatenate them before passing it to a feed-forward Neural Network (FFN) which determines weighted average factor g. Inspired from (Libovický et al., 2018), we take final attention output as g * context-decoder attention + (1-g) * encoder-decoder attention. The rest parts of the decoder is similar to standard transformer decoder.

3.2.1 Stage-1 Fine-tuning

For all our submissions, we perform two-stage fine-tuning. Due to the unavailability of the training set in the task, we fine-tune the model on WMT20 Chat Task (Farajian et al., 2020) data. However, since our objective is to get the highest results for WMT22 version of chat data, we use that as a validation set.

3.2.2 Stage-2 Fine-tuning

We finetune the models obtained from Stage-1 fine-tuning with WMT22 Chat Task Dev Subset. We fine-tune the models for 15 epochs. Since we are using validation set for training, we did not use any validation at this stage. We use last checkpoint from this stage as the final model and use it for testing.

3.3 Submitted Models

We submit our results for English-to-German and German-to-English directions. For each direction, we submit three results. We do not freeze any parameters during fine-tuning process for all of our submissions.

3.3.1 Primary

In our primary submission, we use the model as described in Section 3.2. We use one previous utterance as context during training, validation, and testing. This model consists of about 359M parameters.

3.3.2 Contrastive-1

Li et al. (2020) suggested that improvement in translation quality is observed after introduction of context encoder. However, it can be attributed to the contextual information acting as noise, rather than rich information relevant to the source or target. They showed that, even if context is not used during testing, the models produce similar results due to the fact that the context used during training helped the model for robust training. While this observation was for document translation, we use this method for chat translation. Thus, in this

Table 1: Results of submissions at WMT22 Chat task for En–De; C1: contrastive-1 submission; C2: contrastive-2 submission

submission, we use the same model as on Primary submission, but we ignore the context during testing.

	Context Encoder		Parameters	
Submission	Training	Testing	Training	Testing
Primary	Yes	Yes	359M	359M
contrastive-1	Yes	No	359M	313M
contrastive-2	No	No	313M	313M

Table 2: Comparison of methodologies for our submissions

3.3.3 Contrastive-2

We submit the results from a model without using any context for better comparison. Note that this model is trained with all other methodologies similar to Primary and Contrastive-1, which includes two-stage pre-training with the same data.

3.4 Post-Processing

We remove <unk> from the output. Further, we observe tags and modify them to the original tag, if mistranslated. For Example, we change "# PRS _ ORG #" to "#PRS_ORG#", "# Address #" to "#ADDRESS#", etc.

4 Results

We obtain a COMET (Rei et al., 2020) score of 0.768 and 0.907 on En-De and De-En directions. Further, we obtain chrF (Popović, 2015) scores of 0.730 and 0.729 for En-De and De-En. We obtain BLEU scores of 0.551 and 0.587 for Agent and Customer subsets. With contrastive-1 submission, we obtain similar results. For Agent subset, COMET score improved by 0.001 whereas, decreased by 0.002 for Customer subset. Similarly for contrastive-2 submission, COMET decreased by 0.003 whereas chrF and BLEU score decreased by 0.001 and 0.006 respectively for Agent subset. Without context method generated better results for Customer subset, improving BLEU and chrF by 0.005 and 0.002 respectively, whereas we observe a decrease of 0.005 on COMET metric. Thus, our experiment suggests that the usage of context played very limited role in the submitted systems. We suggest this is due to a lower Context Window in our experimental setting. We use only one previous sentence as a context. While it has been observed that using one context is usually sufficient on conversational or document-level datasets, WMT22 Chat Task data contain very shorter and repetitive sentences. This includes one or two word utterances (Thanks, #EMAIL#, #NAME#, Good Bye, etc), App navigational information (Tap Settings, Tap Device information, etc), etc. These utterances has very limited information to be useful as a context. Further, appearance of duplicate utterances is a challenge during training process. However, unlike general MT, conversational datasets can not be de-duplicated easily. This is because removal of some utterance from a conversation will break its structure and might not be as meaningful.

5 Conclusion

Task translation is a challenging and important task for our society. One of the major challenges in chat translation is context-dependency. We participated in WMT22 Chat Translation Task, where we submit results obtained from multi-encoder based transformer model. We obtain COMET scores of 0.768 and 0.907 on English-to-German and German-to-English directions, respectively. We found that role of context in our experimental setting is limited. In future, we would like to explore these methods with larger window size. Further, we would like to explore data de-duplication strategies for conversations.

Abstract

This paper introduces the joint submission of the Beijing Jiaotong University and WeChat AI to the WMT'22 chat translation task for English⇔German. Based on the Transformer (Vaswani et al., 2017), we apply several effective variants. In our experiments, we utilize the pre-training-then-fine-tuning paradigm. In the first pre-training stage, we employ data filtering and synthetic data generation (i.e., back-translation, forward-translation, and knowledge distillation). In the second fine-tuning stage, we investigate speaker-aware in-domain data generation, speaker adaptation, prompt-based context modeling, target denoising fine-tuning (Meng et al., 2020), and boosted self-COMET-based model ensemble. Our systems achieve 0.810 and 0.946 COMET (Rei et al., 2020) scores[1] on English→German and German→English, respectively. The COMET scores of English→German and German→English are the highest among all submissions.

1 Introduction

We participate in the WMT 2022 shared task on chat translation in two language directions, English→German and German→English. In this year's chat translation task, we apply the two-stage training strategy. In the first stage, we investigate model architecture and data augmentation. In the second stage, we mainly focus on exploiting speaker-aware in-domain data augmentation, speaker adaptation, prompt-based context modeling, target denoising fine-tuning (Meng et al., 2020), and model ensemble strategies. This task aims to build machine translation systems to translate conversational text and thus supports fluent communication between an agent speaking in English and a customer speaking in a different language (e.g., German), which is different from the first pre-training stage (Farajian et al., 2020; Liang et al., 2021a, 2022a; Liu et al., 2021; Gain et al., 2021, 2022; Buschbeck et al., 2022). Therefore, we mainly pay attention to the second fine-tuning stage.

In the first pre-training stage, we follow previous work (Meng et al., 2020; Zeng et al., 2021; Meng and Zhang, 2019; Yan et al., 2020) and utilize several effective Transformer variants. Specifically, we combine the Multi-Head-Attention (Vaswani et al., 2017), Average Attention Transformer (Zhang et al., 2018), and Talking-Heads Attention (Shazeer et al., 2020), which have shown significant model performance and diversity. For data augmentation, we employ the back-translation method to use the target-side monolingual data and apply the forward-translation to leverage the source-side monolingual data. To fully utilize the source-side of bilingual data, we use the sequence-level knowledge distillation method (Kim and Rush, 2016).

In the second fine-tuning stage, for speaker-aware in-domain data augmentation, based on the BConTrasT (Farajian et al., 2020) dataset of the WMT20 chat translation task, we firstly adapt our pre-trained model to each speaker by using the speaker tag as a pseudo token and then apply it to the Taskmaster-1 (Byrne et al., 2019) corpus to generate the speaker-aware in-domain data. For speaker adaptation, we follow previous work (Moghe et al., 2020) to prepend the corresponding speaker tag to each utterance on both the source and the target side to get a speaker-aware dataset. For prompt-based context modeling, we exploit the prompt learning to incorporate the bilingual context and then apply the target denoising fine-tuning method (Meng et al., 2020) to train our model. For the model ensemble, inspired by Zeng et al. (2021), we select high-potential can-

[*] Work was done when Yunlong was interning at Pattern Recognition Center, WeChat AI, Tencent Inc, China.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 955 - 961
December 7-8, 2022 ©2022 Association for Computational Linguistics

didate models from two aspects, namely model performance (COMET scores) and model diversity (Self-COMET scores among all candidate models). Based on this, we design a search algorithm to gradually select the current best model of the model candidate pool for the final model ensemble.

2 Model Architectures

In this section, we describe the model architectures we used in two translation directions, where we mainly follow the previous state-of-the-art models (Zeng et al., 2021). We also refer readers to read the paper for details.

2.1 Model Configurations

Given the strong capacity of deeper and wider architectures, we use them in our experiments. Specifically, following Zeng et al. (2021), we use 20-layer encoders for deeper models and set the hidden size to 1024 for all models. We set the decoder depth to 10. For the wider ones, we adopt 12 encoder layers, 2048 for hidden size, and 8192 to 15000 for filter sizes.

2.2 Transformer Variants

Average Attention Transformer. Following Zeng et al. (2021), the average attention transformer (Zhang et al., 2018) are employed to add model diversity. In the AAN, the context representation g_i for each input embedding is calculated as follows:

$$g_i = \mathrm{FFN}(\frac{1}{i}\sum_{k=1}^{t} y_k),$$

where y_k is the input embedding for step k and t is the current time step. FFN denotes the position-wise feed-forward network (Vaswani et al., 2017).

Talking Heads Attention. Similarly, talking-heads attention (Shazeer et al., 2020) also performs well in Zeng et al. (2021), which can transform the attention-logits and the attention scores and thus allow information interaction among attention heads by adding two linear projection layers W_l and W_a:

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}(\frac{QK^T}{\sqrt{k}}W_l)W_aV.$$

3 System Overview

In this section, we describe our system used in the WMT 2022 chat translation shared task, which includes two parts, namely general pre-training and in-domain fine-tuning. The pre-training part includes data filtering and synthetic data generation. The in-domain fine-tuning consists of speaker-aware in-domain data generation, speaker adaptation, prompt-based context modeling, the target denoising fine-tuning (Meng et al., 2020), and boosted Self-COMET-based model ensemble.

3.1 General Pre-training

3.1.1 Data Filtering

We filter the bilingual training corpus (including synthetic parallel data) with the following rules (Zeng et al., 2021): 1) Normalize punctuation; 2) Remove the sentence whose length is more than 100 words or a single word that exceeds 40 characters; 3) Filter out the duplicated sentence pairs; 4) Delete the sentence whose word ratio between the source and the target words exceeds 1:4 or 4:1.

3.1.2 Synthetic Data Generation

For data augmentation, we obtain the general domain synthetic data via back-translation, forward-translation, and knowledge distillation.

Tagged Back-Translation. Previous work has shown that different methods of generating pseudo corpus have a different influence on translation performance (Edunov et al., 2018; Hoang et al., 2018; Zeng et al., 2021). Following them, we attempt two generating strategies: 1) Beam Search: produce translation by beam search (beam size = 5). 2) Sampling Top-k: Select a word randomly from top-k (k = 15) words when inference.

Forward-Translation. We then ensemble models to forward-translate the monolingual data of the source language to further enhance model performance. We obtain a stable improvement in both directions, which is consistent with previous work (Zeng et al., 2021).

Knowledge Distillation. Knowledge Distillation aims to transfer knowledge from the teacher model to student models, which has shown effective for NMT (Kim and Rush, 2016; Wang et al., 2021; Zeng et al., 2021). Specifically, we first use the teacher model to generate synthetic corpus in the forward direction (i.e., En→De). Then, we train our student models with the generated corpus.

Note that we prefix all the synthetic sentences by appending a pseudo tag <BT> when jointly training with genuine data.

3.2 In-domain Fine-tuning

3.2.1 Speaker-aware In-domain Data Generation

Inspired by Moghe et al. (2020), we prepend the corresponding speaker tag (the `<agent>` or the `<customer>`) to each utterance on both the source and the target side to get a speaker-aware dataset based on the BConTrasT dataset of the WMT20 chat translation task (Farajian et al., 2020). Secondly, we adapt our pre-trained model to each speaker on the speaker-aware dataset. Then, we apply the adapted model to the monolingual Taskmaster-1 (Byrne et al., 2019) corpus, which is the original source of BConTrasT (Farajian et al., 2020), to generate the speaker-aware in-domain data.

3.2.2 Speaker Adaptation

As a special characteristic of chat translation, distinguishing between the two speaker roles plays an important role as they both form the complete dialogue. And modeling the speaker characteristic has been demonstrated effective in previous work (Moghe et al., 2020; Liang et al., 2021c, 2022b, 2021b, 2022c). Therefore, our data used in the fine-tuning has a corresponding speaker tag (the `<agent>` or the `<customer>`) appended in the first token of each utterance.

3.2.3 Prompt-based Context Modeling

Previous studies (Wang et al., 2020; Moghe et al., 2020) have shown that the multi-encoder framework cannot improve the model performance after using the context in the chat translation task, while a unified model (Ma et al., 2020; Liang et al., 2021c) can. Therefore, we also investigate incorporating the context in the unified model with prompt learning (without modifying the model architecture). Specifically, we add two preceding bilingual contexts at the tail of each utterance with an indicator `<context begins>`, where we also use a special tag `<SEP>` to separate different utterances of the bilingual context. In this way, our model with context modeling can achieve a better COMET.

3.2.4 Target Denoising Fine-tuning

To bridge the exposure bias (Ranzato et al., 2016), we add noisy perturbations into decoder inputs when fine-tuning. Therefore, the model becomes more robust to prediction errors by target denoising fine-tuning (Zhang et al., 2019; Meng et al., 2020). Specifically, the fine-tuning data generator chooses 30% of utterance pairs (Note that we do not include the indicator word and the bilingual context) to add noise and keeps the remaining 70% of sentence pairs unchanged. For a chosen pair, we keep the source sentence untouched and replace the i-th token of the target sentence with (I) a random token of the current target sentence in 15% probability and (II) the unchanged i-th in 85% probability.

Algorithm 1: Boosted Self-COMET-based Ensemble (BSCE)

```
Input:
    List of candidate models $\mathbb{M}$ = {$m_i$, ..., $m_n$}
    Valid set COMET for each model $\mathbb{C}$ = {$c_i$, ..., $c_n$}
    Average Self-COMET for each model $\mathbb{S}$ = {$s_i$, ..., $s_n$}
    The number of models $n$
    The number of ensemble models $e$
Output: Selected Model Pool $\mathbb{P}$
for $i \leftarrow 1$ $to$ $n$ do
    $weight = \frac{(max(\mathbb{S})-min(\mathbb{S}))}{(max(\mathbb{C})-min(\mathbb{C}))}$
    $score_i =$
        $(c_i - min(\mathbb{C})) \cdot weight + (max(\mathbb{S}) - s_i)$
end for
Add the highest score model to candidates list
    $\mathbb{P}$ = { $m_{top}$ }
while $|\mathbb{P}| < e$ do
    $index = \arg\min_i \frac{1}{|\mathbb{M}-\mathbb{P}|} \sum_{i \in \mathbb{M}-\mathbb{P}, j \in \mathbb{P}} BLEU(i,j)$
    Add $m_{index}$ to candidate list $\mathbb{P}$
end while
return $\mathbb{P}$
```

3.2.5 Boosted Self-COMET-based Model Ensemble (BSCE)

After we get plenty of fine-tuned models, how to search for the best combination for the ensemble model is a difficult question. Inspired by Zeng et al. (2021), we propose a Boosted Self-COMET-based Ensemble (BSCE) algorithm, as shown in algorithm 1. Since the existing boosted Self-BLEU-based pruning strategy (Zeng et al., 2021) is designed for achieving higher BLEU scores with high efficiency, it can not help obtain better COMET scores. Therefore, we adapt it to COMET scores. Then, we can obtain the best ensemble models from n top models by a greedy search strategy.

The algorithm takes as input a list of n strong single models $\mathbb{M}$, COMET scores on the development set for each model $\mathbb{C}$, average Self-COMET scores for each model $\mathbb{S}$, the number of models n, and the expected number of ensemble models e. The algorithm returns a set $\mathbb{P}$ consisting of e selected models. We calculate the weighted score for each model (line 2). The weight (line 3) calculated is a trade-off between the development set COMET score and the Self-COMET score since the performance and the diversity play the same key role in ensemble (Zeng et al., 2021). Then the set $\mathbb{P}$ initially contains the model m_{top} has the highest weighted score. Next, we iteratively re-compute the average Self-COMET between the remaining models in '$\mathbb{M} - \mathbb{P}$' and selected models in $\mathbb{P}$, based on which we select the model that has a minimum Self-COMET score into $\mathbb{P}$.

4 Experiments and Results

4.1 Setting

The implementation of our models is based on Fairseq[2]. All the single models in the first pre-training stage are carried out on 8 NVIDIA V100 GPUs (32 GB memory of each). And all the models in the second fine-tuning stage are conducted on 4 NVIDIA V100 GPUs. We use the Adam optimizer with β_1 = 0.9, β_2 = 0.998. The batch size are set to 8192 and 4096 tokens per GPU for pre-training and fine-tuning, respectively. We set the "update-freq" parameter to 2 and 1 for both stages. The learning rate is set to 0.0005 and 0.0004 for two stages, respectively. We use the warmup step to 4000. We calculate COMET[3] score for all experiments which is officially recommended.

English and German sentences are segmented by Moses[4]. We apply punctuation normalization and Truecasing. We use byte pair encoding BPE (Sennrich et al., 2016) with 32K operations. For the post-processing, we apply de-truecaseing and detokenizing on the English and German translations with the scripts provided in Moses.

4.2 Dataset

The data statistics of the two stages are shown in Table 1. For the general pre-training, the bilingual data is the combination of all parallel data in WMT21. For monolingual data, we use the News Crawl, Common Crawl, and Extended Common Crawl. For synthetic data generation, we back-translate all the target monolingual data and forward-translate the source monolingual data. For the in-domain fine-tuning, we use all the training, valid, and testing data of the wmt20 chat task as our training data. For monolingual data, we select the Taskmaster-1 (Byrne et al., 2019) corpus to build the pseudo-paired data using the method described in Section 3.2.1.

	General pre-training	In-domain fine-tuning
Bilingual Data	74.8M	17,847
Source Mono Data	332.8M	302,079
Target Mono Data	237.9M	-

Table 1: Statistics of all training data.

Models	**En→De**	**De→En**
Chat baseline w/o context	0.403	0.588
Chat baseline w context	0.376	0.680
Pre-trained deeper model w/o context	0.544	0.865
+ in-domain genuine data w/ context (FT1)	0.772	0.905
+ in-domain pseudo data w/ context (FT2)	0.767	0.903
+ in-domain both data w/ context (FT3)	0.781	0.908
Pre-trained wider model w/o context	0.604	0.879
+ in-domain genuine data w/ context (FT4)	0.782	0.908
+ in-domain pseudo data w/ context (FT5)	0.779	0.906
+ in-domain both data w/ context (FT6)	**0.785**	**0.909**

Table 2: COMET scores on the Valid set for both pre-trained models, and each of fine-tuned on (i) in-domain genuine data, (ii) in-domain pseudo data, and (iii) both in-domain data.

4.3 Results

We report COMET scores (Rei et al., 2020) on the validation set (generally, beam size = 5 and length penalty = 0.6).

Pre-training and Fine-tuning. The results in Table 2 show that all pre-trained models outperform the baseline models trained on the chat training data. We observe that in-domain fine-tuning of the pre-trained models always gives large gains even on the in-domain pseudo data. We also find that the performance of different model architectures comes close after in-domain fine-tuning. Though these models perform similarly, as they have different architectures or are trained on different data, they generate diverse translations and show a cumulative effect when ensemble.

Final Submissions. Table 3 shows the results of our primary submission on both the validation and test set. Note that all candidate models with different architectures or trained with different data are used for the ensemble. We find that our BSCE

Models	En→De	De→En
FT6 + no tag	0.779	0.904
FT6 + speaker	**0.785**	**0.909**

Table 4: Valid set COMET scores for fine-tuning with speaker tags .

is effective in both directions (more analyses are shown in Section 5.3). Inspired by Wang et al. (2020), we also tried large beam size. Finally, our primary system achieves the highest results among all submissions[5].

5 Analysis

5.1 Effect of Speaker Tags

As shown in Table 4, we observe that the performance in both directions improves with the addition of tags, which is consistent with Moghe et al. (2020). It shows that adding the speaker tag indeed can improve the chat translation performance.

5.2 Effect of Prompt-based Context Modeling (PCM)

As shown in Table 5, we investigate the effect of the context. The bilingual context involves the utterance in mixed language. Therefore, we investigate the different contexts with prompt learning. The results show that the models achieve slight performance gains with suitable context. And using context in the same language was more beneficial than the mixed context, which is consistent with previous work (Moghe et al., 2020).

5.3 Effect of Boosted Self-COMET-based Ensemble (BSCE)

Inspired by the boosted Self-BLEU-based ensemble (Zeng et al., 2021), we propose the Boosted Self-COMET-based Ensemble. To verify its superiority, we first select the top 10 models with different architecture and training data. The results are shown in the "+Normal Ensemble" of Table 3. For the BSCE, we need to get the translation result of every model to calculate the Self-COMET. After that, we only need to perform the inference process once. Then, we can select the best models for the ensemble. Here, we select 10 models and 4 models for **En→De** and **De→En**, respectively. The results are shown in "+BSCE" of Table 3. Based on it, we obtain better results after using the large beam (beam sizes of 9 and 8 for **En→De** and **De→En**, respectively). These results show the effectiveness of our BSCE method.

Models	En→De	De→En
FT6 + w/o context	**0.782**	**0.905**
using previous context (mix language)		
FT6 + w/ PCM (+ 1 prev)	0.781	**0.905**
FT6 + w/ PCM (+ 2 prev)	0.779	0.901
FT6 + w/ PCM (+ 3 prev)	0.775	0.897
using previous context (same language)		
FT6 + w/ PCM (+ 1 prev)	**0.785**	**0.909**
FT6 + w/ PCM (+ 2 prev)	0.784	**0.909**
FT6 + w/ PCM (+ 3 prev)	0.782	0.904

Table 5: Valid set COMET scores for fine-tuning with different contexts. The numbers before "prev" indicate the number of preceding utterances used as context.

6 Conclusions

We investigate the pre-training-then-fine-tuning paradigm to build chat translation systems, which are some effective transformer-based architectures. Our systems are also built on several popular data augmentation methods such as back-translation, forward-translation, and knowledge distillation. In the fine-tuning, we enhance our system by speaker-aware in-domain data generation, speaker adaptation, prompt-based context modeling, target denoising fine-tuning (Meng et al., 2020), and boosted self-COMET-based model ensemble. Our systems achieve 0.810 and 0.946 COMET (Rei et al., 2020) scores on English→German and German→English, respectively. These COMET scores are the highest among all submissions.

Abstract

This paper describes the submissions of Huawei Translation Services Center(HW-TSC) to WMT22 chat translation shared task on English↔German (en-de) bidirection with results of zero-shot and few-shot tracks. We use the deep transformer architecture with a larger parameter size. Our submissions to the WMT21 News Translation task are used as the baselines. We adopt strategies such as back translation, forward translation, domain transfer, data selection, and noisy forward translation in task, and achieve competitive results on the development set. We also test the effectiveness of document translation on chat tasks. Due to the lack of chat data, the results on the development set show that it is not as effective as sentence-level translation models.

1 Introduction

Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017) has achieved good translation results in most scenarios, but few researches have been done in the field of chat translation, mainly because of insufficient chat data.

WMT20 holds the chat translation shared task (Farajian et al., 2020) for the first time. The data set mainly includes pre-sales conversations between customers and agents (meal booking, air ticket reservation, etc.). This year, the data set focuses on post-sales conversations between customers and agents. Although the translation content is all about chat, the domains are slightly different. The results show that the data from previous years can not effectively improve the quality of the model for this year's task.

We participate in the en-de bidirectional translation task. The en-de bidirectional models we submitted to the WMT21 news task (Wei et al., 2021) are used as the baseline models and the architecture is deep transformer (Vaswani et al., 2017; Dou et al., 2018). Commonly-used optimization strategies are used, such as domain transfer, data selection, back translation, self-training, noisy self-training, finetuning and model averaging.

Considering that the chat task is a context-aware translation task, we conduct a series of document-level (Wang et al., 2017) experiments using WMT document data, but it does not work well on development sets. The analysis shows that the document data deviates greatly from the chat domain, and the data therefore cannot effectively improve chat translation quality. According to the results, the best models are obtained by selecting in-domain data from out domain data by the development sets.

This paper is structured as follows: Section 2 describes our data volume and data pre-processing method. The model structure and method we used are presented in Section 3. Section 4 details our experiment setting. We present the results in Section 5, and finally we conclude our work in Section 6.

2 Data

2.1 Data Size

We use WMT21 news en-de bidirection models as our baselines (Wei et al., 2021). Bilingual data comes for WMT20 chat task Farajian et al. (2020), and monolingual data is from Byrne et al. (2019)

We select data of three related domains, including conversation, subtitle, and shopping, from our in-house English corpus for domain transfer. In addition, the document-level data from WMT22 general task [1] is used to train the document-level translation model. In addition, 40M in-house general bilingual data is used.

For details about the data size, see Table 1 and Table 2.

Table 2: Sentences size of monolingual data used for training

2.2 Data pre-processing

Considering that the data sizes of WMT20 and WMT22 chat tasks are limited, we do not cleanse the chat data. We use the following data cleansing methods for other data:

- Remove duplicate sentences (Khayrallah and Koehn, 2018; Ott et al., 2018)
- Filter out sentences with more than 150 words
- Filter out sentences with length ratios greater than 1.5
- Apply langid (Joulin et al., 2016, 2017) to filter out sentences in other languages
- Use fast-align (Dyer et al., 2013) to filter out sentence pairs that are poorly aligned.

Besides, we adopt joint SentencePiece Model(SPM) (Kudo and Richardson, 2018; Kudo, 2018) for word segmentation with a vocabulary of 32K.

3 System Overview

3.1 Model

Transformer has been widely used for neural machine translation in recent years, which has achieved good performance even with the most primitive architecture. Therefore, the baseline models for WMT21 news en-de task use the Transformer-Big architecture. Deep transformer is an improvement of Transformer, which increases the number of encoder layers and uses pre-layer-normalization to further improve model performance. Therefore, in this task, we adopt the following model architecture:

- Deep 25-6 large Model: This model features 25-layer encoder, 6-layer decoder, 1024 dimensions of word vector, 4096 domensions of FFN, 16-head self-attention, and pre-layer-normalization.

3.2 Document-level NMT

Document-level machine translation (Ma et al., 2021) conditions on surrounding sentences to produce coherent translations. There has been a lot of work on custom model architectures to integrate document context into translation models.

There are many document translation strategies, such as Doc2Sent, Window2Window, Doc2Doc (Junczys-Dowmunt, 2019), DocBT (Junczys-Dowmunt, 2019), DocRepair (Voita et al., 2019), NoisyChannelDoc (Yu et al., 2019) and G-Transformer (Bao et al., 2021). Among the methods mentioned above, Doc2Doc and DocBT are preferred by us because the data processing procedures are simple and the model requires no modification.

To train our document-level model, the bilingual document data is spliced into a long sequence based on paragraph information and the sentences are separated by numbered <SEPX> symbols. For document-level monolinguals, we first generate synthetic bilingual data by back translation and use the same strategy to construct doc2doc data. We then use the document data to fine-tune the sentence-level translation model to ensure the model capable of translating long sequences.

We use two methods for inference. The first one translates single sentences just like a standard translation model. The other method combines a sentence with its context to construct a long-sequence input. After decoding, the model splits the result into single sentences and sacreBLEU[2] (Post, 2018) is calculated on the single sentences.

3.3 Data Selection

Data selection (van der Wees et al., 2017) is a data augmentation method that we use to select in-domain data from out-of-domain data.

For monolingual data selection, we train a FastText (Joulin et al., 2016) classifier using a small number of English monolinguals in subtitle, conversation, and shopping domains, and then select in-domain English monolinguals from the common corpus.

For bilingual data selection, as mentioned by Wang et al. (2019, 2018) , we use the in-domain data to fine-tune the out-domain model, and then

+ Data Selection	49.2(+4.1)	48.1(+1.4)	62.5(+12.2)	65.5(+6.8)
+ Noisy FT	49.0(+3.9)	49.9(+3.2)	**64.3**(+13.1)	65.5(+6.8)
+ Model Average	49.8(+4.7)	49.2(+2.5)	63.2(+12.9)	**65.7**(+7.0)

Table 3: sacreBLEU score on chat20 test set and chat22 dev set

use the model before and after the fine-tuning to calculate the decoding probability score of the out-domain bilingual data. The data with a higher score on the fine-tuned model is selected as the in-domain bilingual data. The specific scoring is carried out according to the formula 1.

$$score = \frac{\log P(y|x;\theta_{in}) - \log P(y|x;\theta_{out})}{|y|} \quad (1)$$

Where θ_{out} represents the model trained with out-domain data, and θ_{in} represents the model after fine-tuning with a small amount of in-domain bilingual data, and |y| represents the length of the target sentence.

3.4 Forward Translation

Forward Translation (FT) (Wu et al., 2019), also known as Self-Training (Imamura and Sumita, 2018) , usually refers to using a forward NMT model to translate source-side monolingual data to target-side text so as to generate synthetic bilinguals. The data is then used to train the forward translation model. Generally, beam search (Freitag and Al-Onaizan, 2017) is used for forward translation. In our experiment, the beam size is set to 4.

Noisy self-training (He et al., 2020) adds noise to the source-side of the pseudo parallel corpus generated by forward translation. Experiments show that this method is effective in low resource tasks. Noisy self-training is therefore used in the last step when a small amount of in-domain monolinguals is used.

3.5 Back Translation

Back-translation(BT) (Edunov et al., 2018) has been recognized as the most effective data augmentation strategy for enhancing NMT model performance. Contrary to forward translation, it translates target-side monolinguals into source-side to generate synthetic parallel corpus. Among the many back translation methods, sampling (Graça et al., 2019), noise (Edunov et al., 2018) and tagged back translation (Caswell et al.) work better. In our experiment, sampling back-translation is chosen.

3.6 Fine-tuning

Fine-tuning (Dakwale and Monz, 2017) is a way to achieve domain transfer. In our translation task, we adopt a three-stage fine-tuning strategy. Firstly, we use synthetic corpus from similar domains to fine-tune the out-of-domain NMT model, and then use bilingual data selected from general domain according to the development set to improve the model performance. After that, we use the synthetic data generated from the in-domain monolingual data to fine-tune the in-domain model for more fine-grained domain transfer.

3.7 Model Averaging

Model averaging (Dormann et al., 2018) is a commonly used technique to improve translation quality. Generally, models (5 in our experiment) that perform best on the development set are selected for parameter averaging, result to significantly improvement.

4 Experiment Setting

During the training phase, we use Pytorch-based Fairseq[3] (Ott et al., 2019) open-source framework as our benchmark system. Each model is trained using 8 GPUs with a batch size of 2048. The update frequency is 4 and the learning rate is 5e-4. The label smoothing rate is set to 0.1, the warm-up steps to 4000, and the dropout to 0.3. Adam optimizer (Kingma and Ba, 2015) with $\beta1$=0.9 and $\beta2$=0.98 is also used. In the evaluation phase, we use Marian[4] (Junczys-Dowmunt et al., 2018) for decoding and then calculate the sacreBLEU scores on the WMT22 chat translation task dev sets to measure the performance of each model.

System	22 en→de sent	22 en→de doc	22 de→en sent	22 de→en doc
baseline	50.3	-	58.7	-

+Bilingual Doc & DOC BT	24.7	0.36	0.11	0.82	0.15

Table 5: The higher the accuracy of pronoun translation, the better the model combines contextual information.

5 Result and Analysis

Table 3 shows the main results on the development sets. Bilingual data selection gains significant improvement on dev sets. Although bilingual data is selected based on dev sets, the selected data consists of 13M sentences. Therefore, there is no overfitting risk. This strategy also improves model performance on chat20 test sets.

Since the dev set is already used to select data, we no longer use the dev set to fine-tune model. We then continue to train our model using noisy self-training strategy on monolingual in-domain data. The result shows that there is an increase in BLEU on the en→de track. After model averaging, performance on de→en track improves, but performance on en→de deteriorates.

Finally, we select the result of data selection after model averaging as the primary submission, noisy self-training after model averaging as the contrastive2. Note that, the two submissions before are few-shot. The result of the baseline model as the submission of the zero-shot track, is contrastive1.

5.1 Document-level NMT

According to the test results shown in Table 4, using document-level data to optimize models does not work well, mostly because this data is from the news domain. From our subsequent experiments, we also find that chat tasks have high requirements on data domain.

From rows 4 and 5 in Table 4, the model using bilingual document data has worse results than the model using DocBT data. We assume that there are two reasons for this phenomenon. One is that the size of bilingual documents is limited, and the other is that the DocBT data generated using the data selection model is closer to the chat domain than the original bilinguals.

To verify the effectiveness of our document-level translation model, we evaluate our model on (Müller et al., 2018) test set, which is a pronoun translation accuracy task.

As shown in Table 5, the pronoun translation accuracy of bilingual document-level model was significantly better than that of other models. But the BLEU is the lowest due to the minimum amount of data. From subsequent domian transfer experiments, we can also find, chat tasks are extremely sensitive to the domain of the data, but we cannot find enough chat data to train the document-level translation model. Therefore, we cannot draw a conclusion that document-level translation is useless for chat translation tasks. Further researches can be carried out when sufficient chat data is available.

5.2 Domain Transfer

Since no chat training data is provided except for the development set, we continue to train the baseline model using development set and monolingual data from previous chat tasks. As shown in rows 3 and 4 in the Table 6, models training with chat20 development set performs well on the chat20 test set. However, little improvement is observed on chat22 dev set. As mentioned above, the data dis-

+ Data Selection	49.2	48.1	62.5(+12.2)	65.5(+6.8)

Table 6: The results of different strategies for the sentence-level model. FT/BT means that forward translation in en→de direction and back translation in de→en direction.

tribution for these two tasks is not consistent.

Monolingual data of similar domains, such as subtitle, conversation, and shopping, is then used for FT or BT enhancement. From rows 5, 6 and 7 in the Table 6, the results are worse than using chat20 data. Although the monolingual data is of higher quality, its domain and style are far away from chat data. So it brings no improvement.

5.3 Bilingual Data Selection

Through the above experiments, we find that this year's chat task has unique features and is very sensitive to domain differences. Using the idea proposed by Wang et al. (2019, 2018), we select 13M data from 40M general bilingual data to optimize our baseline model.

As can be seen from row 8 in the Table 6, this strategy is effective and improves the translation quality in both directions. Besides, we find that the data selected using the chat22 development set also improves model performance on the chat20 task, indicating that this strategy is a general method. We will test its applicability in the future.

6 Conclusion

This paper presents the submissions of HW-TSC to the WMT 2022 Chat Translation Shared Task. For both direction in customer-agent translation task, we perform experiments with a series of preprocessing and training strategies. The results show that bilingual data selection achieves the best results. In the future, we will continue to explore the applicability of bilingual data selection mentioned in this paper.

Besides, the performance of document-level translation model is limited given the amount of data. It has not achieved the expected results on this task, and we will continue to explore the impact of context for the chat task.

Clean Text and Full-Body Transformer: Microsoft's Submission to the WMT22 Shared Task on Sign Language Translation

***Subhadeep Dey, Abhilash Pal, Cyrine Chaabani, *Oscar Koller**
Microsoft - Munich, Germany
{subde,t-apal,t-cchaabani,oskoller}@microsoft.com

Abstract

This paper describes Microsoft's submission to the first shared task on sign language translation at WMT 2022, a public competition tackling sign language to spoken language translation for Swiss German sign language. The task is very challenging due to data scarcity and an unprecedented vocabulary size of more than 20k words on the target side. Moreover, the data is taken from real broadcast news, includes native signing and covers scenarios of long videos. Motivated by recent advances in action recognition, we incorporate full body information by extracting features from a pre-trained I3D model and applying a standard transformer network. The accuracy of the system is further improved by applying careful data cleaning on the target text. We obtain BLEU scores of **0.6** and 0.78 on the test and dev set respectively, which is the best score among the participants of the shared task. Also in the human evaluation the submission reaches the first place. The BLEU score is further improved to **1.08** on the dev set by applying features extracted from a lip reading model.

1 Introduction

Sign languages are natural visual languages that are used by deaf and hard of hearing individuals to communicate in everyday life. Sign languages are actively being researched. However, there is a huge imbalance in the field of natural language and speech processing between oral and signed languages. Since recently, one observes the emergence of a transition shifting sign language processing to be part of the NLP mainstream (Yin et al., 2021). We embrace this development which manifests (among others) in the creation of the first shared task on sign language translation as part of WMT 2022 (Mathias et al., 2022). It is great to have real-world sign language data (Bragg et al., 2019; Yin et al., 2021) as the basis of this shared task, manifested in native signers content and an unprecedentedly large vocabulary. Nevertheless, this leads to a very challenging task with low performance numbers. When participating in the advances of sign language technologies it is worth recapping that deaf people have much at stake, both to gain and lose from applications that will be enabled here (Bragg et al., 2021). We aim to advance the field and the use-cases in a positive way and present our findings in this system paper.

In the remainder of this work we first present a brief view on the relevant literature in Section 2, then we present the employed data in Section 3. Subsequently, we describe our submission in Section 4, additional experiments in Section 5 and we end with a summary in Section 6.

2 Related Work

In this section, we present a limited overview of related work in sign language translation. We focus this review on the translation direction from sign language to spoken language and dismiss approaches that target the opposite direction, i.e. sign language production.

Sign language translation started targeting written sign language gloss to spoken language text translations, hence no videos were involved. Related works were mainly based on phrase-based systems employing different sets of features (Stein et al., 2007, 2010; Schmidt et al., 2013). Then, neural machine translation revolutionized the field. The first research publications on neural sign language translation were based on LSTMs either with full image input (Camgoz et al., 2018) or utilized human keypoint estimation (Ko et al., 2019). Transformer models then replaced the recurrent architectures (Camgoz et al., 2020; Yin and Read, 2020; Yin, 2020). These models perform a lot better, but suffer from a basic drawback that the input sequences must be limited to a maximum length. Previous work (Camgoz et al., 2018; Or-

*Equal Contribution

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 969 - 976
December 7-8, 2022 ©2022 Association for Computational Linguistics

bay and Akarun, 2020) has identified the need for strong tokenizers to produce compact representations of the incoming sign language video footage. Hence, a considerable body of publications target creating tokenizer models that are often trained on sign language recognition data sets (Koller et al., 2020, 2016; Zhou et al., 2022) or sign spotting data sets (Albanie et al., 2020; Varol et al., 2021; Belissen et al., 2019; Pfister et al., 2013).

There are several data sets relevant for sign language translation. Some of the most frequently encountered are RWTH-PHOENIX-Weather 2014T (Koller et al., 2015a; Camgoz et al., 2018) and the CSL (Huang et al., 2018) (which could be also considered a recognition data set). However, there are promising new data sets appearing: OpenASL (Shi et al., 2022a), SP-10 dataset (Yin et al., 2022) (covers mainly isolated translations) and How2Sign (Duarte et al., 2021).

3 Data

To train our system, we used the training data provided by the shared task organizers. The data can be considered real-life-authentic as it stems from broadcast news using two different sources: FocusNews and SRF. FocusNews, henceforth FN, is an online TV channel covering deaf signers with videos of 5 minutes having variable sampling rates of either 25, 30 or 50 fps. SRF represents public Swiss TV with contents from daily news and weather forecast which are being interpreted by hearing interpreters. The videos are recorded with a sampling rate of 25 fps. All data, therefore, covers Swiss German sign language (DSGS). Our feature extractors are pretrained on BSL-1k (Albanie et al., 2020) and AV-HuBERT (Shi et al., 2022b). Additionally, we evaluate the effect of introducing a public sign language lexicon that covers isolated signs [1], which we refer to as Lex. It provides main hand shape annotations, one or multiple (mostly one) examples of the sign and an example of how this sign is used in a continuous sentence. We choose a subset that overlaps in vocabulary with either FocusNews or SRF. As part of the competition, independent dev and test sets are provided, which consist of 420 and 488 utterances respectively.

Table 1 shows the statistics of the training data. We see, that there is about 35 hours of training data in total. In raw form without any preprocessing the data is case sensitive, contains punctuation and digits. In this raw form the vocabulary amounts to close to 35k different words on the target side (which is written German). 22k words of these just occur a single time in the training data (singletons). Through careful preprocessing as described in Section 4.3 we can shrink the vocabulary to about 22k words and the singletons to about 12k.

	SRF	**FN**	**Lex**	**Total**
Videos	29	197	1201	1427
Hours	15.6	19.1	0.9	35.6
Raw: no preprocessing				
Vocabulary	18942	21490	–	34783
Singletons	12433	13624	–	22083
Clean: careful preprocessing				
Vocabulary	13029	14555	821	22840
Singletons	7483	7923	591	12290

Table 1: Data statistics on data used for training. SRF and FN refer to SRF broadcast and FocusNews data, while Lex stands for a public sign language lexicon. Singletons are words that only occur a single time during training.

4 Submitted System

Sign languages convey information through the use of manual parameters (hand shape, orientation, location and movement) and non-manual parameters (lips, eyes, head, upper body). To capture most information from the signs, we opt for an RGB-based approach, neglecting the tracked skeleton features by the shared task organizers. For the submitted system we rely on a pre-trained tokenizer for feature extraction and train a sequence-to-sequence model to produce sequences of whole words (no byte pair encoding). We further pre-process the sentences (ground truths of the videos) to clean it. This step is crucial to push the model to focus more on semantics of the data. Finally, in order to adhere to the expected output format for the submission, we convert the text back to display format using Microsoft's speech service. This applies inverse text normalization, capitalization and punctuation to the output text to make it more readable. The details of various components of the system are described in the next subsections.

4.1 Features

We use a pre-trained I3D (Carreira and Zisserman, 2017) model, based on inflated inceptions with 3D convolutional neural networks, to extract features

[1] https://signsuisse.sgb-fss.ch/

for our task. The model (Varol et al., 2021) was pre-trained to take consecutive video frames as input and predict over 1k sign classes. It was trained on BSL-1K (Albanie et al., 2020) consisting of about 700k spotted sign instances from the British broadcast news. The features are extracted with a context window of 64 frames and a temporal stride of 8. We use the model as a feature extractor, recovering embeddings before the final classification layer (layer: mixed_5c), yielding a sequence of 1024 dimensional vector, extracted for each video. Our input data is required to match the training conditions of the network, hence we apply gray background padding (adding 20% padding left and right, 7.5% up and down) and rescale the videos to 224 × 224 resolution. The front end features are subsequently fed to a sequence model.

4.2 Sequence model

A standard transformer network is trained to predict text sequences. We apply word-based units as the output instead of byte pair encoding. It seems that full words help reduce ambiguity in a data constrained scenario. The model is trained with the fairseq (Ott et al., 2019) toolkit. We apply 3 transformer layers at the encoder side and 2 layers at the decoder with 1024 hidden feed-forward dimension and 22k output units. The model is trained with Adam optimizer for 2k epochs with a learning rate of 1e-3. We found that a beam size of 1 works well on the dev set during decoding.

4.3 Data Cleaning

To reduce ambiguity and noise in the target text, we first applied manual cleaning by removing foreign (French and English) sentences. We then proceeded to removing sentences that start with a hashtag sign, as this seems to indicate inaccurate annotation. Further, we removed status messages that were added by the subtitling agency (such as "1:1-Untertitelung.", "Livepassagen können Fehler enthalten.", "Mit Live-Untertiteln von SWISS TXT") and patterns enclosed by an asterisk which indicate sounds occuring in the show (e.g. "* Beschwingte Blasmusik *"). As a next step, we expanded abbreviations like "Mrd." to "Milliarden" and applied text normalization to remove punctuation and special characters, lower case of the text and expand numbers and dates. As can be shown in Table 1, this plays a major role in reducing the total vocabulary.

Data cleaning	Dev (RedB)	Dev	Test
no	0.49	0.70	0.4
yes	**0.78**	**0.77**	**0.6**

Table 2: The Table shows the effect of data cleaning. Performance of translation systems trained on SRF and FocusNews evaluated on the WMT 2022 dev and test data is provided. We report reduced and standard BLEU score on the Dev set and only standard BLEU on the Test set. RedB stands for the reduced BLEU measure.

4.4 Evaluation metrics

A common evaluation metric for machine translation is BLEU (Papineni et al., 2002). However, the difficulty of the given task and the inherently low performance of the submitted systems cause a bias in the automated evaluation. Spoken languages like Swiss German, which is the target output space for the translation in this challenge, follow a statistical pattern where stop words or function words constitute the classes of words that occur most frequently. This explains one of the observations that we made in regard to the generated system output. In fact, the models which were producing more stop words achieved the highest BLEU scores. For example, the model we submitted achieved a BLEU score of 0.77 on the dev set, while an earlier, clearly worse, checkpoint achieved 0.91. Looking at the stop words, the submitted model output counts 2125 stop words, while the earlier checkpoint counts 2237 of such words. After our stop word removal the submitted reduced BLEU score is 0.78, while the earlier model achieves only 0.66. Hence, for model selection, we propose to use 'reduced BLEU' with an additional step: we first apply a blacklist to remove stop and function words. Using this approach, the model selection process based on the reduced BLEU metric turned to be much more reliable and more reflective of actual performance. In this work, we report both reduced BLEU and standard BLEU for all results on the dev set. Only standard BLEU is reported by the automatic evaluation through the shared task on the test set. The list of employed stop words can be found in the appendix.

4.5 Results

The results of the submitted systems are presented in Table 2, which allows to compare the effect of applying data cleaning. In terms of reduced BLEU, data cleaning improves the performance from 0.49

to 0.78 on the dev data. The test data shows similarly an improvement from 0.4 BLEU to 0.6. Based on the preliminary automatic BLEU scoring this result was the best among the participants of the shared task. However, it has to be noted that the final evaluation will be based on a human eval that has not yet been completed at the time of paper submission. It can be concluded that careful data preparation is fundamental for this data. Nevertheless, the shared task proves to be very challenging and overall, we observe rather low performance compared to published results on benchmark data sets like RWTH-PHOENIX 2014T (Camgoz et al., 2018). This further proves the large amount of variability in the task, which is amplified due to the presence of high numbers of singleton words.

5 Additional Experiments

We perform additional experiments to assess the impact of having dedicated mouth features as well as a lexicon data set on the model performance. The mouth carries important semantic information in sign languages. In the literature, exploiting lip information has shown to be fundamental for increased performance in sign language recognition and translation (Koller et al., 2015b; Shi et al., 2022a).

5.1 Mouth features

To extract features from the lip area, we employ a pre-trained AV-HuBERT model (Shi et al., 2022b) that has been trained on English data. AV-HuBERT is trained to learn a robust audio-visual representation in a self-supervised fashion. The success of the model is evident by the performance on an audio-visual speech recognition task. It has proven to be useful for sign-language task as well (Shi et al., 2022a). For us, the first step is to obtain mouth patches from the video frames. Hence, we rely on the dlib utility provided by the AV-HuBert authors for obtaining facial key point extraction. The face patch is cropped and re-scaled to match the input size (96 x 96) of the model. We use the AV-HuBERT model to extract 768 dimensional embedding (output of the ResNet layer) to obtain a feature vector per frame.

5.2 Comparison to RWTH-PHOENIX 2014 T

To underline the difficulty of the given shared task, we compare our employed pipeline on a standard benchmark data set for sign language translation, namely Phoenix 2014T (Camgoz et al., 2018). We noticed a small difference between the original PHOENIX 2014T corpus as referenced and shared in of (Camgoz et al., 2018) and the publicly available embeddings and experiments of (Camgoz et al., 2020). In the latter full stops mark the end of each utterance, while in the original version this is not the case. The effect is small, but for the sake of completeness, we show it here. Furthermore, considering the statistics of PHOENIX 2014T and this WMT 2022 shared task, the difference becomes apparent. Table 3 shows the key statistics for the two tasks side by side. We can see that the WMT 2022 task has a nearly 8 times larger vocabulary, with 11 times more singletons that occur only once in training. However, it has not even 4 times more video material.

	WMT 2022	PHOENIX 2014T	Factor
Hours	35.6	9.2	3.9
Vocabulary	22840	2887	7.9
Singletons	12290	1077	11.4

Table 3: Comparison between the training data for the WMT 2022 shared task and PHOENIX 2014T.

	Training data	Features	
		Full body	Mouth
RedB	SRF + FN	0.78	0.95
	SRF + FN + Lex	0.54	1.08
Stand.	SRF + FN	0.77	1.15
	SRF + FN + Lex	0.68	1.27

Table 4: The effect of adding lexicon data to systems trained with full body features (I3D) and mouth features (AV-HuBERT). Configurations are evaluated on the WMT 2022 Dev dataset using the reduced BLEU (RedB) and standard BLEU (Stand.) score as metric.

5.3 Results

Table 4 shows the results of applying AV-HuBERT features as input to the sequence model. It can be observed that the model trained with AV-HuBERT features performs better than the I3D model. In fact, it achieves a 0.95 reduced BLEU score, while the full body I3D features reach only 0.78. On visual inspection, we found that the model trained with AV-HuBERT is able to predict infrequent words but fails on simple words such as "auf wiedersehen". Therefore, we assess the effect of adding a lexical data set (‘Lex’) to boost representations of those simple words. Table 4 shows that the addition of lexical data further improves the model performance which reaches 1.08 reduced BLEU. We believe that this is likely due to the matching lip movement patterns in the lexical training dataset and dev dataset. Unfortunately, due to time constraints, we were not able to submit this model.

Table 5 shows results on PHOENIX 2014T. We can see that our submitted pipeline matches the performance of (Camgoz et al., 2020) (19.80/20.24 BLEU on the dev/test sets compare to 20.69/20.17). However our employed embeddings, which were not trained on PHOENIX 2014T, do not generalize well to PHOENIX 2014T and are hence significantly outperformed by the ones employed in (Camgoz et al., 2020). The experiments show that the WMT 2022 shared task is significantly more challenging than PHOENIX 2014T. We also see that the addition of full stops at the end of each utterances in PHOENIX 2014T amounts to a difference in BLEU of about 1% relative (14.22/13.22 BLEU with full stops opposed to 14.06/13.13 without full stops).

6 Summary

In this paper, full body information is applied successfully for a challenging sign language task as part of the WMT 2022 competition. As such, we employed a pre-trained I3D model to extract an embedding for a sequence of frames of the video. The features are further fed as input to a standard transformer network. We obtain reasonable performance of 0.4 in terms of BLEU score on the test set. The model is further enhanced by applying careful cleaning to the text output. We obtain the result of 0.6 BLEU score on the official test data. Based on the automatic BLEU scoring this result was the best among the 7 participants of the shared task, but also in the human evaluation our submission reaches the first place. With additional experiments, we validate the usefulness of a pre-trained lip reading model for this task and the addition of a lexical data set. This improves the results to 1.08 reduced BLEU on the dev set.

Limitations

One major limitation to our work resides within the data set used for training our model. In fact, the signing interpreter is usually not a native signer and often seems to be heavily influenced by the source language, a.k.a the spoken language. As stated previously, we used a signing interpreter for SRF data. Another issue we have identified lies in the limited domain of the data, as it is constrained to Broadcast news. The trained model may therefore be too specialized to generalize well beyond this area. Furthermore, due to the small number of individuals present in the data set, it remains unclear if and how much ethnicity bias is introduced to the model. Our team did not proceed with any experiments to identify and measure this. However, we do believe that it is crucial to further analyze possible biases in the future. One evaluation metric that we did take into consideration for the model performance is the BLEU score. The experiments consistently returned extremely low values which reflects a poor accuracy. One thing that remains unclear to us is how significant small BLEU differences are for human perception and subjective evaluation.

DFKI-MLT at WMT-SLT22
Spatio-temporal Sign Language Representation and Translation

Yasser Hamidullah and **Josef van Genabith** and **Cristina España-Bonet**

Abstract

This paper describes the DFKI-MLT submission to the WMT-SLT 2022 sign language translation (SLT) task from Swiss German Sign Language (video) into German (text). State-of-the-art techniques for SLT use a generic seq2seq architecture with customized input embeddings. Instead of word embeddings as used in textual machine translation, SLT systems use features extracted from video frames. Standard approaches often do not benefit from temporal features. In our participation, we present a system that learns spatio-temporal feature representations and translation in a single model, resulting in a real end-to-end architecture expected to better generalize to new data sets. Our best system achieved 5 ± 1 BLEU points on the development set, but the performance on the test dropped to 0.11 ± 0.06 BLEU points.

1 Introduction

Text-to-text machine translation (MT) is achieving a great success with even (close to) human performance for some language pairs and domains (Akhbardeh et al., 2021). However, the situation in sign language translation (SLT) is much different. One important reason is that the SLT is a low-resource scenario where one does not have the same amount of data as in high-resourced text-to-text to achieve a similar level of performance. A more specific reason is that SLT involves two modalities, text and video. Various problems arise when dealing with these modalities. Besides data scarcity, the lack of temporal boundaries in the input videos is a challenge. To overcome the lack of temporal boundaries, the most common solution tends to ignore or not benefit from temporal features. This approach relies on the Transformer (Vaswani et al., 2017) capabilities to learn sequence-to-sequence tasks. The state-of-the-art SLT technique (Camgöz et al., 2020) is practically a normal Transformer but uses a custom embedding layer for 2D features extracted from video frames. In this approach, training a SLT system requires a pre-extraction step to convert frame features to vectors and train a Transformer separately to translate the vectors into spoken language. This type of approach has been widely used on a very specific dataset, the weather forecast corpus PHOENIX14T (Camgoz et al., 2018), where researchers reported a relatively good performance in terms of BLEU (∼20) (Camgöz et al., 2020; Min et al., 2021).

Despite its good performance on a specific dataset, there is the doubt whether such type of architecture generalizes to new data sets. In order to build a more general technique, we focus on fundamental SLT problems such as the design, implementation and evaluation of a fully end-to-end model and representation learning for sign language videos. Having a fully end-to-end model facilitates the task of data collection and diminishes the need for annotation (e.g. in terms of sign language glosses), which is necessary to build larger and richer datasets. It also allows training video embeddings fully optimized for the translation task. Text translation is one of the most mature areas in natural language processing, and therefore we focus here on the sign language representation part of the architecture and use an in-house state-of-the-art Transformer for text generation.

This paper reports our approach for end-to-end SLT used for the WMT-SLT translation shared task from Swiss German Sign Language into German. In the next sections we introduce our approach (Section 2), experimental setup (Section 3), results (Section 4) and conclusions & perspectives (Section 5).

2 Our Approach

The main idea of our approach is to learn feature representation and translation in a single model, and be able to train them together. Figure 1(a) sketches our general pre-processing pipeline and

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 977 - 982
December 7-8, 2022 ©2022 Association for Computational Linguistics

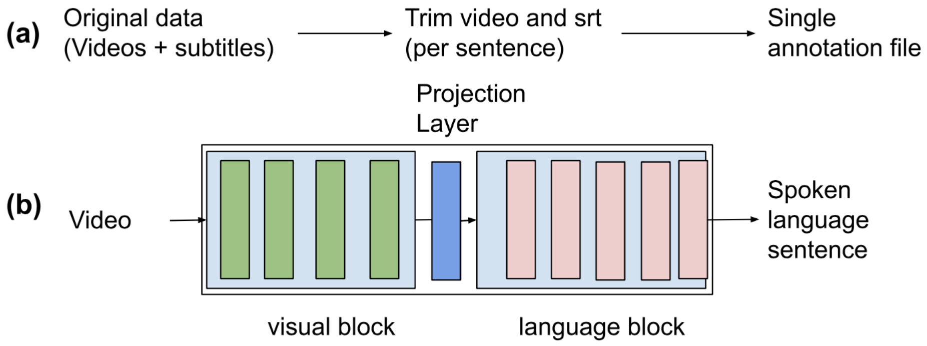

Figure 1: End-to-end architecture for sign language translation.

Figure 1(b) the architecture. The system architecture consists of two connected blocks: the first block made of CNNs is intended for vision and the second one is for language which is Transformer architecture.

Both the CNNs used for the video representations and the Transformers used for the text representations come with large numbers of parameters. As we are operating in a low resource scenario, besides the combination of the two networks, we experiment to find the best trade-off between data size and number of parameters.

2.1 Visual feature representation

Our goal is to build a sentence embedding-like model for the visual sign language encoder, as a word/sign level-like representation is limited by the lack of temporal boundaries in videos. We hypothesize that a sentence embedding will still contain and distinguish all the information given by individual signs.

In the shared task, we use ResNet3D (Hara et al., 2017) as our spatio-temporal visual feature representation block. We prefer it instead of a normal 2D with temporal convolutions (Wang et al., 2019) to develop a fully end-to-end trainable model. There are many available architectures in the literature, but ResNet is unique in providing different models with different scales. This gives us the possibility to experiment with various sizes which help us to weight the importance of each of the vision and text blocks in our trade-off experiments.

Our visual encoding in the submitted system is composed by the original 3D ResNet10 with output conversion. The conversion creates a sequence of vectors from the single output vector to adapt to the transformer encoder input. We define the **SWM** parameter (Sentence to Words Mapping), which is the number of splits from the output vector. This output is projected through a linear layer which is connected directly to the language block. We experiment with 3D ResNet10, 3D ResNet34 and 3D ResNet50 and show the comparative results in Section 3.

2.2 Language representation

The language block is a normal language Transformer. Its training end-to-end with the visual model can constrain the visual model and force it to take into account the language representation to build the visual embedding. This should result in more specific visual representations for sign language which has not yet been explored extensively in SLT. For this shared task, we use the Transformer for the language block with parameters shown in Table 1. This choice is motivated by Camgöz et al. (2020) which improved their previous results with LSTMs and GRUs (Camgoz et al., 2018) by more than 10 BLEU points. Furthermore, the Transformer makes the visual and language fusion more intuitive and easier for SLT, because it can process the whole sentence at the same time.

2.3 Loss and optimizer

In our experiments, we use a generalized loss. The general loss is considering both vision and text as a single model so the backpropagation starts from the last layer of the language part to the first layer of the visual one. We used the regular cross entropy loss from (Vaswani et al., 2017), with smoothing value = 0.1. Our optimizer has the following configuration: Adam with beta values =(0.9, 0.98), epsilon =1e-8, weight decay = 0.001.

Parameter	Value	Comments
Training corpus	FN+SRF	Remove sentences with >50 tokens
Batch size	10	Using few workers (<=5) on a single GPU
End of training criteria	PPL	Stop after 14 epochs without improvements
Language model	Transformer "base"	The number of encoder/decoder layers is 3 instead of 6
Visual model	3D ResNet (outsize= 2048, depth=50)	Additional custom module that converts the output size to our Sentence to Words Mapping (SWM)
SWM	32	Numbof the splits.
Scheduler	LambdaLR	Using warmup=4000
Max. output length	50	Maximum decoder output size
Gradient accumulation step	32	To get 320 sentences

Table 3: Number of videos and video statistics in seconds.

3 Setup and Experiments

3.1 Data description

For the submission, we use only the training and validation data given for the shared task and made up of FocusNews and SRF corpora, both parallel in Swiss German Sign Language and German text. SRF contains longer videos (approximately 30 minutes), FN contains more videos but shorter ones (approximately 5 minutes). The statistics of the German part of the corpus are summarized in Table 2 and the video statistics in Table 3.

3.2 Data preprocessing and batching

Since the input videos are long and contain more than one sentence (Table 3), we perform a subclipping step as preprocessing. By reading the subtitle files entries (*srt* in Figure 1(a)), we extract the time intervals and the corresponding sentences. We use ffmpeg to cut videos using these timestamps. We save the resulting subclips and add paths with subtitles (sentences) in one single annotation file.

We resize our input images to 224x224 pixels to leave a door open for pretraining approaches later. The batching is done using the Videodataset class (Wang et al., 2019). The depth is the number of frames in a video, it constitutes the third dimension in the 3D model. In our experiments, we initialize it to 100. To make sure that the language model keeps its original performance, we need to simulate a higher batch size. However, only a small number of videos can be placed in the same batch. We use gradient accumulation and update every 320 sentences for this purpose.

We do not do any preprocessing for the German textual data besides tokenization.

3.3 Experimental protocol

For the sake of reproducibility, we detail the setup for our primary submission in Table 1.

3.4 Evaluation

We use the same automatic metrics used by the shared task organisers in their preliminary automatic evaluation results (Müller et al., 2022). We use SacreBLEU (Post, 2018) to calculate BLEU[1] (Papineni et al., 2002) and chrF2++[2] (Popović, 2017). As semantic metric we use BLEURT[3] (Sellam et al., 2020).

4 Results and Analysis

Our best model according to BLEU is obtained with the largest 3D ResNet model and reaches 4.8 points on the development set, much higher than the performance of any system on the official test set. However, different metrics do not correlate, and chrF2++ and BLEURT —which correlate better with human judgments than BLEU— point towards a different model. Table 4 shows how per-

Table 6: Sample outputs in the translation of the development set by the DFKI-MLT.3 system.

formance varies depending on the size of the 3D ResNet model. The smallest models seem to perform better across metrics and therefore we use ResNet10_3D in our submissions.

The low scores obtained with all our models correspond to a system that simply matches the most frequent words like "Die", "Der", "Und" as illustrated in Table 6. The rest of the generated sentence is a series of <UNK> tokens that are removed after decoding. We observe that training passes through some remarkable steps. It starts to output the most frequent words repeatedly, 1-grams, and as training advances the system starts to predict higher n-grams. In our experiments, the model stayed at the 1-gram stage.

We submitted 5 runs to the shared task, three of them using ResNet10_3D and the parameters are provided in Table 1. DFKI-MLT.1 was created with our main system using a checkpoint before the end of the training, DFKI-MLT.2 is the best checkpoint. We realized that both submissions had encoding issues and contain <UNK> tokens. We therefore sent a follow-up submission for DFKI-MLT.2, DFKI-MLT.3, containing the corrected format and without <UNK> tokens. As its translation quality was not even 0.5 BLEU points in the leaderboard, which may be less than a random walk from the vocabulary, we sent random walk results with repetitions (DFKI-MLT.4 and DFKI-MLT.5) to compare the performance.

A preliminary automatic evaluation has been made available by the organizers and it is shown in Table 5. Our final submission reached 0.11 ± 0.06 BLEU, 6.3 ± 0.4 chrF2++ and 0.083 ± 0.008 BLEURT, where confidence intervals are at 95% level. Results are therefore not statistically better than the baseline at 95% level. Interestingly, according to BLEURT, the random walk though the vocabulary is not significantly worse than the combination of 3D CNNs and Transformers.

In general, translation quality is always very bad, but results are slightly better for the FocusNew subset. FocusNews' input videos are shorter and this might imply a better alignment between videos and subtitles, improving the training. Some of our test outputs contain repetitions of (parts of) sentences from FocusNew dataset. Since this subcorpus is dominant in the final training (Table 2) the system is biased towards its vocabulary and this also explains the better performance in its subtest.

5 Conclusion

This paper presented an overview and some insights on spatio-temporal sign language representation which were used in the DFKI-MLT submission for the WMT-SLT 2022 shared task. To achieve our goal of building a fully end-to-end sign language model, we worked closely on the representation learning of visual features. Most of previous techniques for SLT simplify the feature representation by extracting spatial features and not benefiting from temporal features. This choice is motivated by the lack of temporal boundaries in sign language videos. To extract spatio-temporal features one can use 2D + 1D CNN approaches but this does not allow a fully end-to-end training as it still requires pretraining in another well-resourced task like object classification. In order to construct a specific representation model for SL and learn temporal modeling in a single model, we choose 3D CNNs and trained them from scratch simultaneously with the textual counterparts.

The translations produced by this architecture are very short and output only high frequency tokens; in few cases, full fluent and grammatical sentences are constructed but their meaning unrelated to the source. The generation of short sentences might be a limitation of our approach that builds a sentence representation with an output conversion method that does not split a sentence in subunits that can be weighted by the Transformer's attention mechanism to generate the output.

However, all the systems in this shared task's leaderaboard have translation scores close to zero. This shows the extreme difficulty of SLT and how bad current systems generalize to new data sets. We believe that system comparisons with such a bad translation quality do not allow to extract meaningful conclusions. In our future work, we investigate on different temporal modeling coupled with the 3D CNNs approach to further pursue the goal of developing a high-quality end-to-end system.

Abstract

This paper describes the participation of DFKI-SLT at the Sign Language Translation Task of the Seventh Conference of Machine Translation (WMT22). The system focuses on the translation direction from the Swiss German Sign Language (DSGS) to written German. The original videos of the sign language were analyzed with computer vision models to provide 3D body keypoints. A deep-learning sequence-to-sequence model is trained on a parallel corpus of these body keypoints aligned to written German sentences. Geometric data augmentation occurs during the training process. The body keypoints are augmented by artificial rotation in the three dimensional space. The 3D-transformation is calculated with different angles on every batch of the training process.

1 Introduction

Despite the enormous progress of the Machine Translation (MT) of spoken (and written) languages, the MT of sign languages is in a very early stage (Yin et al., 2021; De Coster et al., 2022). Two major challenges are (a) the multimodal and multilateral nature of the sign languages and (b) the lack of data. On the one side, the multilateral and multimodal nature of the sign languages requires deep-learning topologies that differ substantially from the ones used in text-based MT. On the other side, the lack of data makes difficult the utilization of end-to-end deep learning algorithms, which usually require vast amounts of data. As a result, deep-learning experiments have been executed for very few sign languages (e.g. German Sign Language, DGS; American Sign Language, ASL) and narrow domains (e.g. weather forecasts), leaving open questions on the generalization of the methods to other sign languages and broader domains.

This year's Sign Language Translation (SLT) Task of the Seventh Conference of Machine Translation (WMT22) is contributing significant to this direction, by adding a new language pair (Swiss German Sign Language - DGSG - to German) and allowing extensive experimentation from several participants on the same dataset.

Our system uses computer vision models to analyze the sign language videos into body keypoints and uses these keypoints as the source-side input of the neural MT transformer, allowing to perform data augmentation via geometrical augmentations. Despite the difficulty of this shared task and the low results obtained, we publish this paper as a technical report, with the hope that it can contribute to the further research of this direction.

The rest of the paper is organized as following. Section 2 positions our contribution amidst related work. Section 3 describes the methods for training the system and Section 4 the technical set-up of the experiment. Section 5 provides and discusses some results, while Section 6 gives some conclusion and ideas for further work.

2 Related Work

Latest work on MT of sign languages has shown significant improvements using deep learning methods from the fields of computer vision and MT. State of the art work (Camgöz et al., 2018; Yin and Read, 2020; Camgöz et al., 2020; Zhou et al., 2022) employees transformers, which are given frame embeddings extracted from the videos of the signers.

Contrary to the use of pixel-based frame embeddings, Nunnari et al. (2021) suggests to use body keypoints from the hands, the skeleton and the face as input to the transformers. This requires to split the translation pipeline into a first phase, recognizing 3D keypoints from videos, and has the advantage that they can be augmented by applying transformation techniques. Our paper presents an implementation of that idea, applied to the case of DSGS.

The use of body keypoints has been considered

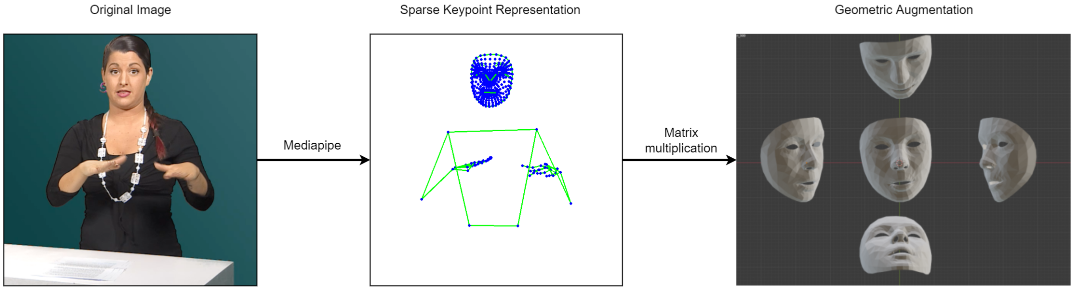

Figure 1: Mediapipe is used to extract sparse keypoint representations of the signer. The nature of the resulting 3D data allows for rotation, translation and shearing using matrix multiplication at virtually no cost.

by Gan et al. (2021), where skeleton pose information is processed together with the video frame input. Ko et al. (2018, 2019) use 2D coordinates of body keypoints to train the neural MT systems, but contrary to our work, they do not perform any geometrical transformations to the keypoints. Moryossef et al. (2021) analyze the applicability of the pose estimation systems to sign language recognition by evaluating the failure cases of the recognition models.

3 Method

Our system consists of three modules. The first module converts images of the signer into intermediate keypoint representations. The second module employs data augmentation to increase sample efficiency and decrease the effect of spurious feature correlations. Spurious data correlation in high dimensional spaces can lead to Clever Hans effects (Kauffmann et al.). The last module is the trainable transformer that translates from keypoint representation to German text, while interacting with the augmentation module.

3.1 Keypoint extraction

There are multiple reasons to believe that keypoint representations could prove beneficial in SLT. Only few and small datasets are available for SLT. That is because firstly there are only few known data sources for SL. Secondly the data transcription for SL needs expert knowledge which is costly and hard to find. Thirdly SL data inherently needs video footage of signing human, which makes anonymisation near impossible thus leads to privacy problems when detecting new potential data sources.

A end-to-end SLT pipeline needs to make sense of the movement of the human signer and translate these motions into written language. Practically speaking this means the pipeline internally needs to learn two tasks on limited data. However only the translation task depends on the costly and limited SLT datasets, while the task of detecting the motion could be eased by employing pose estimation which is not specific to SLT and therefore is more explored and cheaper in terms of data acquisition.

The extraction of the keypoints was done by using the computer vision models of MediaPipe Holistic (Grishchenko and Bazarevsky, 2020) which combines three pre-trained computer vision pipelines that detect the hand keypoints (MediaPipe Hands; Zhang et al., 2020), the keypoints of the body pose (BlazePose; Bazarevsky et al., 2020), and a keypoint mesh for the face (BlazeFace; Bazarevsky et al., 2019).

When data points were missing, the values were substituted by zero values.

3.2 Geometrical transformation

The geometrical transformation is applied during the training process of the transformer model. For every iteration of the training process, the 3D keypoints are given to the geometrical transformation module. This returns the co-ordinates of the original keypoint mesh after being rotated. The 3D keypoints get rotated around the x, y and z axis by some angle R_x, R_y and R_z respectively, using rotation matrices. First, the rotation around the x-axis takes place, followed by y and then the z axis.

The rotation angle is drawn at random at every training iteration, such that every batch is rotated to a different setting. The angle of the rotation is limited to a particular range, which makes sense for the particular axis. R_x is drawn from [-60°, +60°] while R_y and R_z are drawn from [-10°, +10°].

3.3 Sequence-to-sequence model

The sequence-to-sequence model is based on a NMT transformer model similar to (Camgöz et al., 2018). We provide the network the keypoint representation, by concatenating all mediapipe keypoints and then flattening them into a 708 dimensional vector. The target language is the Swiss German text.

4 Experiment setup

The experiment took place using only the corpora FocusNews, as provided by the shared task organizers, including keypoints precomputed with MediaPipe. Due to time restrictions, the SRF corpus was not used, since it did not provide any keypoints. The training set had 10,136 sentences, the validation set 420 sentences and the test set 488 sentences. Due to problems with the keypoint-subtitle alignment only 393 of the 420 sentences of the validation set were used.

For training the model we modified the NMT toolkit JoeyNMT[1] (Kreutzer et al., 2019), extending the SLT branch created by Camgöz et al. (2020). We followed the text pre-processing of the previous implementation, which included text lowercasing. The geometrical transformations were done with array computations using NumPy (Harris et al., 2020). The automatic evaluation metrics were computed using SacreBLEU (Post, 2018).

In order to optimize the system we ran several experimental rounds. The training parameters for all rounds can be seen in Table 2. The experimental rounds were run by modifying the following parameters:

- **max. rotation**: The maximum angle for the random rotation that took place for every iteration. A max. rotation of 10° here means that for every iteration batch, a random degree value within [-10°, +10°] was drawn.
- **patience**: The learning rate scheduler stops when no significant progress is measured with the evaluation metric, after a number of epochs. This parameter defines how patient the scheduler is in that regards.
- **LR scheduler metric**: The metric used for measuring the progress on the validation set.
- **layers**: The number of layers for the encoder and the decoder of the transformer.

5 Results

As part of our parameter we ran 5 experimental rounds which are shown in Table 1. Due to time limitations it was not possible to experiment with the full spectrum of parameters, including ablation tests which would indicate the contribution of possible parameter values. Even in that case, the very low metric scores would not lead to more significant conclusions.

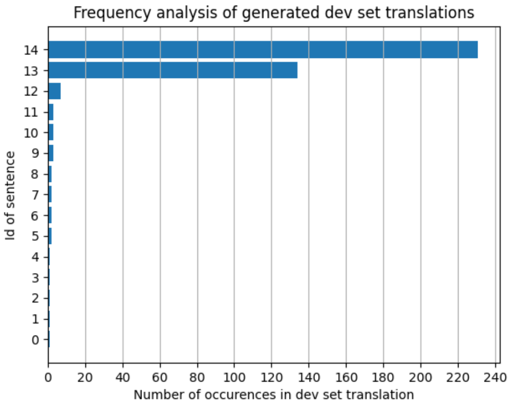

Figure 2: Overview over the translation sentence frequencies over the dev set

From the first experiments it was obvious that the use of BLEU-4 as a validation metric could not contribute to the optimization, because its values are always zero and also the training time was very short. For this reason we chose ChrF as validation metric for our last two experiments. Increasing the patience deemed necessary, so that the training mechanism can get enough random samples from the augmentation process. For our best iteration we experimented with both 3 and 4 layers, resulting into slightly better performance with the 4 layer setting.

In overall, the results of our experiments, as measured by automatic metrics, showed very low performance. No version of our pipeline could achieve non-zero BLEU-4 score on the provided development set, meaning that no n-gram of order 4 was correctly matched between the hypothesis and the reference. The experiments measured with BLEU-3 and ChrF indicate as better run the configuration with 60 degrees rotation range at the X axis, 10 degrees on the other axes, and a patience of 500. When analyzing the output on the validation set we found that for the 393 different sentences of the validation set, only 15 different translations were repeatedly produced as highlighted in figure 2 and listed in Appendix A. The two most common translations make up for 92% of the cases. This behaviour suggests that the model learned two main

6 Conclusion and Further Work

Due to the poor results, very little can be concluded about the effect of the proposed geometric augmentation strategy. As suggested by the preliminary results of the shared task (Müller et al., 2022) no group was able to achieve good results on the task. Unfortunately, due to the strict workshop timeline we could not perform further experiments to empirically prove the causes of this low performance. We are planning to do this in future work, including an ablation study of the different modules and a comparison with the state-of-the-art on other datasets. Further research should be invested in exploring the possible use cases for geometric data augmentation in MT of SL.

Abstract

We describe TTIC's model submission to WMT-SLT 2022 task (Müller et al., 2022) on sign language translation (Swiss-German Sign Language (DSGS) → German). Our model consists of an I3D backbone for image encoding and a Transformer-based encoder-decoder model for sequence modeling. The I3D is pretrained with isolated sign recognition using the WLASL dataset. The model is based on RGB images alone and does not rely on the pre-extracted human pose. We explore a few different strategies for model training in this paper. Our system achieves 0.3 BLEU score and 0.195 Chrf score on the official test set.

1 Introduction

Sign language, a full-fledged natural language that conveys meaning through gestures, is the primary chief of communication among Deaf people. Sign language translation is a task for automatically translating sign languages into written languages. Due to its widespread potential applications, it has recently received growing research interest (Camgoz et al., 2018, 2021).

Existing methods for sign language translation are primarily based on gloss, a transliteration system annotating sign language with symbols from written language. Utilizing gloss usually boosts the performance of current translation systems by a large margin. In the widely used German sign language translation benchmark Phoenix14T (Camgoz et al., 2018), state-of-the-art gloss-based models (Chen et al., 2022) are roughly 15 points better (in Bleu-4) than gloss-free models (Camgoz et al., 2018). However, gloss is more expensive to annotate than written language translation. There have been relatively few amounts of studies for gloss-free sign language translation. Specifically, Orbay and Akarun (2020); Shi et al. (2022) utilize local visual features (e.g., hands) to enhance the translation performance. Those systems require domain-specific training data (e.g., labeled handshape data used in Orbay and Akarun (2020)), which is not always accessible for the target sign language. The fusion of visual features at different scales also increases the complexity of the modeling pipeline.

In this paper, we study a simple model for sign language translation between DSGS and German in a gloss-free setting. Our model uses a 3D convolutional network for visual feature extraction and a Transformer-based encoder-decoder for sequence modeling. It is built on raw RGB images rather than pose keypoints, thus avoiding potential mistakes from pose estimation and remaining fast in inference. We further study the impact of hyperparameters and different pretraining strategies on translation quality. Without ensembling, our model achieves 0.3 Bleu score and 0.195 Chrf score on the official test set.

2 Method

In this section, we describe our method for sign language translation. Our model consists of an Inflated 3D ConvNet (I3D) (Carreira and Zisserman, 2017) for visual encoding and a Transformer-based encoder-decoder model (Vaswani et al., 2017) for sequence modeling, which are described respectively below.

I3D I3D (Carreira and Zisserman, 2017) is a 3D convolutional neural network proposed in action recognition. I3D has previously been explored in sign language processing (Albanie et al., 2020; Li et al., 2020; Vaezi Joze and Koller, 2019) and achieved competitive performance in isolated sign recognition (Li et al., 2020). More formally, given a sequence of image frames $\mathbf{I}_{1:T}$, the I3D model $\mathbf{M}^v$ encodes them into a sequence of visual features $\mathbf{f}_{1:T'}$: $\mathbf{f}_{1:T'} = \mathbf{M}^v(\mathbf{I}_{1:T})$, where T and T' respectively denote the length of video and visual feature sequence. Note due to the temporal stride in convolutional kernels of I3D, T' is not equal to T and is usually several factors smaller.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 989 - 993
December 7-8, 2022 ©2022 Association for Computational Linguistics

To encourage the visual encoder $\mathbf{M}^v$ to capture more signing-related visual cues (e.g., arm movement, handshape, and so on), we pretrain the I3D model with isolated sign recognition on WLASL, a large-scale dataset consisting of isolated American sign language (ASL) signs. Though ASL and DSGS are two different sign languages, visual features regarding body movement are shared. Empirically, we observed considerable gains in isolated sign pretraining. For computational efficiency, the pretrained I3D network $\mathbf{M}^v$ is frozen in translation model training.

Transformer-based encoder-decoder We employ a Transformer-based encoder-decoder (Vaswani et al., 2017) model $\mathbf{M}^{(s)}$ to decode visual feature $\mathbf{f}^{(v)}_{1:T'}$ into text $w_{1:N}$: $w_{1:N} = \mathbf{M}^{(s)}(\mathbf{f}^v_{1:T})$. $\mathbf{M}^s$ is a standard sequence-to-sequence model widely used in machine translation (Vaswani et al., 2017; Barrault et al., 2020; Akhbardeh et al., 2021). Thus we only briefly review it here and a more detailed description can be found in Vaswani et al. (2017). Our sequence-to-sequence model $\mathbf{M}^s$ includes a Transformer encoder and Transformer decoder, which are joined via attention. Specifically, the Transformer encoder transforms the visual features $\mathbf{f}^v_{1:T}$ into $\mathbf{e}_{1:T}$ by injecting temporal information based on self-attention and positional embedding. The Transformer decoder generates token sequence $w_{1:N}$ in an auto-regressive manner while attending to the encoder output $\mathbf{e}_{1:T}$ through the attention mechanism.

Training loss We use cross-entropy loss for model training. More formally, given the translation pair $(\mathbf{I}_{1:T}, \hat{w}_{1:N})$, suppose the model outputs probability vector $\mathbf{p}(\cdot|\mathbf{I}_{1:T}, \hat{w}_{1:n-1})$ at decoder step n. The loss is then computed as

$$l = -\sum_{n=1}^{N} \log p(\hat{w}_n|\mathbf{I}_{1:T}, \hat{w}_{1:n-1}) \qquad (1)$$

Inference At test time, we use beam search for decoding image sequence $\mathbf{I}_{1:T}$. The beam width and length penalty are hyperparameters tuned using the development set.

3 Experimental Setup

Data We use FocusNews and SRF data to train our translation model. Both FocusNews and SRF consist of DSGS-German pairs, which include 19 and 16 hours (10,136 and 7,071 sequences) of DSGS videos, respectively. The two datasets differ in multiple aspects. For example, FocusNews are live signing from teleprompters by deaf signers based on news from 2008 to 2014, whereas SRF dataset contains news videos from 2020 to 2021 which is interpreted into DSGS by hearing interpreters. Both datasets are incorporated into training. Note that frame rates in videos of FocusNews and SRF differ, we feed the raw videos in FocusNews and SRF without frame rate conversion. To pretrain the visual encoder, we use WLASL (Li et al., 2020), a large-scale isolated sign dataset including $\sim 21k$ pairs of American sign language video clips and English words.

Training We use sentencepiece unigram tokenizer (Kudo, 2018) to tokenize the German translation. The number of subword units is tuned to 18,000 We use a 2-layer Transformer with 512 hidden dimensions and 2048 hidden dimensions for both encoder and decoder. A dropout layer with a zeroing probability of 0.1 is added between the self-attention layer and the feedforward network. The model is trained with Adam (Kingma and Ba, 2015) for 18K steps at a batch size of 32. The learning rate is linearly increased to 0.0008 for 2K steps and decayed to 0 in the remaining steps. The visual backbone I3D is pretrained on WLASL and frozen during translation model training. During isolated sign training, we initialize I3D from a model trained on the action recognition dataset Kinetics (Carreira and Zisserman, 2017). We use SGD with a 0.9 momentum value to train the model for 50 epochs at a batch size of 4. The initial learning rate is 0.001 and is halved if accuracy on the validation set does not increase for 3 epochs. Before feeding into I3D, each isolated sign video is truncated to a 64-frame clip, which is padded with all-zero frames if the length is shorter than 64. Each image frame is resized to 240 × 240. It is randomly cropped to 224 × 224 and horizontally flipped at a probability of 0.5 in training. At test time, we only center cropping to every image frame.

Evaluation We evaluate the system using BLEU-{1,2,3,4} (Lin, 2004) and ROUGE (Lin, 2004) scores.

4 Experimental Results

In this section, we report results and conduct some analyses of the translation model on the development set.

4.1 Main Results

Table 2 shows the performance of our model on the development set compared to the Sockeye baselines reported from the official repo (Müller et al., 2022). Our model outperforms Sockeye baselines, which are models based on the pre-extracted human pose. However, the overall values in different metrics are very low. We further show translation examples produced by our model (see Table 1). We noticed the phrases that are translated correctly by our model are usually duplicate phrases frequently appearing in training (e.g., willkommen zur "tagesschau"). For most of the sentences, the model is unable to capture its meaning generally though many predictions are grammatically correct. Such observation shows that large-vocabulary sign language translation is very challenging.

4.2 Hyperparameter Tuning

Among the set of hyperparameters, we find that the following two hyperparameters have the most significant effect on translation performance: learning rate and the number of layers. We detail their impact on model performance below. Other hyperparameters (e.g., dropout, learning rate schedule) are also tuned in our experiments. However, their impact is relatively negligible and thus not detailed in the paper.

Learning rate We tuned the learning rate among $\{0.001, 0.002, 0.004, 0.008, 0.016\}$. As is shown in Table 3, increasing the learning rate consistently improves the model performance across all the metrics. The benefit plateaus around 0.008, which is the optimal value among the set of values we consider.

Number of layers We further tuned the number of Transformer layers (see Table 4). We keep the number of encoder and decoder layers the same and set the hidden/feedforward dimension to 512/2048 in the corresponding experiments of Table 4. Increasing number of transformer layers degrades the performance. This is probably because the 3D convolutional kernels of I3D capture some temporal relations in the video, which reduces the reliance of

LR	Rouge	B1	B2	B3	B4

Table 3: Impact of learning rate on translation performance

the whole model on Transformer modules to capture sequential information. Furthermore, larger models (i.e., more layers) usually require more training data. The total amount of sign language videos (35 hours) is probably insufficient to train a deep transformer encoder-decoder.

6	6.17	7.32	1.55	0.52	0.24

Table 4: Impact of Transformer layers on translation performance

4.3 Effect of I3D pretraining

The I3D backbone is pretrained on WLASL. Here we compare three options of I3D pretraining: WLASL, BSL-1K, and Kinetics-400. BSL-1K is a coarticulated sign dataset of 1064 British sign language (BSL) signs (273K video clips in total), collected from BBC videos interpreted into BSL. Kinetics (Carreira and Zisserman, 2017) is the action recognition dataset with 650K videos from 400 human action categories. As is shown in Table 5, pretraining with sign-language specific datasets (WLASL, BSL-1K) consistently outperforms pretraining with general human action videos (Kinetics). This is expected as signing-related visual cues (e.g., handshapes), essential for sign language translation, are better captured in isolated sign datasets. Pretraining with WLASL achieves better results than BSL-1K. Though BSL-1K contains an overall larger number of video clips than WLASL (21K vs. 273K), it has fewer unique signs (1064 vs. 2000). This probably suggests that a sign language corpus with more signing categories will be more beneficial to sign language translation compared to its counterpart with fewer signs.

PT Data	Rouge	B1	B2	B3	B4

Table 5: Impact of Transformer layers on translation performance

5 Conclusion

This paper describes TTIC's DSGS-German translation system submitted to the WMT-SLT 2022 challenge. Our model consists of an I3D model for visual feature extraction and a Transformer-based encoder-decoder for sequence modeling. The system is based on RGB images alone and remains conceptually simple. Our experiments show that pretraining the visual frontend with isolated sign recognition helps achieve better translation performance. However, the overall translation quality is still in a very low regime. Our future work includes combining pose and RGB-based models for sign language translation.

Abstract

This paper describes the system developed at the Universitat Politècnica de Catalunya for the Workshop on Machine Translation 2022 Sign Language Translation Task, in particular, for the sign-to-text direction. We use a Transformer model implemented with the Fairseq modeling toolkit. We have experimented with the vocabulary size, data augmentation techniques and pretraining the model with the PHOENIX-14T dataset. Our system obtains 0.50 BLEU score for the test set, improving the organizers' baseline by 0.38 BLEU. We remark the poor results for both the baseline and our system, and thus, the unreliability of our findings.

1 Introduction

The submission of the Universitat Politècnica de Catalunya (UPC) to the WMT22 Sign Language Translation (SLT) Task experimented with vocabulary size, data augmentation techniques and a pretrained system with the PHOENIX-14T dataset (Camgoz et al., 2018). Up to the author's knowledge, our implementation is the first to build on Fairseq, a popular modeling toolkit by Meta AI (Ott et al., 2019).

SLT is a highly complex task because sign language understanding requires a very precise estimation of the signer pose, especially, of its hands. In addition, sign languages have grammatical structures different from spoken languages, which prevents an easy knowledge transfer. Sign languages are represented in continuous and high-dimensional spaces, while the transcribed version of spoken languages are represented by discrete tokens of well-defined vocabularies. Moreover, the few available sign language datasets can be considered very low-resourced, as they typically contain less than one hundred thousand sentences (Goyal et al., 2022). In particular, the total number of sentences from the two datasets provided in WMT-SLT22 is 17k.

We focus on the sign language translation task of WMT-SLT22 which requires participants to predict the translation in spoken language (written) from a sign language video. Specifically, it consists of translation from Swiss German Sign Language (DSGS) videos to German (DE) text.

The organizers of WMT 2022 SLT track propose a Transformer baseline (Müller et al., 2022) that achieves a very low BLEU (Papineni et al., 2002) score,[1] which indicates a very poor translation quality. The training data provided consists of two datasets: FocusNews (Müller et al., 2022b) and SRF (Müller et al., 2022a). The first one contains 197 episodes in DSGS that have an average length of 5 minutes, which amount for a total duration of 19 hours. The second dataset contains 29 videos from live sign language interpretation, that have an average of 30 minutes length, and totals a duration of 16 hours. The paired subtitles are given in Standard German from Switzerland, which is a dialect of German.

The organizers provide keypoints extracted with two off-the-shelf human pose estimators: OpenPose (Cao et al., 2019) and MediaPipe (Lugaresi et al., 2019).

2 Baseline system

For the sake of self-containment, we briefly define and discuss the baseline model proposed by the organizers for this task (Müller et al., 2022). This solution is built on sockeye (Hieber et al., 2017), with results for the official development (dev) partition.

Regarding the model implementation, they use a Transformer encoder-decoder, with a symmetrical number of layers for the encoder and decoder. The architecture has 6 layers, 8 heads, 2048 neurons in

[*] Equal contribution

[1] For simplicity, we refer to BLEU-4 score as BLEU score.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 994 - 1000
December 7-8, 2022 ©2022 Association for Computational Linguistics

the feed forward network layers, and an embedding dimension of 512.

The input data are 2D OpenPose keypoints, concatenating the hands and body landmarks. This results in an array $X = x_0, \ldots, x_T$ where $x_t \in \mathbb{R}^{2K}$, K is the number of keypoints selected, and T the number of video frames.

Three baseline results were provided by the WMT-SLT22 organizers, shown in Table 1. The first two scores correspond to the models trained individually with each of the two benchmark datasets. The last result is from a model trained on both datasets, which obtains the lowest performance. We hypothesize this might be due to a domain shift between the FocusNews and SRF datasets. These BLEU scores are extremely low, as already noted by Müller et al. (2022). As a comparison, the SLT state-of-the-art BLEU score for PHOENIX-14T dataset (Camgoz et al., 2018) is 25.59 (Voskou et al., 2021) and for the How2Sign dataset (Duarte et al., 2021) is 1.25 (Duarte et al., 2022).

Train dataset	BLEU
FocusNews	0.216

FocusNews + SRF	0.157

Table 1: Results provided by the organizers for the official dev partition, which contains FocusNews + SRF samples. Scores on test partition, which also contains FocusNews + SRF samples, were not released by the organizers.

3 Method

Our submission also adopts a Transformer architecture, which we implement with the Fairseq sequence modeling toolkit (Ott et al., 2019). Up to the author's knowledge, this is the first time that Fairseq is used for sign language video understanding. We publish our source code [2], offering the SLT community a novel tool widely used in machine translation for spoken languages. On top of this, we experiment with the vocabulary size, data augmentation techniques and pretraining the system with PHOENIX-14T dataset. Details are described in this section.

3.1 Preprocessing steps

The WMT-SLT22 organizers provide both OpenPose and MediaPipe keypoints from the body pose estimators. We choose MediaPipe poses because they provide 3D coordinates (x, y, z) normalized between $[0, 1]$. Moreover, based on our experience, OpenPose is more prone to errors, like detecting several people in videos when there is only one signer in the recording.

Although MediaPipe poses are available from WMT-SLT22, we re-extract them with *pose-format* (Moryossef, 2022). This library defines a standardized way of storing poses, and provides different functionalities to work with them. After the extraction, we obtain an array with the same shape as described in Section 2.

While the video recordings in the SRF dataset have a rate of 25 frames per second (fps), the FocusNews dataset present a frame rates of either 25, 30 or 50 fps. We perform cubic interpolation for the extracted poses, to achieve a unified frame rate of 25fps, using the *interpolate_fps* function from *pose-format*.

We build an independent vocabulary with the training split of each dataset. For the SRF dataset, organizers provide parallel and monolingual data. The latter contains all German subtitles, including much more sentences than the former. Therefore, we choose to build our SRF vocabulary from the monolingual data. Note that this data does not have paired (or parallel) videos, so it can not be used for training the model.

3.2 Architecture

We build a smaller Transformer architecture than the WMT-SLT22 baseline, since we observed signs of overfitting when checking the training losses. With the baseline architecture the system was simply generating the most frequent words from the training set. Therefore, we concluded that training a smaller model would hinder the overfitting and might improve the results.

In particular, our Transformer model has a symmetrical structure for the encoder and decoder, with 3 layers, 4 heads, 1024 neurons in the feed forward network layers, and an embedding dimension of 256.

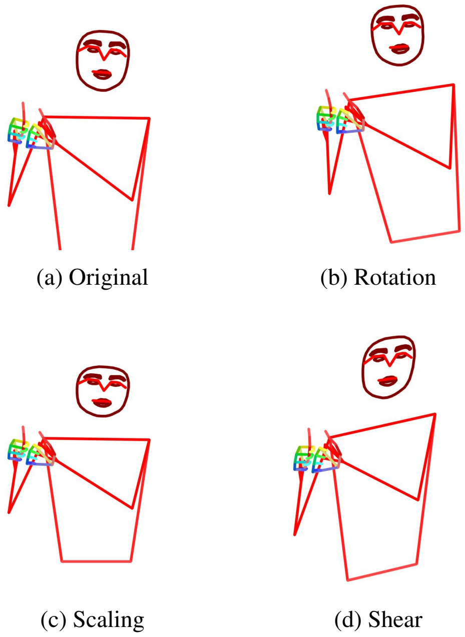
3.3 Data augmentation

The performance of deep learning models depends on the quality, quantity, and domain of training data, however datasets that provide all qualities needed for models are often not available. To diminish the consequences of the data scarcity, a common practice is to apply data augmentation techniques.

[2] https://github.com/mt-upc/fairseq/tree/wmt-slt22

This approach is really useful to improve the performance of models, and makes them more robust to slight changes in the input data.

We made use of the *augment2d* function from the *pose-format* library, which allows applying various transformations directly to the keypoints, such as random rotation, shear effect, and scaling. Specifically, the rotation angle in radians, the shear factor and the scaling factor we apply are obtained by sampling from a normal distribution with zero mean and standard deviation of 0.2. Some examples of augmented poses are shown in Figure 1.



(a) Original
(b) Rotation
(c) Scaling
(d) Shear

Figure 1: Data augmentation transformations.

3.4 Vocabulary size

State-of-the-art Machine Translation systems use subword dictionaries instead of word-level vocabularies (Tran et al., 2021; Yang et al., 2021). These dictionaries are built by decomposing words into smaller pieces based on their frequency (Sennrich et al., 2016). Analogously to the baseline approach, we use SentencePiece tokenizer to obtain the subword vocabulary (Kudo and Richardson, 2018).

The vocabulary size is a hyperparameter that, in practice, is either chosen arbitrarily or via trial-and-error (Salesky et al., 2020). However, it has been studied that using a greater vocabulary size might help in reducing the class imbalance present in the training dataset (Gowda and May, 2020). The baseline used a vocabulary size of 1000 subwords, and we experiment with 2000 and 4000. Our goal was to detect whether downsampling a vocabulary of 20k unique words, for FocusNews dataset, to 1k subwords may be oversimplifying the problem.

3.5 Pretraining with PHOENIX14-T

We also explore transfer learning to overcome the data scarcity problem. Given that the scope of WMT22 is on Swiss German Sign Language, we chose the PHOENIX14-T dataset (Camgoz et al., 2018). For the three datasets, the target language is either spoken (written) German or Standard German from Switzerland. However, PHOENIX14-T presents an important domain shift with respect to the WMT-SLT22 datasets, since it is limited to live interpretation of weather forecast on broadcast TV.

We pretrained our model with the PHOENIX14-T dataset. In order to implement the transfer learning pipeline, we built a vocabulary by merging the training data from the three available datasets: FocusNews, SRF and PHOENIX14-T.

3.6 Checkpoint Averaging

We choose the best-performing models as those with the best BLEU dev scores. However, in the best-performing cases, and as thee final step in our trainings, we average the weights of the 3 best model checkpoints for each run. This methodology, which was firstly introduced by (Vaswani et al., 2017), proved to be a useful and easy to implement technique to generate more robust predictions on Transformers (Popel and Bojar, 2018), and has been widely used in the Machine Translation field.

4 Results

We train our systems with FocusNews and SRF. For both datasets, we provide results for the dev set, which contains recordings from FocusNews and SRF. We choose the 6 best-performing models for dev to submit to the official challenge submission.

Table 2 shows the results of models trained with FocusNews. We notice an improvement in the performance of our baseline implemented iin Fairseq with respect to the one from the organizers (1-2). We then analyze the effect of the vocabulary size based on the BLEU obtained for the dev set. We notice that using 4000 subwords provides the best results in terms of vocabulary size (2-4). Therefore, we choose this configuration to experiment with pretraining and data augmentation. For this set of experiments, we see a slight improvement when fine-tuning a network that has been pretrained with the PHOENIX14-T dataset (6). However, adding data augmentation (5) or a combination of both

ID	System	Vocab. size	Data Augm.	Pretrain	BLEU (dev)	BLEU (test)
1	Baseline (Müller et al., 2022)	1k			0.22	-
2	Our Baseline (§3.2)	1k			0.47	**0.50**
3	2 + 2k subwords	2k			0.47	-
4	2 + 4k subwords	4k			0.62	-
5	4 + data augmentation	4k	✓		0.51	-
6	4 + pretrain w/ Phoenix	4k		✓	**0.64**	0.41
7	6 + data augmentation	4k	✓	✓	0.48	-
8	6 + checkpoint average	4k		✓	0.57	0.35

Table 2: Results of models trained with the FocusNews dataset. *BLEU (dev)* corresponds to the results obtained in the challenge dev set, and *BLEU (test)* to the results extracted by the organizers using the official test partition (Müller et al., 2022). In bold are the best results for each partition.

ID	System	Vocab. size	Data Augm.	Pretrain	BLEU (dev)	BLEU (test)
1	Baseline (Müller et al., 2022)	1k			0.59	0.12
2	Baseline (§3.2)	1k			0.64	-
3	2 + 2k subwords	2k			**0.69**	**0.28**
4	2 + 4k subwords	4k			0.63	**0.28**
5	3 + checkpoint average	2k			0.60	0.24

Table 3: Results of models trained with the SRF dataset. *BLEU (dev)* corresponds to the results obtained in the challenge dev set, and *BLEU (test)* to the results extracted by the organizers using the official test partition (Müller et al., 2022). In bold are the best results for each partition.

data augmentation and pretraining (7) does not improve the results. Checkpoint averaging does not bring an improvement either (8). Surprisingly, we cannot extract the same conclusions from the test results. After we received the preliminary findings from the organizers (Müller et al., 2022), we found that the best-performing model for dev (6) was not the best for test, but the simplest one (2).

Results of models trained with SRF are presented in Table 3. Similarly to FocusNews, our proposed baseline improves the organizers' in this dataset (1-2). However, in this case, the optimal number of subwords is 2000, with a slight improvement over other vocabulary sizes (2-4). Similar to the FocusNews case, we observe that checkpoint averaging does not improve results. Due to technical issues and time limitations, experiments with SRF are limited to analyzing the vocabulary size, hence the best experiment with FocusNews could not be replicated using SRF. Although results for dev are better for models trained with SRF, results for test show a poorer performance than FocusNews models.

We optimized our systems to obtain the best BLEU metric, without taking other metrics into consideration. However, organizers also compute chrF++ (Popović, 2017) and BLEURT (Sellam et al., 2020) metrics (Müller et al., 2022). We find that the BLEURT score shows a similar performance than BLEU. However, for the chrF++ metric, which correlates better with respect to human relative rankings, our models score lower compared to other submissions.

We provide some examples of the sentences generated by our best-performing model in Table 4. We see that the translations are poor and lack correlation with the video, which relates to the poor overall performance in the BLEU metric.

5 Discussion and Conclusion

We proposed a pipeline to tackle the Sign Language Translation Task for the newly released datasets:

Table 4: Example reference and predictions from our best-performing model for the official dev partition.

Focusnews and SRF. Our fresh implementation with Fairseq slightly improved the baseline provided by the organizers.

Our findings showed that when training with FocusNews, our baseline system has the best performance for test. The changes in vocabulary size did not affect the test performance. Furthermore, we showed that using checkpoint averaging does not help for this task. In all cases, we still think that the results are extremely low, which indicate a really poor translation, and there is potential unreliability of the findings due to the close to 0 BLEU score.

We consider the results we obtained can be further improved, so we leave some experiments for future work. Firstly, we believe that a joint training from the two provided datasets could boost the performance of the models by bridging the domain gap between these datasets. Secondly, we did not see any improvement by pretraining the models with PHOENIX14-T dataset. However, we think that solving the WMT-SLT22 task must require some sort of transfer learning from a pretrained model.

Limitations

As stated by the organizers, results are still poor. When inspecting the predictions, it seems evident that the model is learning the most frequent words in the vocabulary, thus failing to provide meaningful predictions from the video. We consider that this is due to the high complexity of the task paired with a lack of data.

	Length	**Words**	**Ratio**
FocusNews	19 h	21 k	0.90
SRF	16 h	19 k	0.84
How2Sign	79 h	16 k	4.93
PHOENIX14-T	11 h	3 k	3.67

Table 5: Comparison between SLT datasets based on the duration of the videos (in hours) and number of unique words (in thousands) in the vocabulary. The Ratio column provides an indication of the difficulty of solving the SLT task for each dataset.

As shown in Table 5, the ratio between the training data and vocabulary size is much lower compared to other SLT datasets such as How2Sign and PHOENIX14-T. We take these results as an indication of the complexity of the datasets. We hypothesize that the low BLEU scores reported in the baseline, may be caused by the low ratio between video hours per unique words in the vocabulary, hence the dataset might be too complex. Therefore, we decide to experiment with data augmentation since it artificially improves the amount of training samples.

Our experiments with the SRF dataset, have been computationally expensive. Due to technical details, we have to read full sequences of around 30 minutes every time we load a sample. Processing them, even with the dimensional reduction provided by pose estimators, has been a challenge for the machines of our academic lab. A slightly better set of results might have been produced, but we still think it would not have made a significant difference.

In addition, we present the input poses as a sequence of one-dimensional arrays with the XYZ coordinates. We think that this may not be the optimal way of processing the graph-like structure from poses. Using graph neural networks to preprocess input poses (Yan et al., 2018, 2019; Bull et al., 2020; Jiang et al., 2021) might be an interesting approach to improve SLT results.

We also lacked the time to experiment with other features, such as processing the RGB videos with a convolutional network (Vaezi Joze and Koller, 2019; Li et al., 2020; Albanie et al., 2020). We tried extracting i3d features fine-tuned on PHOENIX14-T, but the output features contained an excessive number of 0's, and we never run a proper experiment with this setup. This might happen because the visual appearance of the videos is too different between PHOENIX14-T and the WMT-SLT22 datasets, specifically due to the spatial segmentation of the signer in the frames provided in these datasets.

Abstract

We participated in the WMT 2022 Large-Scale Machine Translation Evaluation for the African Languages Shared Task. This work describes our approach, which is based on filtering the given noisy data using a sentence-pair classifier that was built by fine-tuning a pre-trained language model. To train the classifier, we obtain positive samples (i.e. high-quality parallel sentences) from a gold-standard curated dataset and extract negative samples (i.e. low-quality parallel sentences) from automatically aligned parallel data by choosing sentences with low alignment scores. Our final machine translation model was then trained on filtered data, instead of the entire noisy dataset. We empirically validate our approach by evaluating on two common datasets and show that data filtering generally improves overall translation quality, in some cases even significantly.

1 Introduction

This paper presents Masakhane NLP's submission to the WMT 2022 large-scale machine translation evaluation for African languages. We participated in the constrained translation task and chose to focus on a subset of all the language pairs considered for this task due to resource constraints. We specifically explore the language directions **{hau, ibo, lug, swa, tsn, yor, zul}**↔**eng** and **wol**↔**fra**, and submitted our primary and secondary systems which were competitive with other submissions for this task.

Machine translation has received much attention recently, especially for low-resourced languages (Adelani et al., 2022a; Fan et al., 2021; Haddow et al., 2022; Hoang et al., 2018; Nekoto et al., 2020). A promising approach for such setups is to fine-tune large pre-trained language models on the available small amount of translation data (Neubig and Hu, 2018; Adelani et al., 2021a, 2022a). While most of these language models are trained on predominantly high-resourced language datasets (Conneau et al., 2020; Devlin et al., 2019; Radford et al., 2018), there have been a few models that were pre-trained (Ogueji et al., 2021) or adaptively fine-tuned (Alabi et al., 2022) only on low-resourced languages.

Recent works have tried, successfully, to supplement the existing small amounts of natural data in low-resource languages with artificially generated parallel data. For instance, in machine translation, Sennrich et al. (2016) and Ueffing (2006) padded the true parallel data with automatic translations of monolingual sentences through back-translation and self-learning respectively. Others, such as Bañón et al. (2020); El-Kishky et al. (2020); and Schwenk et al. (2021), have used different approaches for detecting potentially aligned sentences within web datasets. While significant improvements have been achieved with these synthetic datasets, an in-depth investigation by Kreutzer et al. (2022) has found them to be fraught with many issues, such as misalignment, wrongful language codes, etc.

Similarly, research has shown that data quality plays an important role in the performance of natural language processing (NLP) models, in machine translation specifically (Arora et al., 2021; Dutta et al., 2020; Hasan et al., 2020; Tchistiakova et al., 2021), but also more generally in other NLP tasks (Abdul-Rauf et al., 2012; Alabi et al., 2020). It was found that often times, models that were trained on smaller amounts of high-quality data outperform their counterparts that are trained on larger amounts of noisy datasets (Gascó et al., 2012; Przystupa and Abdul-Mageed, 2019; Abdulmumin et al., 2022; de Gibert et al., 2022). This has led to many studies (Eetemadi et al., 2015) and prior WMT tasks (Koehn et al., 2018, 2019, 2020) that

[*] Equal contribution.

attempt to find ways to improve the quality of existing data, which, as mentioned before, is often rife with errors.

Therefore, in our submission to the shared task, we experimented with filtering web-mined data for African languages using pre-trained language models and evaluated the effect of using this filtered data on machine translation performance. We defined our filtering approach as a sentence-pair binary classification task and fine-tuned a pre-trained language model using positive and negative samples. We used sentences from the high-quality MAFAND-MT (Adelani et al., 2022a) dataset (which was included in the training data for the constrained task) as positive examples and created negative examples by extracting sentences with low language-agnostic sentence representations (LASER) (Artetxe and Schwenk, 2019b) alignment scores from the `wmt22-african` (NLLB Team et al., 2022) corpus that was provided for this task. Our results highlight the importance of filtering on the quality of the final machine translation system. We also detail how to create a high-quality filter for African languages using a few gold-standard parallel sentences. We release our codes on GitHub.[1]

The rest of the paper is organized as follows: in Section 2, we review related work, and in Section 3, we present the dataset we used. Section 4 provides an overview of the bitext filtering approach, while Section 5 details experimental settings and the translation model architecture. In Section 6, we evaluate the model's performance, and lastly in Section 7, we conclude and highlight some future research directions.

2 Related Work

One of the difficulties when dealing with low-resourced settings, as we do here, is that high-quality parallel texts are particularly scarce (Koehn and Knowles, 2017). To curate data for such language pairs, methods for automatically mining parallel text from the web using heuristics (Resnik, 1999) or latent space and similarity-based filters (Artetxe and Schwenk, 2019a; Schwenk et al., 2021) have been proposed. These have led to the curation of publicly available web-mined datasets such as CCAligned (El-Kishky et al., 2020), CC-Matrix (Fan et al., 2021; Schwenk et al., 2021), ParaCrawl (Esplà et al., 2019), and WikiMatrix (Schwenk et al., 2019) to mention just a few.

However, the recent research work by Kreutzer et al. (2022) shows that the automatically aligned and mined parallel bitexts, especially for low-resource language pairs, contain various degrees of errors and less than half of the data are of good quality. Additionally, many approaches generate large amounts of synthetic data, often through back-translation, where synthetic parallel data is generated by automatically translating monolingual data (Bojar and Tamchyna, 2011; Lambert et al., 2011; Sennrich et al., 2016). While additional data has the potential to improve the trained models, these synthetic datasets are often of low quality (Xu et al., 2019). These observations have led to an increased interest in the automatic filtering of noisy bitexts as a key research topic in machine translation (MT).

One approach to improve data quality is to filter out the noisy or invalid parts of a large corpus, keeping only a high-quality subset thereof (Abdulmumin et al., 2021). In this vein, numerous filtering methods have been developed (Axelrod et al., 2011; Eetemadi and Toutanova, 2015; Junczys-Dowmunt, 2018). For instance, Xu et al. (2019) use the cosine similarity between sentence embeddings as a measure of how closely aligned two sentences are. Imankulova et al. (2017) perform back-translation and then filter based on the sentence-level BLEU score, keeping only those sentences with a high BLEU. Similarly, Adjeisah et al. (2021) perform a round-trip translation and only use the sentence pair if it is sufficiently close to the original sentence, according to a chosen similarity measure. There has also been work on alignment between two parallel corpora, and Hasan et al. (2020) uses the LASER score[2] to evaluate alignment, and filter out all sentences below a specific threshold.

3 Datasets

We participated in the constrained translation track and used only the provided dataset. We present the various dataset used, their sizes and corresponding sources in Table 9 in Appendix A. For our experiment, we selected 8 language pairs and developed different multilingual machine translation systems for them. These language pairs are **{hau, ibo, lug, swa, tsn, yor, zul}**↔**eng** and **wol**↔**fra**. According to the recommendation

Table 1: Examples of noise in the auto-aligned bitext

of Kreutzer et al. (2022), we carefully examined the training dataset provided by manual inspection and divided it into two categories based on the source of the data and the amount of noise included therein. In the following subsections, we describe these two categories of data.

3.1 Clean Bitext

This category of training data comprises all the datasets that are considered to be manually curated. The datasets in this category include: bibleuedin (Christodouloupoulos and Steedman, 2015), MAFAND-MT,[3] QED (Abdelali et al., 2014), Mozilla-I10n,[4] Tanzil,[5] and several others listed in Table 9. The clean bitext consists of sentences mostly in the news and religious domains, with a few in the health, education, and technology domains. We also refer to the clean bitext as True Parallel in this paper.

3.2 Noisy Bitext

We categorized all the automatically aligned bitext as noisy bitext. This also includes the LASER filtered data. The sentences in this category make up the majority of the training dataset, making up 99.2% of the total training data. The datasets in this category include: CCAligned, CCMatrix, LASER wmt22_african,[6] WebCrawl African,[7] and the following datasets from OPUS (Tiedemann, 2012): MultiCCAligned (El-Kishky et al., 2020), TED2020 (Reimers and Gurevych, 2020), WikiMatrix (Schwenk et al., 2019), XLEnt (El-Kishky et al., 2021) and others highlighted in Table 9.

Language pair		Data size	% of original
eng	hau	9, 122, 559	99.9
	ibo	520,544	99.6
	lug	3,511,275	99.8
	swa	32,898,533	99.6
	tsn	6,036,656	99.1
	yor	1,718,105	99.3
	zul	4,142,146	97.6
fra	wol	237,348	100.0

Table 2: Training data after filtering using heuristics

On manual inspection, however, we found numerous issues with the data, including non-parallel sentences, sentences that consist of only numbers and/or punctuation, sentences in different languages, etc. Examples of noise in the auto-aligned data can be seen in Table 1.

3.3 Validation and Test Data

For the optimization of our translation systems, we combined the FLORES-101 (Goyal et al., 2022) and MAFAND-MT (Adelani et al., 2022a) development sets for each of the 8 language pairs. To compare the performance of the developed MT engines, we evaluated on the FLORES-101 devtest set and the MAFAND-MT test set.

4 Parallel Data Filtering

To attempt to deal with the highly noisy data, we opted to use filtering techniques to remove many invalid or incorrectly aligned sentences, similar to prior work (Arora et al., 2021; Hasan et al., 2020; Xu et al., 2019). We first used some simple heuristic approaches, described in Section 4.1, and then progress to an automatic filtering method, detailed in Section 4.2.

4.1 Heuristics

We filtered sentences that consist of only numbers and/or punctuation marks. After filtering, the statis-

tics of the resulting training dataset are shown in Table 2. The table shows that 2.4% of the original Zulu (zu) data consisted of just numbers or punctuation, while other languages had smaller invalid portions, between 0.0% and 0.1%.

4.2 Automatic Filtering

Due to the large size of the automatically aligned dataset, we adopted an automatic approach to determine the quality of parallel sentences to train our translation models. The approach we adopted is sentence-pair binary classification (Nguyen et al., 2021), where we used a transformer-based model to predict the probability that two aligned sentences are actual translations of each other. We explain the process of training data generation and the experimental choices for building the filtering model.

4.2.1 Positive and negative samples

To create the training and evaluation data for the sentence-pair classification-based filtering, we generated positive and negative samples from the training data available for this task. We used the train, dev and test sets from the MAFAND-MT dataset, which is a gold-standard parallel dataset, as positive examples. For the negative examples, however, we sorted the sentences in wmt22_african dataset that was provided for this task based on their LASER alignment scores, and selected the least scored sentences in equal amounts to each of the positive examples. The distribution of the train, dev and test samples is presented in Table 3.

4.2.2 Model

We fine-tuned two pre-trained language models, ALBERT (Lan et al., 2020) and AfroXLMR (Alabi et al., 2022) for the sentence pair binary classification task. ALBERT was selected based on its performance on downstream NLP tasks (Lan et al., 2020), even though it has fewer parameters than other BERT-based models (Nguyen et al., 2021). AfroXLMR, on the other hand, was chosen because it was trained on African languages (Alabi et al., 2022), and such a setup has been shown to improve performance on downstream tasks for these languages (Adelani et al., 2022a).

4.3 Filter Training Setup

The filtering models were trained to accept a pair of sentences from the source and target languages. During training, the [CLS] token hidden representation of the input sentence pairs is fed into a linear Layer and the model is optimized using binary cross entropy loss. However, at inference time, we add a sigmoid layer to the output to predict a number between 0.0 and 1.0 indicating the likelihood of the bitexts being translations of each other. We fine-tuned these models using each language's train split of positive and negative samples, then evaluated performance on the test set while optimizing on the development set.

The performance of the various automatic filtering models and the subsequent sizes of the filtered datasets for the 8 language pairs are shown in Table 4. This table shows the number of sentence pairs the models classified as actual translation pairs using a threshold of 0.5 and 0.7 as well as the F1 score when using the 0.5 threshold. Additionally, in Table 5, we show the number of sentences that were classified by two or all three of the models as being high-quality.

5 MT Experiments

To evaluate the effect of our filtering techniques, we trained some multilingual NMT models for the 8 language pairs that we have selected for this task. In the following subsections, we highlight the model architectures, training setups, and different multilingual models that were trained.

5.1 Model Architecture

For our experiments, we fine-tune M2M-100 (Fan et al., 2021) on different subsets of the provided data. M2M-100 is a pretrained translation model trained on several languages including African languages, as such it has seen all the languages we have chosen for this task during pre-training. We use the model with $418M$ parameters.

5.2 Training Setup

We fine-tuned the M2M-100 model based on the implementation within the Fairseq[8] toolkit (Ott

Table 5: Data overlap after filtering using the sentence-pair classifier models

et al., 2019). We used batch sizes of $2,048$ tokens, a maximum sentence length of $1,024$, and a dropout of 0.3. For optimization, we used Adam (Kingma and Ba, 2015) with β_1 = 0.9 and β_2 = 0.998, a learning rate of $5e - 5$ and a warmup of $2,500$ updates. The optimizer uses a label-smoothed cross-entropy loss function with a label-smoothing value of 0.2. All models were trained for a maximum of $1,000,000$ update steps. We tokenized all data using the model's SentencePiece (Kudo and Richardson, 2018) tokenizer.

To evaluate our models and to choose the best checkpoints, we used the BLEU score (Papineni et al., 2002) calculated with the SacreBLEU (Post, 2018) implementation. In addition, we also evaluated the models using CHRF (Popović, 2015).

5.2.1 Baseline models

We train many-to-many (M2M) translation models by fine-tuning M2M-100 on the following subsets of the datasets described in Section 3. These include, the clean bitexts described in Section 3.1, noisy bitext described in Section 3.2, and a mixture of the clean and noisy bitexts. The noisy bitext was only partially cleaned, as evidenced in Table 2, using the heuristic rules mentioned in Section 4.1 without applying the proposed automatic filtering on data.

We trained these baseline models to compare and measure the efficacy of our filtering technique on the quality of the translation models. We submitted the model in (i) as our secondary system for this task.

5.2.2 Models on filtered data only

To evaluate the effect of the filtered data on the quality of the translation output, we train M2M models on the filtered data from the different models using a threshold of 0.5 and 0.7.

5.2.3 Models on filtered and clean data

We went further to train multilingual models on the concatenation of the noisy and clean text, and on the filtered and clean data for easier comparison. With this system, we were able to measure the amount of improvement we can obtain by including the clean bitext compared to training models only on the filtered bitext.

6 Results and Discussion

In Tables 6 and 7, we report the BLEU and CHRF scores obtained by the different models that we trained, as evaluated on the FLORES-101 devtest and MAFAND-MT test datasets, respectively.

6.1 Baseline Models

On average, the baseline model trained on the clean bitext performed impressively on the two evaluation datasets, despite the limited dataset size. On MAFAND-MT, the model trained on the clean bitext obtained a higher BLEU score than the model trained on the noisy bitext, and on FLORES-101, the reverse was true. This is likely due to the fact that the MAFAND-MT data is present in the clean

Table 6: Performance of the multilingual model on the **FLORES-101** devtest set, with the maximum BLEU per column in **bold**. x represents African languages.

bitext, and that the noisy bitext contains sentences that were taken from the web, including Wikipedia, which is the source of the FLORES-101 dataset. When we compared the model trained on the clean bitext to the model trained on the noisy bitext, we saw between a +1 and +2 improvement on FLORES-101 and between +5 and +8 improvement on MAFAND-MT for lug, wol, and yor. This confirms not only the importance of the data domain, but also the importance of data quality on the quality of the machine translation output.

After mixing the two datasets, the performance improved over using only the clean bitext by more than 6 BLEU on hau↔eng, and almost 3 BLEU on average across all languages on FLORES. The performance, though, was similar to using only the noisy bitext. On the MAFAND-MT test set, however, the performance deteriorated by almost 2 BLEU when compared to training on the clean bitext only. At language-pair level, eng→ibo was affected more (−9.14 BLEU), followed by eng→wol, whereas yor→eng benefited tremendously (+17.83 BLEU). On average, training on the two bitexts marginally improves over using only the noisy bitext, and this is consistent on all the test sets.

Investigating the results in more depth, we found that the BLEU scores of the models are lower when translating into an African language, similar to the findings of Adelani et al. (2022a). This effect is exacerbated for the languages with the fewest parallel sentences, such as lug, wol, and yor, except for ibo, which overall has the second-fewest parallel sentences, as shown in Table 9.

6.2 Data Filtering Analysis

We generally see that more filtering results in improved performance, corresponding to removing more noisy sentences from the data. Using less filtering, with a threshold of 0.5, generally performed slightly worse than using a threshold of 0.7. Both of these settings outperformed (a) using no filtering and (b) using no additional data.

We can also see the effect of the filtering steps on the training data in Tables 2 and 4. Filtering the data using heuristics resulted in only a small portion of the data being filtered out. Using the classifier, however, caused a large amount of noisy data to be removed. When looking at the F1 scores of the classification models, we can see that ALBERT-xlarge has the lowest F1, followed by ALBERT-base and AfroXLMR-base. Looking at Table 5, we can see that ALBERT-xlarge is also the most strict filter, removing the most data, whereas AfroXLMR-base removes the least amount of data. Interestingly, the number of sentences marked as high-quality by all three models is surprisingly low, possibly indicating that these different models (particularly ALBERT-xlarge and AfroXLMR-base) focus on different features of the data.

Finally, we saw that a higher threshold resulted in improved translation performance, but ALBERT-xlarge (which is quite strict) had a lower F1 than the

Table 7: Performance of the multilingual model on the **MAFAND-MT** test set, with the maximum BLEU per column in **bold**. x represents African languages.

other models, possibly suggesting that F1 performance does not fully indicate the expected downstream performance on the actual translation task.

6.2.1 The effect of filtering on translation models

We fine-tune M2M-100 for multilingual translation on the filtered data, and as expected, our results (on average) demonstrate a considerable improvement when the translation model is trained on the filtered data rather than the original noisy texts. In particular, for many languages, training on the filtered data from ALBERT-xlarge with a threshold of 0.7 outperformed the model trained on just the noisy bitext with at least a BLEU point.

Furthermore, we compared the performance of the model trained on only the clean data and on only the filtered data. Just as we saw with the baseline system, on MAFAND-MT, the model trained on the clean bitext performed better than the model trained on the filtered bitext, and on FLORES-101, the reverse was true. These results again confirm the importance of the filtering approach and further supports the observation that NMT engines are less robust to noise as found by Khayrallah and Koehn (2018), especially for low-resource settings.

6.3 Clean vs. filtered data

We find that on FLORES-101, adding in noisy, unfiltered data improves the results over just using the true parallel data. On MAFAND-MT, however, it generally reduces the BLEU score significantly. For both datasets, adding appropriately filtered data results in the highest performance averaged over all the languages, although for some specific languages, just using true parallel data resulted in the best performance.

Our performance on the test set provided by the organizers (Adelani et al., 2022b) is shown in Table 8. Here we can see that our primary model, which was trained on the clean bitext as well as the filtered data (filtered using ALBERT-xlarge, $t = 0.7$), significantly outperforms the model trained only on the clean bitext. We also see that our approach seems to have a larger performance gain when translating *from* African languages compared to translating *to* them.

7 Conclusion and Future Work

In this work, we used a sentence-pair classifier to classify parallel data as being aligned, or not. Using this approach, we filtered out a large portion of the original, noisy, data and fine-tuned existing large language models on this new data. Our results show that training on the filtered data significantly increases the performance of the models, resulting in improved translations. In particular, our approach outperforms (i) training only on clean data, (ii) training only on filtered data, and (iii) training on the original dataset, consisting of clean and noisy data. This provides additional evidence in favor of prioritizing data quality over quantity, as well as the need for more advanced noise detection

Table 8: Performance of the submitted models on the wmt22 test sets as provided by the organizers. We submitted two models. The primary one, denoted *Filtered + Clean*, was trained on the clean bitext as well as the data filtered by ALBERT-xlarge with a threshold of 0.7. The secondary (or contrastive) approach, denoted *Clean only*, was trained only on the clean bitext. The $x \rightarrow$ afr and afr $\rightarrow x$ columns contain the average performance for translations to and from African languages, respectively. *avg* contains the average over all language pairs.

and filtering tools. There are numerous potential avenues for future work; one option is to use a multilingual model as the sentence classifier instead of using a separate model per language, to leverage commonalities between different languages (Adelani et al., 2021b; Conneau et al., 2020). Secondly, a more in-depth study of the effect of the threshold parameter on the final BLEU score would be useful. We would also like to understand the reasons behind the performance by analyzing the filtered data more in depth. Finally, given more computational resources, we will (i) train the classifier for more epochs, using other language models and/or using different quality thresholds, (ii) use longer sentence length than the current 128, (iii) train the translation models on AfroXLMR and ALBERT-base filtered data, and (iv) use the filtering approach on more languages, to evaluate its generalizability. Ultimately, we hope that this filtering approach could lead to the use of cleaner data to train translation models, improving the overall translation quality for low-resourced languages.

Acknowledgements

Idris Abdulmumin acknowledges funding from Google through the Africa Travel Grants. Computations were performed using High Performance Computing infrastructure provided by the Mathematical Sciences Support unit at the University of the Witwatersrand, LIAAD INESC TEC, Portugal, and DFKI GmbH. We acknowledge support from the Machine Learning Group, EISLAB, Luleå University of Science and Technology, Sweden. In addition, we thank the organizers for the compute grant, which allowed us to run some of our experiments. Finally, we thank Dr. Rachel Bawden, and the anonymous reviewers of the 2022 WMT shared task for their helpful feedback. We also acknowledge the useful inputs of Julia Kreutzer and Angela Fan.

Language Adapters for Large-Scale MT: The GMU System for the WMT 2022 Large-Scale Machine Translation Evaluation for African Languages Shared Task

Md Mahfuz Ibn Alam Antonios Anastasopoulos
Department of Computer Science, George Mason University
{malam21,antonis}@gmu.edu

Abstract

This report describes GMU's machine translation systems for the WMT22 shared task on large-scale machine translation evaluation for African languages (Adelani et al., 2022b). We participated in the constrained translation track where only the data listed on the shared task page were allowed, including submissions accepted to the Data track. Our approach uses models initialized with DeltaLM, a generic pre-trained multilingual encoder-decoder model, and fine-tuned correspondingly with the allowed data sources. Our best submission incorporates language family and language-specific adapter units; ranking ranked second under the constrained setting.

1 Introduction

There has traditionally been a significant concentration of machine translation research on a few languages - usually Indo-European (Blasi et al., 2022). Data scarcity has hindered the progress of many languages, many with millions of speakers (Joshi et al., 2020). The shared task and our submission aim to reverse the trend by focusing on low-resource African languages that have been traditionally ignored by mainstream research.

Our submission leverages different approaches to produce a multilingual MT system that can handle all 26 languages covered by the shared task:

- All data available under the constrained setting,
- Delta-LM (Ma et al., 2021), a pre-trained multilingual encoder-decoder model,
- adapter units (Houlsby et al., 2019) are designed to adapt the multilingual model to specific language pairs, and
- phylogeny-inspired organization of the adapters (Faisal and Anastasopoulos, 2022), which allows for information sharing across similar (related) languages.

We expand on each of these components in our system description and the related work section.

Our DeltaLM model was fine-tuned in the first step using parallel data collected from all 26 languages. After fine-tuning the previous model, we adapter-tune the language-specific adapters. Our third step is to adapter-tune the family-specific and sub-family-specific adapters based on the previous adapter-tune model. We submit the second and third models as our submissions to the shared task.

2 Data

Data Sources We use bilingual data from multiple sources. Our main source was the OPUS-100[1] website and Shared Task[2] website. The datasets are:

- ELRC, KDE4, OpenSubtitles, GlobalVoices, Tanzil, EUbookshop, Europarl, infopankki, memat, Tatoeba, Wikimedia) (Tiedemann, 2012),
- MultiCCAligned, CCAligned (El-Kishky et al., 2020),
- WikiMatrix (Schwenk et al., 2019a),
- QED (Abdelali et al., 2014), bible (Christodouloupoulos and Steedman, 2015),
- CCMatrix (Schwenk et al., 2019b),
- TED (Reimers and Gurevych, 2020),
- ParaCrawl (Bañón et al., 2020),
- NLLB Crawled Data (NLLB Team et al., 2022),
- LAVA corpus,[3]
- MAFAND-MT[4] (Adelani et al., 2022a),

(a) Bilingual data statistics of the 26 languages for fine-tuning. The columns indicate the size of data for each language in comparison to the remaining 25 languages.

(b) Data-set statistics of the bilingual data of the 100 language pairs for adapter-tuning.

Figure 1: Data statistics for fine-tuning (left) and adapter-tuning (right). Training data size is logarithmically transformed (base 10) for better visualization.

- WebCrawl African[5] (Vegi et al., 2022),
- KenTrans[6] (Wanjawa et al., 2022).

Figure 1(a) shows the data-statistics of the bilingual data for 26 languages. We use these data to fine-tune the DeltaLM model at first. Figure 1(b) shows the data statistics of the bilingual data for 100 language pairs. We use these data to adapter-tune the fine-tuned model at first for language adapters and then for family and sub-family adapters.

2.1 Data Pre-Processing

Filtering We removed sentences longer than 768 words and shorter than five words. We removed sentences where the whole sentence was made of punctuation. After that, we removed duplicate sentence pairs from the whole data set.

Tokenization After data filtering, we used the SentencePiece model (Kudo and Richardson, 2018) to tokenize all raw training and validation datasets. We keep the SentencePiece model consistent with the one used for DeltaLM.

Use in Training We shuffled the whole training dataset before launching the fine-tuning of multilingual models. Our multilingual model was then fine-tuned on the entire dataset; note that the dataset is potentially noisy as we have not removed any sentence pairs which have potentially incorrect language identification or character encoding. Each source sentence was prefixed with a tag to indicate the target language. For example, the English source sentence `"I love MT"` would be changed to `"<am> I love MT"` to translate into Amharic.

3 Model and Training

3.1 Initialization with DeltaLM

We have based all our experiments on the DeltaLM_large architecture, which consists of 24 Transformer encoder layers and 12 interleaved decoder layers with embedding sizes of 1024, dropouts of 0.1, feed-forward networks of 4096, and attention heads of 16. We directly initialize our model with the publicly available DeltaLM_large checkpoint.

3.2 Multilingual Fine-tuning

Given training data as bi-text corpora $D_b = \{D_b^1, D_b^2, ..., D_b^n\}$, where n is the number of different translation directions. For 26 languages n is 625. We mix all corpora of all directions and shuffle the whole data $D_b^{1...n}$. Then we optimize the model's parameters θ using the standard NLL objective:

$$L_{MT} = E_{\mathbf{x},\mathbf{y} \epsilon D_b^{1...n}}[-logP(\mathbf{y}|\mathbf{x};\theta)]$$

Where $\mathbf{x}, \mathbf{y}$ denotes a sentence pair. $L_M T$ is the translation objective for the multilingual model. We refer to this model as "Fine-Tune" for the remainder of the paper.

[6] https://dataverse.harvard.edu/dataset.xhtml?persistentId=doi:10.7910/DVN/NOAT0W

3.3 Multilingual Adapter-tuning

Adapter Units Between the layers of the pre-trained network, we have added lightweight adapter layers and fine-tuned them using the same corpus as above. In each adapter, an up projection to the starting dimension follows a down projection to a bottleneck dimension (Philip et al., 2020). The bottleneck keeps the number of parameters of the adapter module at a limit. A residual connection coupled with a near-identity initialization enables a pass-through and allows us to maintain the parent model's performance while training the adapter units.

The training data is also the bi-text corpora $D_b = \{D_b^1, D_b^2, ..., D_b^{100}\}$ for the 100 language directions specified by the shared task evaluation schema. We trained the multilingual model as before, but now training only the parameters of the adapters $\theta_{Adapter}$:

$$L_{MT} = \sum_{i=1}^{100} E_{\mathbf{x},\mathbf{y}\in D_b^i}[-logP(\mathbf{x}|\mathbf{y};\theta_{Adapter})]$$

where $\theta_{Adapter}$ are the parameters of the adapters only; i denotes the language direction. In this stage, we add language-specific adapters as shown in Figure 2(a) to every layer of the encoder and decoder. The adapters of the same language on the encoder and decoder side do not share parameters. We refer to this model as "Language-Tune".

Family-specific Adapter In this stage, we add family-specific and genus-specific adapters along with language-specific adapters as a stack, as shown in Figure 2(b), to every layer of the encoder and decoder. The adapters on the encoder and decoder side of the same language, family, and sub-family do not share parameters. But for languages that belong in the same family or genus (group), their family and genus adapters are shared. For example, the Afro-Asiatic family adapter is shared between Hausa, Amharic, Oromo, and Somali, and Oromo and Somali also share the Cushitic adapter. The training data and optimization objective is the same as above.

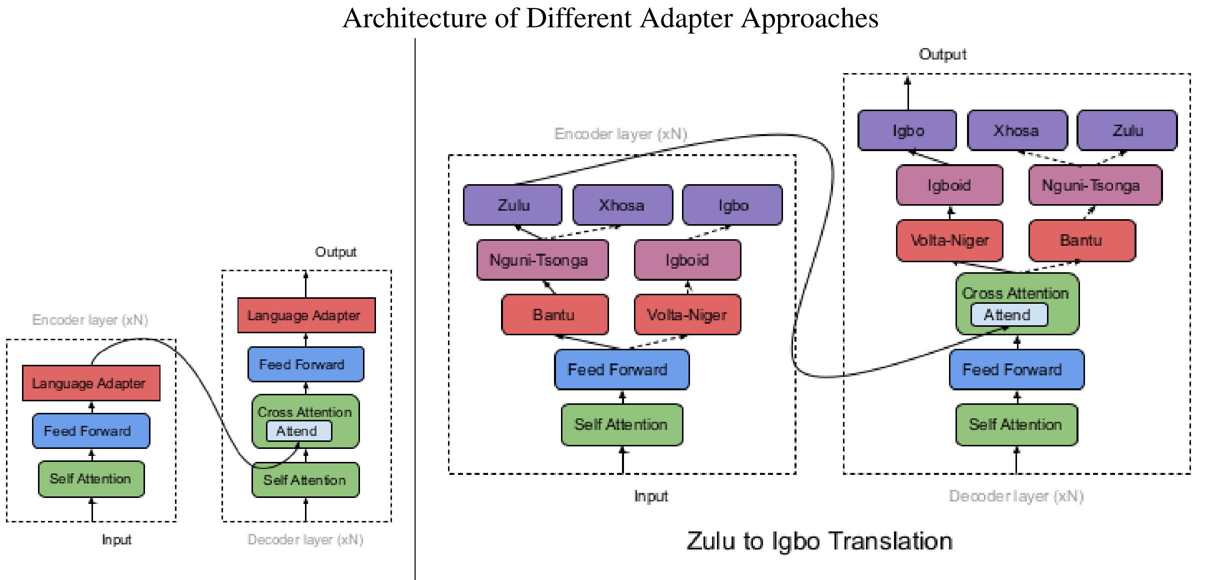
Table 1 shows the phylogeny-informed tree-hierarchy of all 26 languages. On the encoder side, only adapters associated with the source language are active for a specific language direction. On the decoder side, the adapters associated with the target language get active. For example, when training (or translating) from Nigerian Fulfulde to Xhosa, the `Senegambian`, `Fula`, and `Nigerian Fulfulde` adapters will be used on the encoder side, and the `Bantu`, `Nguni-Tsonga`, and `Xhosa` adapters will be used on the decoder side. The resulting model will be referred to as "Family-Tune" for the rest of the paper.

Family	Genus (Group)	Language
Indo-European	Germanic	English Afrikaans
	Romance	French
Afro-Asiatic	Hausa	Hausa
	Amharic	Amharic
	Cushitic	Oromo
	Cushitic	Somali
Nilo-Saharan	Luo	Luo
Senegambian	Wolof	Wolof
	Fula	Nigerian Fulfulde
Volta-Niger	Igboid	Igbo
	Yoruboid	Yoruba
Bantu	Bangi	Lingala
	Shona	Shona
	Nyasa	Chichewa
	Umbundu	Umbundu
	Sotho-Tswana	Tswana
		Northern Sotho
	Nguni-Tsonga	Zulu
		Xhosa
		Swati
		Xitsonga
	Northeast-Bantu	Kamba
		Swahili
		Kinyarwanda
		Luganda

Table 1: The phylogeny-informed language tree hierarchy that we impose on our language adapters.

3.4 Training Details

Fine-Tuning We train multilingual models with the Adam optimizer (Kingma and Ba, 2014) ($\beta1 = 0.9$, $\beta2 = 0.98$). The learning rate is set as 1e-4 with a warm-up step of 4000. The models are trained with label smoothing with a ratio of 0.1. All experiments are conducted on 4 A100 GPUs. The batch size is 1536 tokens per GPU, and the model is updated every 4 (for 4 A100 GPUs) steps



(a) Language-specific Adapter

(b) Family, Sub-family and Language-specific Adapter

Figure 2: Current practice uses language-specific adapters between layers (a). In order to incorporate linguistic information into our models, we impose phylogenetic tree hierarchies based on phylogeny, as in (b), where the solid line shows the path the model has to take for Zulu to Igbo translation, and dotted lines show other possible paths for different language pairs.

to simulate a larger batch size. We have kept the max source and target positions as 512 and have skipped any inputs that have invalid sizes.

Adapter-Tuning We use the same parameters as above. As we do not use the whole dataset to train but data of each language direction, we set the warm-up step as 1000. We train the model for a maximum of 5 epochs or a maximum of 20000 updates (whichever comes first). The dimension of the bottleneck layer of the adapter on both the encoder and decoder sides is set to 64.

Language-Specific We add language adapters to DeltaLM and train only the adapters and keep all other parameters frozen.

Family-Specific We add family and sub-family adapters to DeltaLM where language adapters have already been inserted. We train only the family and sub-family adapters and keep all other parameters frozen, including the language adapters.

4 Evaluation Results

We use the dev and the hidden test set of the FLORES200 (Guzmán et al., 2019; Goyal et al., 2021; NLLB Team et al., 2022) benchmark as our validation set and test set respectively. A beam search strategy with a beam size of 5 is used during inference in order to generate target sentences. Based on the loss on the validation set, we select the best checkpoint for evaluation. We report BLEU, CHRF++, and SentencePiece-based BLEU using spBLEU scores.

Our model using language-specific adapters significantly outperforms the fine-tuning model. Table 2 shows that the model with language-specific adapters outperforms the fine-tuning model on average for all directions from 0.2 to 0.6 BLEU points. Our work solidifies the argument made in previous work that some language-specific elements help the model to better model each language.

Our model with family-specific adapters does not seem to outperform the language-specific adapters on average. But we do obtain some gains for **Avg**$_{X\rightarrow eng}$ and **Avg**$_{fra\rightarrow Y}$. Going deeper to the results, we do find significant gains for some individual language pairs: for instance, for Tswana-English (tsn-eng) we obtain a 1.0 BLEU point gain, and for English-Hausa (eng-hau) this model is better by 1.2 BLEU points.

Table 3 shows that our model with language-specific adapters also achieves better results than the fine-tuning model for different regions of African to African language pairs. We were able to gain BLEU points from 0.1 to 0.25 on average. For family-specific adapters, we see some gains for some regions like Nigeria and for translating between regions.

Metrics	Models	**Avg**$_{all}$	**Avg**$_{X\rightarrow eng}$	**Avg**$_{eng\rightarrow X}$	**Avg**$_{African\rightarrow African}$	**Avg**$_{Y\rightarrow fra}$	**Avg**$_{fra\rightarrow Y}$
BLEU	Fine-Tune	13.00	25.44	11.62	7.57	20.28	10.03
	Language-Tune	**13.28**	25.83	**12.00**	**7.70**	**20.83**	10.53
	Family-Tune	13.28	**25.88**	11.98	7.68	20.73	**10.75**
CHRF++	Fine-Tune	34.80	45.82	34.52	29.56	41.55	31.85
	Language-Tune	**35.42**	46.50	**35.33**	**29.94**	**42.45**	33.58
	Family-Tune	35.42	**46.55**	35.30	29.92	42.30	**34.03**

	Language-Tune	**16.23**	27.97	**15.24**	**10.85**	**24.30**	13.55
	Family-Tune	16.20	**28.00**	15.12	10.82	24.28	**13.65**

Table 2: Evaluation results of Constrained Track for our methods of 100 language directions on the hidden test set of the FLORES-200 benchmark. **Avg**$_{X\rightarrow eng}$ denotes the average score of directions between other languages and English. **Avg**$_{eng\rightarrow X}$ denotes the average score of directions between English and other languages. **Avg**$_{African\rightarrow African}$ denotes the average score of directions between African languages to other African languages. **Avg**$_{Y\rightarrow fra}$ denotes the average score of directions between other languages and French. **Avg**$_{fra\rightarrow Y}$ denotes the average score of directions between French and other languages. **Avg**$_{all}$ denotes the average result of all translation directions.

Tables 5, 6, and 7 show the complete results on all 100 language pairs tested on devtest, hidden test and on the TICO-19 (Anastasopoulos et al., 2020) dataset.

Discussion on Pre-training Membership Among the 24 African languages, only 7 of them (Afrikaans, Amharic, Hausa, Oromo, Somali, Swahili, and Xhosa) were used in the pre-training of the DeltaLM model. As previous work has shown (Muller et al., 2021), models tend to perform worse for languages not included in pre-training. Nevertheless, our model is still competitive; we attribute this to the fact that we have used any dataset that we could get our hands on from the OPUS website discarding the fact that these data may be noisy or may have high domain mismatch.

Table 4 shows the result between languages present in the pre-training of DeltaLM vs languages not present. For all averages, we see the same trend as adapter-tuning is better than the fine-tuned model. Between non-present languages (npl) and present languages (pl) we see **Avg**$_{npl}$, **Avg**$_{pl}$, **Avg**$_{npl-source}$ and **Avg**$_{pl-source}$ shows the same pattern where the present languages have higher scores than the non-present languages. But we see the opposite pattern for **Avg**$_{npl-target}$ and **Avg**$_{pl-target}$ where the present languages have lower average.

Limitations One glaring limitation of our approach is that it is not making use of the potentially large amounts of monolingual data in the languages, e.g. through back-translation (Sennrich et al., 2016). In our training, we have not used any monolingual data at all. Monolingual data are more available than parallel data and are less noisy. We could have used monolingual data to pre-train the DeltaLM with the span corruption objective. We could then use that pre-trained model as our base model to fine-tune using the parallel data. We could also do iterative back-translation using the monolingual data to create synthetic parallel data and train the model with these data along with the real parallel data. This approach has proven to be effective for low-resourced settings before, and we will further explore it in future work.

In addition, our phylogeny-inspired adaptors follow a pre-defined path along the trees. This is perhaps too rigid, especially for communities that use a lot of code-switching, or for creole languages and pidgins that are the result of language contact. In future work, we will explore ways to *learn* the path through the tree, or allow for soft sharing of parameters through attention or mixture of experts units.

5 Related Work

Multilingual neural machine translation (Dong et al., 2015; Johnson et al., 2016; Arivazhagan et al., 2019; Dabre et al., 2020; Philip et al., 2020; Lin et al., 2021) is now the de facto architecture because of its ability to produce translations between

multiple languages. This is because there are thousands of languages worldwide, and if we were to make bilingual models, we would need thousands of models to represent all the languages. This is not ideal because it is neither scalable nor adaptable. Various research tries to improve the performance of multilingual translation models. Either through various training methods (Aharoni et al., 2019; Wang et al., 2020), model structures (Wang et al., 2018; Gong et al., 2021; Zhang et al., 2021), or data augmentation (Tan et al., 2019; Pan et al., 2021). The M2M model (Fan et al., 2020) utilizes large-scale data derived from the web and explores the techniques for enlarging the model and effectively training it.

Multilingual pre-trained language models like mBART (Liu et al., 2020) which pre-trains a multilingual model with the multilingual denoising objective, have proven to be effective in improving multilingual machine translation. These pre-trained models also have drawbacks, like adapting to new languages not seen during pre-training.

Adapters (Houlsby et al., 2019) are designed to adapt a large pre-trained model to a downstream task with lightweight residual layers (Rebuffi et al., 2018) that are inserted into each layer of the model. As part of machine translation, Bapna et al. (2019) proposed bilingual adapters to improve pre-trained multilingual machine translation models or to adapt them to domains. Philip et al. (2020) designed language-specific adapters to improve zero-shot machine translation. Finally, Stickland et al. (2020) use language-agnostic task adapters for fine-tuning BART and mBART to bilingual and multilingual MT. Faisal and Anastasopoulos (2022) imposes a phylogeny-informed tree hierarchy over adapters, leading to improved zero-shot performance for languages unseen during pre-training in tasks like dependency parsing. Our work, in contrast to previous ones, uses the family-specific and genus-specific adapters on top of language-specific adapters as a stack for encoder-decoder models and for generation tasks like machine translation, to leverage the idea that languages in the same family should have similar traits. This may aid languages with very little parallel corpora which may be related to other languages with more resources.

6 Conclusion

This paper describes GMU's submission to the large-scale machine translation for African languages of the WMT22 shared task. Here we explore if pre-trained models can be useful even for languages on which they have not been pre-trained. Our multilingual adapter-tuning translation model, built on DeltaLM, achieves substantial improvements over simply fine-tuning DeltaLM. We further try to enhance the model performance with adapter-tuning using phylogeny information. As a result, our submitted systems rank third on the data-constrained track.

Table 4: Evaluation results of Constrained Track for our methods of languages present in the pre-training of DeltaLM vs languages not present. **Avg**$_{npl}$ denotes the average score of language directions where no language was present in the pre-training of DeltaLM. **Avg**$_{pl}$ denotes the average score of language directions where at least one language was present in the pre-training of DeltaLM. **Avg**$_{npl-source}$ denotes the average score of language directions where the source language was not present in the pre-training of DeltaLM. **Avg**$_{pl-source}$ denotes the average score of language directions where the source language was present in the pre-training of DeltaLM. **Avg**$_{npl-target}$ denotes the average score of language directions where the target language was not present in the pre-training of DeltaLM. **Avg**$_{pl-target}$ denotes the average score of language directions where the target language was present in the pre-training of DeltaLM.

Abstract

This paper describes the submission of the joint Samsung Research Philippines - Datasaur AI team for the WMT22 Large Scale Multilingual African Translation shared task. We approach the contest as a way to explore task composition as a solution for low-resource multilingual translation, using adapter fusion to combine multiple task adapters that learn subsets of the total translation pairs. Our final model shows performance improvements in 32 out of the 44 translation directions that we participate in when compared to a single model system trained on multiple directions at once.

1 Introduction

In this paper, we describe two systems that we submit to the WMT22 Large Scale Multilingual African Translation shared task: a baseline finetuned MT5 (Xue et al., 2020) model trained on multiple directions at once (referred to as `SRPH-DAI-Baseline`), and an MT5 model successively finetuned with task composition using multiple pair-specific adapters (referred to as `SRPH-DAI-Fusion`).

We first outline the preprocessing steps and filtering heuristics used to clean the contest dataset, then we show the training setup and experimental design used for constructing our submitted systems. We then report our results on the hidden test set via BLEU, spBLEU, and CHRF2++ automatic evaluation metrics.

2 Preprocessing

In this section, we detail the preprocessing steps used to filter the contest dataset to ensure that data quality is as high as possible.

Given that the contest dataset contains sentence pairs that were artificially aligned from crawled data, we use a number of filters to reduce the possibility of mismatched pairs in the final training dataset:

- We filter out pairs where one or both sentences have too few ($<= 3$) or too many ($>= 150$) tokens post-sentencepiece tokenization.
- We remove pairs if one or both sentences have too many repeated ($>= 5$) punctuations or symbols of the same type (e.g. "/////"), or contiguous punctuations/symbols of considerable ($>= 3$) length (e.g. "`word` $&**$").
- We also remove sentence pairs where one sentence has punctuation that is missing from the other (e.g. "`word`!!" → "`word`?").
- If a pair has a sentence where a large percentage of the total characters (total $>= 70\%$) are numbers or punctuations (e.g. "`word` ??! +22 8456 8967"), the pair is dropped.
- An average word length filter is also used to remove pairs where one sentence has words that are disproportionately longer than the words in the corresponding sentence. We get a ratio r by taking the sum of the lengths of each token in a sentence, then dividing it by the number of tokens. We only keep sentence pairs where both sentences have a ratio r within $3 <= r <= 15$.
- HTML and URL-containing sentence pairs are also removed as this contributes to unnecessary noise during training.
- Lastly, we also check for known word matches within each sentence pair. For instance, if we detect a number (e.g. "1" or "one"), we also check the corresponding sentence for the same number. Sentence pairs that have mismatched

Table 1: Final dataset statistics after running the sentence pair filters.

(e.g. source sentence has “1” but target sentence has “11”) words are dropped as these are likely from misaligned data.

After applying the filters for the entire dataset, we perform one deduplication step to ensure that no duplicate entries have been added. No further preprocessing is done on the data itself to preserve as much information within the sentences as possible.

When formatting the data for translation training, we insert a target language token at the beginning of the sentence. For example, a sentence to be translated from English to Afrikaans would look like:

<afr> This is an example sentence.

We only participate in a subset of the shared task’s translation pairs (44 total directions), opting to train only on English → African and African → English pairs due to resource constraints.

3 Experiment Design

In this section, we describe the construction of our two submitted systems: `SRPH-DAI-Baseline` and `SRPH-DAI-Fusion`.

3.1 Common Settings

Both systems use MT5-Small, a Transformer-based (Vaswani et al., 2017) model, as an initialization point. We opted to use the small variant (∼300 million parameters) as opposed to the bigger base (∼580 million) and large (∼1.2 billion) variants due to resource constraints in our setup. We expect the performance of our models to further improve as we scale to larger variants of pretrained models.

As a remedy to constrained resources as well as a way to improve stability during training for low-resource data, we decided to use adapters (Houlsby et al., 2019; Pfeiffer et al., 2020b) instead of fully finetuning all the model parameters.

Before proceeding to training for translation, we first train a language adapter (Pfeiffer et al., 2020b) on English + African languages in order to better condition the MT5 model for the languages it will encounter later. We mimic MT5’s pretraining and use span corruption on the provided monolingual training data for the shared task (which is likewise filtered like our parallel data).

We freeze the pretrained weights and train the adapter for a total of 150K steps using the Adafactor (Shazeer and Stern, 2018) optimizer, utilizing a learning rate schedule that warms up for the first 10K steps to a maximum of $1e-4$, then linearly decaying after. We use a maximum sequence length of 512 for language adapter training, using gradient accumulation to train with a total batch size of 128 sequences per training step. The output language adapter is used in both of our submission systems, and is stacked below the translation task adapter(s).

3.2 Baseline Model

We construct our baseline model `SRPH-DAI-Baseline` by stacking a blank task adapter on top of our language adapter and training it on all 44 translation directions at once. In this setup, the language adapter is frozen. This model is trained for a total of 300K steps on the combined filtered dataset using the Adafactor optimizer. We use a learning rate of $5e-5$ and a weight decay of $1e-8$, warming up for the first 10K steps, then linearly decaying after.

Unlike other systems, we do not perform any other techniques such as backtranslation (Edunov et al., 2018), noisy channel reranking (Yee et al., 2019), or clever pair sampling (Fan et al., 2021) in order to further boost performance. This mimics an "ablation" setup where only the direct finetuning method is used in order to accurately observe the effect of using task composition later on. Since no further modifications are made on the model beyond the training method, any improvements on performance made by task composition can be attributed to task composition and not anything else.

3.3 Exploring Task Composition

In the conventional multidirectional setup like in our baseline, the model learns generic cross-lingual information at the same time that it learns task-specific information. Learning cross-lingual information is useful in cases where a number of the languages in the model are similar or come from the same family (Saleh et al., 2021; Siddhant et al., 2022). However, in cases where a number of the languages are dissimilar or come from different families, we hypothesize that it may be useful to learn cross-lingual information *separately* from task-specific mappings. This ensures that the model learns each translation direction in a non-destructive manner with respect to other language pairs.

In cases where certain language pairs are underrepresented in the training set, learning each direction separately also removes the need for specialized data sampling methods to ensure that the model sees each pair enough times. In addition, using adapters for low-resource pairs also helps prevent overfitting the small dataset (Mao et al., 2021).

Motivated by this, instead of finetuning a task adapter for multiple translation directions, we instead opt to train *multiple* translation task adapters to learn task-specific information, then *composing* the multidirectional setup afterwards via Adapter Fusion (Pfeiffer et al., 2020a) to mix cross-lingual and cross-task information. This is how we construct our SRPH-DAI-Fusion model.

For this setup, we follow the same training routine as in the baseline, except we only train on one language pair at a time. We train an adapter to produce translations for *two* directions: English $\rightarrow X$ and $X \rightarrow$ English. Training in more than one direction ensures that the task adapters learn to properly embed the target language token at the beginning of every sentence. This results in a total of 22 task adapters for each of the 22 English $\rightarrow X$ pairs.

Finally, we add an Adapter Fusion setup for all 22 single-pair task adapters, freeze the adapters,then further finetune the model to learn cross-task and cross-lingual information. We finetune for 100K steps with a learning rate of $2e-5$ using the Adafactor optimizer. Like in previous setups, we also use a warmup of 10K steps with a linear decay afterwards.

4 Results

We outline the performance of our two models on the hidden test set on Table 2.

Overall, SRPH-DAI-Fusion outperforms SRPH-DAI-Base on average across all three metrics, with an improvement of 0.09, 0.19, and 1.33 on average BLEU, spBLEU, and CHRF2++, respectively. Both models perform relatively better on the African to English translation directions compared to the English to African ones. We hypothesize that this is likely due to English being a pivot language, and thus cross-lingual and cross-task information learned while training each pair contributed to better performance when translating into English.

When comparing the two models, we note an "improvement" in the performance if at least two of the three metrics had an increase in score. We observe that 32 out of the 44 translation directions had an improvement once task composition was used for finetuning, most of which are very low-resource pairs. Best gains are observed in the English to African translation directions, with some pairs such as Eng $\rightarrow$ Orm improving from an initial 0 score from the baseline model.

We observe that SRPH-DAI-Base outperforms the task composition model in cases where there is a relative abundance of training data. For pairs that have sub-million examples, SRPH-DAI-Fusion performs much better, likely due to the model being able to learn more specialized information about these translation directions separate from the other directions.

Interestingly, we observe that for language pairs with a relative abundance of data, the drop in performance when using task composition is substantial. For example, Afr $\rightarrow$ Eng suffers a 2.2, 2, and 4.2 points drop in BLEU, spBLEU, and CHRF2++, respectively. We hypothesize that this is because SRPH-DAI-Fusion has more intact task-specific knowledge related to low-resource pairs that may not be useful to the higher-resourced pairs. Since task adapters are frozen during fusion layer training, the model has an added burden in learning how to adapt knowledge that may not be useful when translating higher-resourced translation directions.

5 Conclusion

In this paper, we described our submissions for the WMT22 Large Scale Multilingual African Translation shared task. We approached the contest as a way to explore task composition as a solution for multilingual translation, especially among low-resource languages. In our experiments, we show that using task composition – training task adapters to learn pair-specific knowledge, then using a fusion layer to learn cross-task information – improves performance for less-represented language pairs in a multilingual translation dataset. While the model's results for a number of translation directions are far from state-of-the-art, the results show the methodology's promise for further exploration.

For future work, we would like to conduct experiments for larger models than is constrained by our resources. We expect that using Base and Large variants of MT5 would further improve performance for all language pairs. In addition, it would be beneficial to test the methodology while adding in common "best practices" in translation such as using backtranslated data and better data sampling. Lastly, we would like to explore setups where the pair-specific task adapters are *transformable* to some extent instead of being fully frozen as a remedy to the problem of higher-resourced pairs performing worse in the task composition setup.

University of Cape Town's WMT22 System: Multilingual Machine Translation for Southern African Languages

Khalid N. Elmadani Francois Meyer Jan Buys
Department of Computer Science
University of Cape Town
{ahmkha009,myrfra008}@myuct.ac.za, jbuys@cs.uct.ac.za

Abstract

The paper describes the University of Cape Town's submission to the constrained track of the WMT22 Shared Task: Large-Scale Machine Translation Evaluation for African Languages. Our system is a single multilingual translation model that translates between English and 8 South / South East African Languages, as well as between specific pairs of the African languages. We used several techniques suited for low-resource machine translation (MT), including overlap BPE, back-translation, synthetic training data generation, and adding more translation directions during training. Our results show the value of these techniques, especially for directions where very little or no bilingual training data is available.[1]

1 Introduction

Southern African languages are underrepresented in NLP research, in part because most of them are low-resource languages: It is not always possible to find high-quality datasets that are large enough to train effective deep learning models (Kreutzer et al., 2021). The WMT22 Shared Task on Large-Scale Machine Translation Evaluation for African Languages (Adelani et al., 2022) presented an opportunity to apply one of the most promising recent developments in NLP — multilingual neural machine translation — to Southern African languages. For many languages, the parallel corpora released for the shared task are the largest publicly available datasets yet. For some translation directions (e.g. between Southern African languages), no parallel corpora were previously available.

In this paper we present our submission to the shared task. Our system is a Transformer-based encoder-decoder (Vaswani et al., 2017) that translates between English and 8 South / South East African languages (Afrikaans, Northern Sotho, Shona, Swati, Tswana, Xhosa, Xitsonga, Zulu) and in 8 additional directions (Xhosa to Zulu, Zulu to Shona, Shona to Afrikaans, Afrikaans to Swati, Swati to Tswana, Tswana to Xitsonga, Xitsonga to Northern Sotho, Northern Sotho to Xhosa). We trained a single model with shared encoder and decoder parameters and a shared subword vocabulary.

We applied several methods aimed at improving translation performance in a low-resource setting. We experimented with BPE (Sennrich et al., 2016b) and overlap BPE (Patil et al., 2022), the latter of which increases the representation of low-resource language tokens in the shared subword vocabulary. We used initial multilingual and bilingual models to generate back-translated sentences (Sennrich et al., 2016a) for subsequent training.

First, we trained a model to translate between English and the 8 Southern African languages. Then we added the 8 additional translation directions and continued training. For some of these additional directions no parallel corpora were available, so we generated synthetic training data with our existing model. By downsampling some of the parallel corpora to ensure a balanced dataset, we were able to train our model effectively in the new directions, while retaining performance in the old directions.

We describe the development of our model and report translation performance at each training stage. Our final results compare favourably to existing works with overlapping translation directions. While there is considerable disparity in performance across languages, our model nonetheless achieves results that indicate some degree of effective MT across all directions (most BLEU scores are above 10 and most chrF++ scores are above 40). We also discuss our findings regarding techniques for low-resource MT. We found overlap BPE and back-translation to improve performance for most translation directions. Furthermore, our results confirm the value of multilingual models, which proves critical for the lowest-resource languages.

2 Background

2.1 Multilingual Neural Machine Translation (MNMT)

Multilingual models help low-resource languages (LRLs) by leveraging the massive amount of training data available in high-resource languages (HRLs) (Aharoni et al., 2019; Zhang et al., 2020). In the context of Neural Machine Translation, a multilingual model can translate between more than two languages. Current research in MNMT can be divided into two main areas: training language-specific parameters (Kim et al., 2019; Philip et al., 2020) and training a single massive model that shares all parameters among all languages (Fan et al., 2020; NLLB Team et al., 2022). Our work lies in the second category, as we are building a single multilingual translation system by exploring back-translation and different vocabulary generation approaches.

2.2 Back-Translation

Given parallel sentences in two languages A and B (A_b, B_a), with goal of training a model that translates sentences from A to B ($A \rightarrow B$). Back-translation works as follows: First, one trains a ($B \rightarrow A$) model using the available (A_b, B_a) data. Then the B_a sentences are passed to the model to regenerate A_b. This model's output (A'_b) is then considered as additional synthetic parallel data (A'_b, B_a). The final step of back-translation is training an ($A \rightarrow B$) translation model using (A'_b, B_a) as parallel data. The motivation behind back-translation is that the noise added to the A'_b sentences from regeneration increases the model's robustness (Edunov et al., 2018). The same approach can be extended to multilingual models (Liao et al., 2021).

2.3 Overlap-based BPE (OBPE)

Byte Pair Encoding (BPE) is a vocabulary creation method that relies on n-gram frequency (Sennrich et al., 2016b). The starting point is a character-based vocabulary. At each step, the BPE algorithm identifies the two adjacent tokens with the highest frequency, joins them together as a single token, and adds the new token to the vocabulary. The dataset is then restructured based on the expanded vocabulary. In the case of multilingual training, a single BPE vocabulary can handle all languages by running the BPE algorithm on the union of the data from all the languages. However, when constructing a multilingual vocabulary, BPE will prefer frequent word types, most of which are from HRLs, leaving a smaller proportion of the vocabulary for words from LRLs.

Nguni	Xhosa(xho)	Zulu(zul), Swati(ssw)
Sotho-Tswana	Tswana(tsn)	Sepedi(nso)
Bantu	Shona(sna)	Xitsonga(tso)

Table 2: The languages included in our translation system, grouped by language family and whether they are used as L_{HRL} or L_{LRL} for the OBPE algorithm.

Overlap-based BPE (OBPE) is a modification to the BPE vocabulary creation algorithm which enhances overlap across related languages (Patil et al., 2022). OBPE takes into account the frequency of tokens as well as their existence among different languages. Given a list of HRLs (L_{HRL}) and LRLs (L_{LRL}), OBPE tries to balance cross-lingual sharing (tokens shared between HRLs and LRLs) and individual languages' representation. The optimal OBPE vocabulary for a set of languages from different families is produced by considering the highest resource language from each family as L_{HRL} and the rest of the languages as L_{LRL}.

3 Datasets

The WMT22 dataset is released along with the shared task. It contains bitext for 248 pairs of African languages, referred to as `WMT22_african`.[2] We use `WMT22_african` for both training and validation; the first 3 000 sentences from each language pair is reserved for validation and the rest for training. Table 1 shows available number of sentences for each language pair. No data was provided for Shona-Afrikaans and Afrikaans-Swati, so we generated synthetic data for these translation directions (see section 4.2.1). For testing, we used the Flores dev set, which contains 997 parallel sentences for each language pair. Additionally, we report the results of the final translation system as evaluated by the shared task organizers on a hidden test set.

3.1 OBPE

We trained BPE and OBPE tokenizers using the $eng \leftrightarrow$ LRL data only (the first 8 rows of table 1). The vocabulary size for both BPE and OBPE is set to 40K. For OBPE, the L_{HRL} contains the highest-resource language from each language family (eng, xho, tsn, sna), while L_{LRL} includes the rest of the languages (see table 2). We used Patil et al.'s (2022) implementation for both BPE and OBPE. This implementation is based on the Hugging Face Tokenizers library.[3]

4 Methodology

In this work, we only focus on South and South East African languages, their translation to/from English, and eight translation directions between these languages. We divided the training of the translation system into two stages. In the first stage, we trained a multilingual model for translating from all LRLs to English and vice versa. To incorporate the translation directions between LRLs into the system, we did further training on the translation model from stage 1. We divided the training process into stages instead of training the model in one session due to computational resource constraints. Both stages are explained in more detail below.

All models were trained with the `Fairseq` toolkit (Ott et al., 2019). We used the `transformer-base` architecture (Vaswani et al., 2017) for training all bilingual models. We base the multilingual models on the `BART` architecture (Liu et al., 2020), using Tang et al.'s (2021) implementation and hyperparameters, including adding a token to indicate the source language before the input sentence and a token for the target language before the output sentence.

Table 3: BLEU score differences between the OBPE multilingual model (13th epoch) and the BPE multilingual model (10th epoch) on Flores dev set. We stopped training the BPE model at this point as the OBPE model is computationally more efficient. The translation directions are sorted based on the available amount data.

4.1 Stage 1: Translation Between LRLs and English

We used BPE and OBPE vocabularies to train two multilingual models for all directions between English and LRLs. Bilingual models were trained for each translation direction using a single vocabulary for each model. Finally, we performed back-translation for all directions using the model with the highest BLEU score in each case.

4.1.1 Multilingual Training

Multilingual models generally have more parameters and require more training time and computational resources than bilingual models. Computational constraints prevented us from fully training two multilingual models and then doing back-translation from them. Subsequently we used BPE and OBPE vocabularies to train two multilingual models till the 10th and 13th epochs, respectively. At this point, we found that the difference in trans-

[2] https://huggingface.co/datasets/allenai/wmt22_african

[3] https://huggingface.co/docs/tokenizers

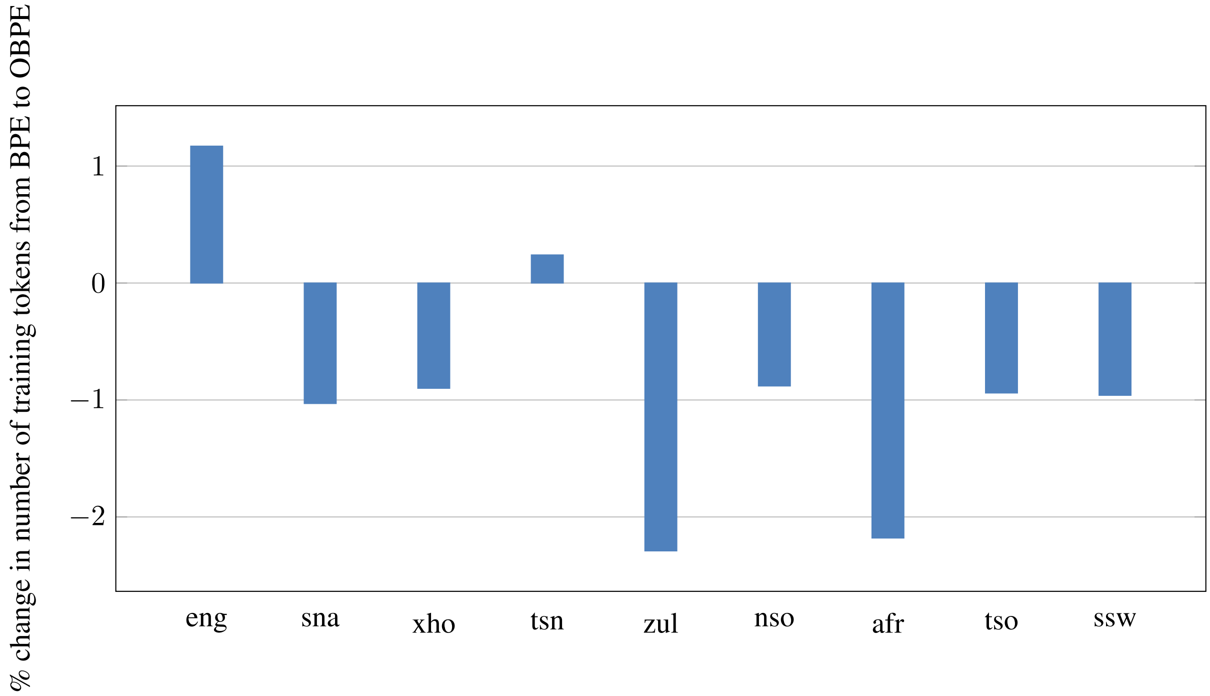

Figure 1: The change in the number of tokens in the training set per language when using OBPE instead of BPE. Less training tokens correspond to better a representation of a language in the shared subword vocabulary, so negative percentage changes reflect an improvement in low-resource language representation.

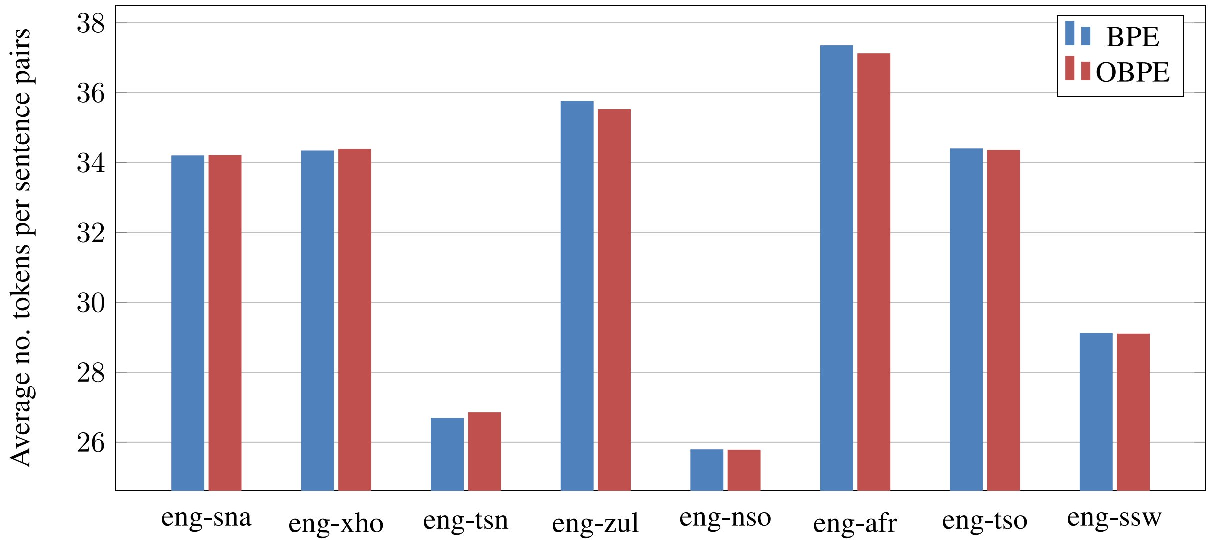

Figure 2: The average number of tokens per sentence pair for all language pairs with English, comparing BPE and OBPE vocabularies. More tokens lead to slower training.

lation quality between the two models is negligible (see table 3). However, the OBPE model is slightly faster in training and represent LRLs better. A language l is represented better in vocabulary V_1 than V_2 if V_1 contains more subword tokens from l than V_2. The total number of tokens in l's training data will influence its representation in the vocabulary. Reducing the number of tokens in the training sentences requires increasing the vocabulary capacity. Therefore, fewer tokens in the training data corresponds to a better vocabulary representation. We are interested in comparing BPE and OBPE's vocabulary representation for all languages. We used the following formula to measure the relative change in the number of training tokens when using OBPE instead of BPE,

$$\text{change}_l = \frac{T^l_{\text{OBPE}} - T^l_{\text{BPE}}}{T^l_{\text{BPE}}}\% \quad (1)$$

where T^l_{BPE} and T^l_{OBPE} are the total number of tokens in language l's training data when using BPE and OBPE vocabularies, respectively. Figure 1 shows the change in number of training tokens for all languages. The negative sign in the figure indicates that OBPE represents the language better than BPE. It can be clearly seen that OBPE represents most LRLs better than BPE.

As we are training autoregressive models, the training speed depends on the number of target tokens, which is controlled by the target language representation in the subword vocabulary. Therefore we use the average number of tokens per training example for each language pair (*eng-l*) as a proxy for training speed. Fewer tokens leads to faster training. Both source and target tokens are included, as we are training the model to translate in both directions:

$$\text{AvgTokens}^V_{eng-l} = \frac{\text{Tok}^l_{eng-l} + \text{Tok}^{eng}_{eng-l}}{N_{eng-l}} \quad (2)$$

where $\text{AvgTokens}^V_{eng-l}$ indicates the average number of tokens in one training example from the $eng - l$ dataset using V vocabulary. Tok^l_{eng-l} and Tok^{eng}_{eng-l} represent the total of l and eng tokens, respectively, in the $eng - l$ dataset, while N_{eng-l} represents the number of training examples in the same dataset. Figure 2 shows the average number of training tokens in each language pair when using BPE and OBPE vocabularies. We observe that training with OBPE is slightly faster than training with BPE. The speed difference is higher for languages that are better represented by OBPE (see figure 1).

For these two reasons, and due to time and resources constrains, we chose to continue with training the OBPE multilingual model only.

4.1.2 Bilingual Training

Multilingual models often harm performance on high-resource languages compared to their bilingual counterparts (Yang et al., 2022). For back-translation, we used bilingual models for the subset of language pairs where this happens. We had two translation directions for each language (from/to English) and two vocabulary options (BPE/OBPE) for each direction. We ended up with 32 bilingual models.

All bilingual models were trained on either an `Nvidia` A100 full card (40GB) or a division of half a card (20GB) for 45 epochs with a batch size of 12 288 tokens. The training time depends on the language pairs, but the highest-resource language pair took three days of training.

4.1.3 Back-Translation

For each translation direction, we choose one of the following models for generating back-translation sentences: OBPE bilingual, BPE bilingual, and the 17th epoch checkpoint from the OBPE multilingual model. The selection is based on the models' performance on the Flores dev set, as measured by their BLEU score. We generated the back-translation sentences from the available parallel data only; no additional monolingual data was used. Results from table 4 show the performance of those three models. It can be seen that bilingual models are performing better in both directions of the higher-resource language pairs and for *eng-afr*. We discuss the results in more details in section 5.

We trained the OBPE multilingual model until the 17th epoch. That checkpoint was then used to generate back-translation data for the directions where the multilingual models outperform bilingual ones. Due to resources and time constraints, we started training the back-translation multilingual model from the 17th epoch checkpoint of the OBPE multilingual model. The OBPE multilingual model continued training regularly from the 17th epoch.

We ran all multilingual experiments on 2 `Nvidia` A100 cards (40GB each). One epoch of back-translation or OBPE multilingual models took 16 hours. Both models trained for 45 epochs with a batch size of 16 384 tokens, leading to a total training time of 30 days for each model.

After training both multilingual models, we had four models for each translation direction; two bilingual and two multilingual models.

4.2 Stage 2: Translation Between LRLs

At this stage we found that our models showed adequate performance in the English-centric directions (similar evaluation scores to existing works with overlapping translation directions). The goal of the next stage was to add new translation directions between specific LRLs. Our best multilingual model at this point (based on BLEU scores in the English-centric directions) was the OBPE-based model that was partially trained on back-translated data. Therefore we selected this model to continue training in the new directions. The model trained for an additional 39 epochs on a training set covering the old and new directions (details in section 4.2.2). This took 9 days on a full `Nvidia` A100 card (40GB), at which point validation performance had stopped improving. This resulting model is the system we submitted to the shared task.

4.2.1 Synthetic training data

As shown in table 1, the translation directions between LRLs (new directions) generally had smaller datasets than the directions from/to English (old directions). In fact, two of the new directions (Shona to Afrikaans and Afrikaans to Swati) had no parallel corpora at all. To add these two directions to the model, we generated partially synthetic training data using the available English-centric parallel corpora. Using our multilingual model, we translated the English sentences in the English-Afrikaans corpus to Shona, and the English sentences in the English-Siswati corpus to Afrikaans. This produced parallel corpora for Shona-Afrikaans and Afrikaans-Siswati, where the target sentences were real and the source sentences were synthetic.

4.2.2 Balancing parallel corpora

The challenge in adding new translation directions is to strike a balance between gaining performance in the new directions, while ensuring that performance in the old directions does not deteriorate in the process. For this stage our model was trained on parallel corpora in the old and new directions. Including training data for the old directions ensures that the model does not lose its translation abilities for these directions. However, the parallel corpora for the old directions are on average much larger than those of the new directions. Therefore training on such an unbalanced dataset would likely result in suboptimal performance for new directions.

To counter this, we downsampled the training data for the old directions to match the corresponding corpora in the new directions in order to balance the model's exposure to the old and new directions during training. For example, to balance Xhosa to Zulu training (1M sentences), we trained on 1M sentences only from both the English to Zulu and the Xhosa to English corpora. Therefore the encoder is trained for Xhosa balancing the Xhosa-English and Xhosa-Zulu data, while the decoder is trained for Zulu balancing the English-Zulu and Xhosa-Zulu setting.

Another potentially better approach is upsampling the training data for new directions. This technique would ensure that the model is exposed to all training data of old directions. However, we did not explore this due to time constraints.

5 Results

We primarily used BLEU score for evaluating all models on the Flores dev set. The final test set evaluation by the shared task organizers additionally used sentence piece BLEU (spBLEU) and chrf2.

5.1 Translation Between English and LRLs

Table 4 shows our results on the translation between English and LRLs. For each translation direction, we selected the best model among the two bilingual models and the 17th epoch checkpoint of the OBPE multilingual to perform back-translation. Although the multilingual model was trained only for 17 epochs, it outperformed the fully trained bilingual models in some language pairs. Most of these pairs are resource-poor ($eng \leftrightarrow nso, tso, ssw$). The exception of this finding was the translations between English and Afrikaans. These two languages are from the same family, so we hypothesize that the bilingual models did not need help from other resource-rich pairs or additional training examples to translate between the two languages. The training data of resource-richer language pairs ($eng \leftrightarrow xho, zul, tsn$) were sufficient to train good bilingual models.

After we fully trained both OBPE and OBPE+back-translation multilingual models, the OBPE model performed better than the

M-OBPE-final is the system we submitted for the shared task. **Bold** represents the best results.

back-translation model in most directions with English as a target language, namely, $sna, tsn, nso, tso, ssw \rightarrow eng$. However, for the three eng generation directions where the back-translation model performed similarly or better than the OBPE model ($xho, zul, afr \rightarrow eng$), the back-translation data was generated from the bilingual models, not the OBPE multilingual model. This synthetic data contains actual English sentences and synthetic LRLs sentences. These translation pairs were relatively resource-rich. In contrast, most of the remaining pairs were resource-poor, and their back-translation data was generated from the partially trained OBPE multilingual model. These results show that although the 17th epoch checkpoint of the OBPE multilingual model was better than bilingual models in resource-poor language pairs, it was not yet good enough for generating text in LRLs. This led to a performance drop for the back-translation model on most of the eng generation directions compared to the OBPE multilingual model.

On the other hand, the back-translation model outperformed the OBPE model in all directions translating into LRLs. These directions require synthetic English sentences and actual LRLs sentences for back-translation. A plausible explanation for this is that learning to translate to English is easier than translating to LRLs for both bilingual and multilingual models.

Table 6: The performance of our final system on the shared task test set. Δ CHRF2++ is the difference between the best submission and our system.

5.2 Translation between LRLs

Table 5 shows the performance of the OBPE+back-translation model before and after continued training for translation between LRLs. The model's performance improved on both the initial language pairs (in table 4) and the new translation directions. Moreover, $sna \rightarrow afr$ and $afr \rightarrow ssw$ were improved using only synthetic data (see section 4.2.1). We ascribe the success in improving the model's performance in translating between English and LRLs to the balancing approach (see section 4.2.2), as we used real training data (not back-translated sentences) in the continued training.

5.3 Official Results

Table 6 shows the results provided by the shared task organizers for our system as evaluated on a hidden test set. The table also compares the best constrained submission for each translation direction and our system. Our model did not achieve the best performance in any direction. However, the teams whose models performed better all trained on all languages included in the shared task (not just Southern African languages).

We hypothesize that this is the main reason for the gap in performance between our system and the better performing ones, as those models could benefit from more training data and increased cross-lingual transfer. The fact that our model performs relatively worse when translating into English provides some evidence for this: the other systems could benefit learning to translate to English in many more translation directions and with much more data in total. Given our computational resources, it would have required a total training time of 106 days to cover all language directions in the shared task. Unfortunately this was not feasible in the time provided for the shared task. The findings paper for the shared task presents more details about other teams' submissions (Adelani et al., 2022).

6 Conclusion

We have presented our multilingual neural MT model for 8 Southern African languages. Until recently, it would not have been possible to train a multilingual model for these languages because of data scarcity. During model development we found the benefits of multilingual modelling to be especially great for the lowest-resourced languages. Our results show that overlap BPE, back-translation, and synthetic training data generation are all valuable techniques for low-resource MT. More generally, we find multilingual modelling to be a fruitful approach to Southern African MT. For future work we would like to investigate further approaches for training large multilingual models for low-resource languages with a limited compute budget.

Abstract

This paper describes Tencent's multilingual machine translation systems for the WMT22 shared task on Large-Scale Machine Translation Evaluation for African Languages. We participated in the **constrained** translation track in which only the data and pretrained models provided by the organizer are allowed. The task is challenging due to three problems, including the absence of training data for some to-be-evaluated language pairs, the uneven optimization of language pairs caused by data imbalance, and the curse of multilinguality. To address these problems, we adopt data augmentation, distributionally robust optimization, and language family grouping, respectively, to develop our multilingual neural machine translation (MNMT) models. Our submissions won the **1st** place on the blind test sets in terms of the automatic evaluation metrics.[1]

1 Introduction

Multilingual neural machine translation (MNMT) aims to translate between multiple language pairs with a unified model (Johnson et al., 2017). It is appealing due to the model efficiency, easy deployment, and knowledge transfer between high resource languages and low resource languages. Hence, MNMT has attracted more and more attention from both academia and industry. To improve the performance of MNMT models, previous researchers have proposed various approaches on advanced model architectures (Sen et al., 2019; Zhang et al., 2021), training strategies (Wang et al., 2020a,b), and data utilization (Siddhant et al., 2020; Wang et al., 2022). In addition, industrial companies have released massive multilingual pretrained models (Tang et al., 2021) and large-scale multilingual translation models (Fan et al., 2021; Team et al., 2022) to facilitate translation among hundreds of languages. However, existing efforts on MNMT for African languages are not sufficient due to the lack of high quality and standardized evaluation benchmarks.

In this paper, we build a system integrating several advanced approaches for WMT22 Large-Scale Machine Translation Evaluation Task (Adelani et al., 2022), which involves a set of 24 African languages. We participated in the Constrained Translation track, where only the data provided by the organizer are allowed. This task is challenging due to three potential problems:

- The absence of training data for some to-be-evaluated language pairs;
- The uneven optimization of language pairs due to data imbalance;
- The curse of multilinguality in MNMT models caused by the hundreds of language pairs.

For the first problem, we adopt data augmentation techniques to construct synthetic data for the language pairs without parallel training data (§3.1). Specifically, we use back-translation (Sennrich et al., 2016) and self-training (Jiao et al., 2021), and attach a special tag to the synthetic side of the data. For the second issue, we utilize distributionally robust optimization (DRO) method (Oren et al., 2019; Zhou et al., 2021) to balance the optimization process for different translation directions (§3.2). For the third issue, we isolate the potential conflicts between language pairs by language family grouping and finetune a model for each language group (§3.3).

Experimental results show that our system can significantly improve the performance of vanilla MNMT models, from 15.50 to 17.95 BLEU points (§4.2). Extensive analysis suggests that data augmentation could be harmful to the translation performance if used for training the final models

directly, due to the error-prone synthetic sentence pairs. Instead, we utilize the resulting MNMT models as pretrained models to further finetune on clean datasets for the final models. The DRO technique is very effective in improving the translation quality across all language pairs, particularly on the dominant languages (e.g., eng and fra), which also calls for an improved DRO to benefit more on other languages. As for language family grouping, it especially improves the translation quality on one-to-many translations, which demonstrates its effectiveness in alleviating the curse of multilinguality issue. Finally, our submission won the **1st** place in the official evaluation in terms of the automatic evaluation metrics.

2 Data

In this section, we present the details of our data preparation.

2.1 Language Pairs

We utilize all available datasets from the official website (including those from the Data Track participants)[2], which provide either monolingual or parallel sentences. According to the evaluation instruction, we group the language pairs into 7 groups, namely, English-Centric (ENGC), French-Centric (FRAC), South/South East Africa (SSEA), Horn of Africa and Central/East Africa (HCEA), Nigeria and Gulf of Guinea (NGG), Central Africa (CA), and Other related pairs (OTHER), to train the MNMT models. Details are listed in Table 1.

We consider three subsets of language pairs for training different models:

- **Base-146**: We train the TRANSF-DEEP (§4.1) models on the to-be-evaluated language pairs in the first 6 groups, as well as the English-French (i.e., eng-fra) pair. In total, there are 81 language pairs but only 73 of them are provided with bitext data, which cover 146 translation directions (i.e., including both forward and backward).

- **Large-234**: The main issues of **Base-146** are that, some to-be-evaluated language pairs (e.g., afr-nso) are missing in the training data and some languages are heavily long-tailed due to the imbalanced choice of language pairs. To alleviate these issues, we extend another 36 language pairs for the long-tail languages and construct synthetic data for all the language pairs in ENGC, SSEA, HCEA, NGG and CA, which enables the training on 234 translation directions. We use these language pairs to train the TRANSF-DWIDE (§4.1) models.

- **Eval-106**: The official evaluation includes 100 translation directions[3], which were notified at the later stage of the competition. We focus on these directions by finetuning the TRANSF-DWIDE models on these directions. To ensure the data amount of each language, we include all ENGC directions, making the final 106 directions.

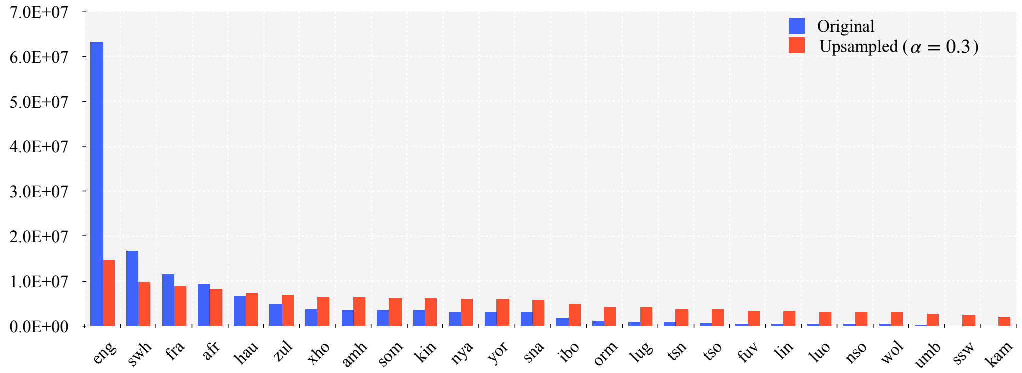

Figure 1: Number of sentences in each language and the upsampled distribution with the smoothing rate of $\alpha = 0.3$.

2.2 Data Preprocessing

We preprocess the raw and potentially noisy data by four steps, namely, reformatting, deduplication, language detection, and length limitation. Details are elaborated as below.

Reformatting. The raw data is stored in various alignment structures, including HTML, JSON, and special spacing. To reduce data noise, we reformat all data into a line-by-line tight structure and realign those missing paired ones.

Deduplication. We remove the duplicated sentences (pairs) in each monolingual and parallel dataset. This aims to reduce information redundancy so that the MNMT models can be trained more efficiently.

Language Detection. Previous studies suggest that incorrect languages in training data induce translation uncertainty for both bilingual (Ott et al., 2018) and multilingual (Wang et al., 2022) NMT models. Therefore, we conduct language detection for all the datasets using `langid`[4]. Since `langid` neither supports all African languages nor performs well when distinguishing two African languages, we adopt a simplified strategy: for the African datasets, we remove sentences (pairs) that are identified as languages other than the 24 designated African languages. In other words, sentences (pairs) in one African language identified as another African language are also considered valid. For English and French datasets, we strictly restrict the correct languages as themselves, i.e., English and French, respectively.

Length Limitation. After multilingual tokenization, we conduct further filtering and retain sentence pairs with tokens between 4 (Wu et al., 2019) and 512 (Yang et al., 2021), as well as the length ratio below 3.

2.3 Multilingual Tokenization

To tokenize the multilingual sentences, we follow (Conneau et al., 2020) to train a Sentence Piece Model (SPM) and apply it directly on the preprocessed text data for all languages. However, the distribution of data across languages is heavily long-tailed, as shown in Figure 1. To balance the vocabulary bandwidth between high-resource and low-resource languages, we follow Conneau et al. (2020) to upsample the low-resource languages with a smoothing rate of $\alpha = 0.3$ over the original distribution when training the SPM model. We use a shared vocabulary with 128K tokens for the 26 languages, and also append 32 special tokens (i.e., "TBD0" to "TBD31") for including extra tasks or data (e.g., tagged-BT (Caswell et al., 2019)).

3 Approach

3.1 Data Augmentation

We adopt data augmentation (DA) to address the first challenge, i.e., " **The absence of training data for some to-be-evaluated language pairs**".

Specifically, we use back-translation (BT) (Sennrich et al., 2016) and self-training (ST) (Jiao et al., 2020, 2021, 2022) to construct synthetic data. However, previous study by Caswell et al. (2019) suggests that the translationese issue in BT limits the performance, which can be mitigated with a special tag at source side (i.e., tagged-BT). To simplify the tagging procedure for the two opposite directions of each language pair, we use both BT and ST for each language pair (Wu et al., 2019) and append a special token at the synthetic side of sentence pairs. Formerly, for a language pair (S, T) with the bitext data $\{\mathbf{x}, \mathbf{y}\}$, the synthetic data by BT and ST will

[4] `https://github.com/saffsd/langid.py`

be $\{[\mathbf{x}'; \langle \texttt{DA} \rangle], \mathbf{y}\}$ and $\{\mathbf{x}, [\mathbf{y}'; \langle \texttt{DA} \rangle]\}$, where $\langle \texttt{DA} \rangle$ denotes the special tag for data augmentation.

We conduct data augmentation for both English-centric and non English-centric language pairs. For English-centric language pairs, we randomly sample up to 1.0M English and non-English monolingual sentences from the training corpora for BT and ST, respectively. As for non English-centric language pairs, we translate the English side of English-centric pairs to non-English languages and construct up to 0.5M BT and ST sentence pairs, respectively. Generally, the augmented data is included in **Large-234** to train the MNMT models. However, the translation quality of those English-centric directions is also unreliable due to the limited data sizes, which may harm the performance of subsequent MNMT models. Besides, adding more synthetic data and language directions also slows down the convergence of the MNMT models. Instead, we use the resulting MNMT models as backbones to finetune on the clean datasets.

3.2 Distributionally Robust Optimization

We adopt the distributionally robust optimization (DRO) (Oren et al., 2019; Zhou et al., 2021) technique to address the second challenge, i.e., "**The uneven optimization of language pairs due to data imbalance** ".

Generally, temperature-based sampling (Arivazhagan et al., 2019; Conneau et al., 2020) is adopted to balance the training data across language pairs, which samples data from the smoothed data distribution as, $p_{\tau,i} = \frac{|D_i|^{1/\tau}}{\sum_j |D_j|^{1/\tau}}$. This is equivalent to optimizing the re-weighted objective:

$$\mathcal{L}_\tau(\theta; D_{\text{train}}) = \sum_{i \le N} p_{\tau,i} \mathcal{L}(\theta; D_i), \tag{1}$$

where $|D_i|$ is the training data size of the i-th language pair, and τ denotes the temperature rate. Obviously, $\tau = 1$ corresponds to the original data distribution while $\tau = \infty$ represents uniform sampling. In practice, $\tau > 1$ is adopted to oversample the low-resource language pairs, which significantly affects the results and needs to be tuned for different settings.

Even if we can build a completely balanced dataset across language pairs, the varied task difficulty and cross-lingual similarity determine that the language pairs will still be optimized unevenly. DRO can address such a problem. In contrast to temperature sampling which optimizes over a fixed training data distribution, DRO aims to find a model θ that can perform well on an entire set of potential test distributions, i.e., $\mathcal{U}(p^{\text{train}})$, which is usually called *uncertainty set*. We adopt DRO with the χ^2-uncertainty set introduced by Zhou et al. (2021), and reproduce the implementation for the practical many-to-many translation scenario.[5] Similarly, we also incorporate the baseline losses calculated from a pretrained MNMT model to stabilize the training process of DRO.

Table 2: Language family grouping.

Group	Target Languages
1	eng, fra
2	afr, nso, sna, ssw, tsn, tso, xho, zul
3	amh, luo, orm, som, swh, wol
4	fuv, hau, ibo, yor
5	kam, kin, lin, lug, nya, swh, umb

3.3 Language Family Grouping

We adopt language family grouping (LFG) to alleviate the third challenge, i.e., " **The curse of multilinguality**" (Conneau et al., 2020).

Specifically, we divide the target languages into 5 groups (see Table 2) based on Table 1. This is partially inspired by Eriguchi et al. (2022), which factorizes the many-to-many translation scenario (with $N \times N$ directions) into N many-to-one scenarios by training a translation model for each. Since we have 26 languages involved in this shared task, factorizing the many-to-many scenario by the family of target languages is a more efficient choice. Since **swh** appears in both HCEA and CA, we include it in both Group-2 and Group-5 for training models. During inference, our scripts will automatically select the model of corresponding group according to the target language to be evaluated. Note that **swh** is only routed to Group-2 in inference.

4 Experiments

4.1 Settings

Model. We adopt the standard sequence-to-sequence Transformer (Vaswani et al., 2017) as our architecture. For the **Base-146** scale, we use a deep encoder of 24 layers and a relatively shallow decoder of 12 layers (Yang et al., 2021), with an embedding size of 1024, the feed-forward network

[5] The referred study only supports one-to-many and many-to-one translation scenarios on very small multilingual translation datasets.

Table 3: Evaluation results of our models on the devtest in terms of BLEU and ChrF++.

Model	X-Eng	Eng-X	X-Fra	Fra-X	X-X	All
	22	22	4	4	48	100
Transf-Deep	23.37/46.80	17.19/41.07	20.20/43.18	16.07/41.93	10.69/33.90	15.50/39.01
Borderline-Deep	25.87/48.83	18.24/42.05	22.31/44.91	16.74/42.32	11.66/34.89	16.86/40.23
Borderline-DWide	28.11/51.30	19.02/42.92	24.74/47.58	17.22/43.23	12.03/34.94	17.82/41.13
Borderline-DWide w/ LFG	28.26/51.37	19.38/43.37	24.87/47.74	17.48/43.72	12.04/35.01	**17.95/41.31**

size of 4096, and 16 attention heads (i.e., 0.59B parameters). To stabilize the training of deep models, we follow Wang et al. (2019) to use pre-layer-normalization (PLN) for both encoder and decoder layers. For the **Large-234** scale, we enlarge the embedding size to 1536 to support more language pairs, which results in 1.02B parameters. By default, we call these two models as Transf-Deep and Transf-DWide. The final models developed by our approaches are renamed as Borderline-Deep and Borderline-DWide for clarity.

Training. We train the MNMT models with the Adam optimizer (Kingma and Ba, 2014) ($\beta_1 = 0.9, \beta_2 = 0.98$). The learning rate is set as 1e-4 with a warm-up step of 4000, followed by inverse square root decay. The models are trained with a dropout rate of 0.1 and a label smoothing rate of 0.1. All experiments are conducted on 32 NVIDIA A100 GPUs. Since the bitext data ($\approx$130M) for this year's shared task is less than 1/10 of that for last year's ($\approx$1.7B), we decide a batch size to be about 1/10 of that used in (Yang et al., 2021). Specifically, we use 2048 max-tokens per GPUs and accumulate the gradients for every 8 steps to simulate the large batch size of 512K tokens. For language family grouping, we use the batch size of 131K tokens for each model. For translation models trained by empirical risk minimization (ERM) on the original training data, we upsample low-resource language pairs with the smoothing rate $\alpha = 0.3$ (Conneau et al., 2020). For those by DRO, we adopt the χ^2-uncertainty set with the distribution divergence bounded by $\rho = 0.1$. We use the ERM model to calculate the baseline losses for DRO. We train these two kinds of models for at least 100K updates, upon which we may finetune for additional updates.

Evaluation. We use the dev and devtest of Flores-200 benchmark[6] as our validation and test sets, and evaluate the MNMT models on the averaged last 10 checkpoints with sentencepiece BLEU and ChrF++. The sentencepiece model for evaluation also comes from the Flores-200 benchmark. The beam search process is performed with a beam size of 4 and a length penalty of 1.0. Similar as the official competition results, we report our results by average-to-eng (X-Eng), average-from-eng (Eng-X), average-to-fra (X-Fra), average-from-fra (Fra-X), average-african-to-african (X-X), and the average for All translation directions.

4.2 Results

We list the evaluation results of our final models on the devtest in Table 3. Both the baseline model Transf-Deep and our Borderline-Deep model are trained for 200K updates, while the two Borderline-DWide models are trained or finetuned for more than 300K updates.

Generally, our models outperform the baseline Transf-Deep model significantly by up to +2.45 BLEU and +2.30 ChrF++ scores. By looking into each category, we have some interesting findings:

- By comparing Borderline-Deep and Transf-Deep, we find that the improvement on X-Eng is much larger than that on Eng-X. Similar phenomenon is also observed for X-Fra and Fra-X. It suggests that while DRO can achieve even improvement for one-to-many or many-to-one scenarios (Zhou et al., 2021), it is heavily biased by the dominant languages (i.e., eng and fra) in the many-to-many scenario.

- By comparing Borderline-DWide and Borderline-Deep, we find that enlarging the model capacity brings improvement to all categories but the most on X-Eng and X-Fra. It indicates that the *curse of multilinguality* cannot be well solved by simply increasing model capacity as the most benefits are still occupied by the dominant languages (i.e., eng and fra).

- Language family grouping (LFG) achieves more improvement on Eng-X and Fra-X than on the

⑪	+ LFG	-/-	17.95	+3.29

other categories, which confirms its effectiveness in alleviating the curse of multilingualty issue.

Ablation Study. We present detailed ablation studies to investigate the effectiveness of various strategies, not only the three introduced in §3 but also some tricks. The results are listed in Table 5, where the lines marked in blue (i.e., ②, ⑤, ⑩ and ⑪) correspond to the four models in Table 3. We list our observations as below:

- ③ *vs.* ②: Directly finetuning the Transf-Deep model on the **Large-234** dataset induces the performance drop. One possible reason is that **Large-234** introduces much more translation directions, aggravating the *curse of multilinguality* issue. Another reason is the low-quality data by data augmentation (§3.1), which harms the optimization of models. Therefore, we only use **Large-234** to pretrain the Transf-DWide model and then finetune on the cleaner **Base-146** and **Eval-106** datasets.

- ⑥ *vs.* ⑤: Previous studies (Wang et al., 2022) suggest that attaching target language tags at encoder (i.e., T-Enc) benefits the zero-shot translation performance, indicating a stronger cross-lingual transfer ability. However, we do not see any improvement of our models with T-Enc. The reason could be that, traditional studies on many-to-many translations are mainly conducted on the datasets with only one central language while we are now handling multiple central languages, making it a more complex scenario.

- ⑨ *vs.* ⑩ *vs.* ⑪: Finetuning on **Eval-106** slightly outperforms that on **Base-146** and the performance can be further improved with language family grouping. Obviously, as we reduce the language pairs involved in a single model, the *curse of multilinguality* is alleviated.

Submissions. The Borderline-DWide and Borderline-DWide w/ LFG models shown in Table 3 (i.e., contrastive and primary versions) are submitted for official evaluation on the blind test sets. Table 4 summarizes the evaluation results of our submissions, where our models outperform the other teams' across all the evaluation groups. Finally, we achieve the **1st** place in this track.

5 Conclusion

In this paper, we describe Tencent's multilingual machine translation systems for the WMT22 shared task on Large-Scale Machine Translation Evaluation for African Languages. We address three key challenges of this task by data augmentation, distributionally robust optimization (DRO), and language family grouping, respectively, to develop our MNMT models. Our submissions won the **1st** place in the **constrained** track. Extensive analyses also point out the drawbacks of larger models and DRO in addressing the curse of multilinguality, which warrants further research in the future.

Acknowledgments

We sincerely thank the evaluation group for their hard work, including but not limited to the instant communication, environment configuration, and official evaluation. We also thank the anonymous reviewers for their insightful suggestions on various aspects of this report.

DENTRA: Denoising and Translation Pre-training for Multilingual Machine Translation

Samta Kamboj, Sunil Kumar Sahu, Neha Sengupta
Inception Institute of Artificial Intelligence
Abu Dhabi, UAE
samta.kamboj@g42.ai, {sunil.sahu, neha.sengupta}@inceptioniai.org

Abstract

In this paper, we describe our submission to the *WMT-2022: Large-Scale Machine Translation Evaluation for African Languages* under the *Constrained Translation track*. We introduce DENTRA, a novel pre-training strategy for a multilingual sequence-to-sequence transformer model. DENTRA pre-training combines denoising and translation objectives to incorporate both monolingual and bitext corpora in 24 African, English, and French languages. To evaluate the quality of DENTRA, we fine-tuned it with two multilingual machine translation configurations, one-to-many and many-to-one. In both pre-training and fine-tuning, we employ only the datasets provided by the organisers. We compare DENTRA against a strong baseline, M2M-100, in different African multilingual machine translation scenarios and show gains in 3 out of 4 subtasks.

1 Introduction

Despite the compelling performance of machine translation (MT) in many European and Asian languages, their quality in African languages is relatively low. This is primarily because there are approximately 2000 known languages in the African continent, out of which very few languages have any significant presence on the Web (Eberhard et al., 2020; Emezue and Dossou, 2021; Adelani et al., 2022a). As a result, many African languages are not included in publicly available bitext resources, which are typically created by employing heuristics on large amounts of data crawled from the Web (Tiedemann, 2012; El-Kishky et al., 2020; Schwenk et al., 2021; Goyal et al., 2022).

To take a step towards addressing the underrepresentation of African languages in MT, WMT-2022 presented the Constrained Translation track under *Large-Scale Multilingual African Translation* (Adelani et al., 2022b), which releases bitext and monolingual corpora for 24 African languages, and participants are only allowed to use the provided data. Our submission is to the aforementioned track.

Roughly 34% of the provided data is monolingual, spread across 24 African languages pertaining to this task. Since the volume of bitext data provided is limited, our submission aims to leverage the monolingual data to improve the performance of a multilingual machine translation model. To leverage monolingual data in translation, pretraining the model is an obvious choice.

There are several existing multilingual pretrained models such as mBART (Liu et al., 2020), mT5 (Xue et al., 2021), byT5 (Xue et al., 2022), mRASP (Pan et al., 2021), mRASP2 (Pan et al., 2021), and M2M-100[1] (Fan et al., 2021) that are trained on monolingual data, bitext data, or both, and have been demonstrated to improve translation performance for specific language pairs. But, these models do not include many of the African languages of interest. For example, the 50 languages covered by mBART50 include only two out of the 24 African languages in the shared task while M2M-100 includes 14. Moreover, all of these multilingual models rely on specially designated language id tokens to translate between each language pair. As a result, adding unseen languages requires pre-training again. Adelani et al. (2022a) investigated a way to leverage pre-trained models including M2M-100, mT5, byT5, and mBART for the translation of unseen languages. But the scarcity of African language texts in the pre-training corpora results in a marginal improvement in the translation quality of the fine-tuned model (Adelani et al., 2022a). Among the pre-trained models, the authors have noted that fine-tuning M2M-100 results in the best translation performance for African languages.

[1] Although M2M-100 is trained for many-to-many translation tasks, it has been used as a pre-trained model by Adelani et al. (2022a) for African MT. Therefore, we also consider it as a pre-trained model in this work.

Figure 1: Pre-training Overview

In its multilingual pre-training strategy, mBART uses a denoising objective (Liu et al., 2020; Lewis et al., 2020) on combined monolingual corpora of several languages to train a Transformer sequence-to-sequence model (Vaswani et al., 2017). This strategy reduces the dependency on bitext by learning meaningful representations for multiple languages. The pre-trained model is fine-tuned for MT using bitext data. While this methodology does result in improved MT performance, the pre-training objective used does not induce the representation of similar sentences across languages to align, since it uses only monolingual data (Lin et al., 2020).

In contrast, mRASP2 combines the use of monolingual and bitext corpora. Their pre-training methodology is geared towards closing the representation gap across languages, bringing words and phrases with similar meanings across languages closer in the feature space. This results in better multilingual translation performance (Pan et al., 2021). To induce cross-language representations, mRASP2 uses word or phrase level dictionaries to augment both monolingual and bitext data, by replacing randomly chosen tokens in the source sentence by its corresponding words in another language. Since in this work we address primarily low-resource or under-represented languages, separate dictionaries are non-trivial to construct.

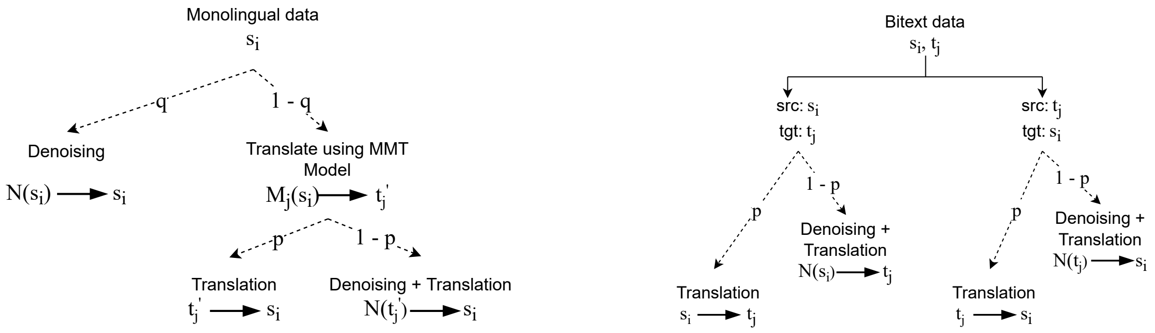
M2M-100 is a massively multilingual model trained on heuristically mined massive bitext corpora spanning 100 languages and 9,900 language pairs (Fan et al., 2021). Fine-tuning M2M-100 with bitext data from the shared task results in minimal improvement over a multilingual model trained from scratch (Section 6). We hypothesize that this is due to M2M-100's subword tokenizer. Since a majority of African languages are written in the Latin script, several subword units are common to many languages. For example, using the M2M-100 tokenizer in the WMT dataset, about 96% of the distinct subwords in African languages also appear in English. Since English corpora dominate the M2M-100 training dataset, the learnt representation of these common tokens are influenced majorly by English, limiting the contribution of African languages.

To address all of the above, we propose DENTRA, which uses a novel pre-training strategy and is trained exclusively on languages from the shared task using both monolingual and bitext data. Inspired by mRASP2 (Pan et al., 2021), our pre-training objective is also designed to explicitly reduce the representation gap between different languages. Figure 1 shows an overview of our pre-training technique.

To measure the effect of pre-training, we fine-tune the pre-trained model in one-to-many and many-to-one configurations of multilingual MT . In three out of four setups, average BLEU score of fine-tuned DENTRA exceeds that of fine-tuned M2M-100 by up to 1.56 points.

2 Definitions and Model Architecture

Task Description: The constrained translation track under WMT-2022 (Adelani et al., 2022b) consists of the following subtasks: English to 22 African languages (eng→{afs}), 22 African languages to English ({afs}→eng), French to 4



Monolingual data
s_i
q
1 - q
Denoising
$N(s_i) \longrightarrow s_i$

Denoising + Translation
$N(t_j) \longrightarrow s_i$

(a) Monolingual data

(b) Bitext data

Figure 2: Pre-training Data Preparation: Pre-training Objective for each example in the corpora are determined using the above trees. Solid lines indicate that both paths are executed. Dotted lines from a node indicate that one of its child nodes are selected at random, with the probability distribution along the edges.

African languages (fra→{afs}), 4 African languages to French ({afs}→fra) and 48 African to African languages within geographical and cultural clusters ({afs}→{afs}). In all tasks, training datasets are from the shared task while the validation and the test sets are from FLORES 200 (Goyal et al., 2022).

Multilingual Machine Translation (MMT): An MMT employs a sequence-to-sequence model to translate between arbitrarily many language pairs (Firat et al., 2016; Aharoni et al., 2019). We denote the set of languages in our corpora as $\mathcal{L} = \{l_1, l_2, \dots l_n\}$ and the bitext data as $\mathcal{D} = \{\mathcal{D}(l_i, l_j), \quad l_i, l_j \in \mathcal{L}\}$ where $\mathcal{D}(l_i, l_j) = \{(s_i, t_j)\}$ is the parallel corpus for languages l_i and l_j. Monolingual data is denoted $\mathcal{M} = \{\mathcal{M}(l_i), l_i \in \mathcal{L}\}$, and $s_i \in \mathcal{M}(l_i)$ denotes an example in the monolingual corpus for language l_i. For training MMT on bitext data $\mathcal{D}$, an artificial token indicating the target language is prefixed to the source, so that $(s_i, t_j) \in \mathcal{D}(l_i, l_j)$ becomes (<J>s_i, t_j) (Johnson et al., 2017). MMT can be trained in three configurations: one-to-many (**1**→**M**), many-to-one (**M**→**1**) and many-to-many (**M**→**M**) (Tang et al., 2021).

Model Architecture: We use the Transformer *big* architecture described in (Vaswani et al., 2017), with 6 encoder and decoder layers, 16 attention heads, and 1024 model dimension. We train our models using FAIRSEQ (Ott et al., 2019) toolkit, and other hyperparameter values listed in Appendix A.1.

3 Methodology

Our overall methodology employs the pre-training followed by fine-tuning pipeline used in prior work in NMT. (Liu et al., 2020; Lin et al., 2020). We present the pre-training strategy used in this work in Section 3.1 and discuss the fine-tuning configurations used in our submission in Section 3.2.

3.1 Pre-training

In our pre-training, we combine monolingual and bitext data in the same corpus. The objective of pre-training is to either denoise, or translate, or both. For each individual example in the corpus, we randomly select which of these objectives to apply. By interleaving denoising and translation, our goal is to drive the model towards learning cross-lingual representations while at the same time learning robust semantic representations. The strong cross lingual representations enable better few-shot and zero-shot translation performance (Pan et al., 2021). Figure 2 illustrates our pre-training methods for both monolingual and bitext data. $N(\cdot)$ is the noising function which we describe in detail in Section 3.1.3, while $M_j(\cdot)$ denotes the translation function using an MMT model for translation to language l_j. In the remainder of this section, we describe each component of the pre-training individually.

3.1.1 Monolingual Data

Figure 2a shows the two ways in which we utilize monolingual data in pre-training. Independently, for each monolingual example $s_i \in \mathcal{M}(l_i)$ one of denoising or translation is selected with probability q and $1 - q$ respectively.

If denoising is selected, we apply a denoising objective similar to mBART (Liu et al., 2020) by masking or shuffling randomly chosen spans. If translation is selected, s_i is first translated to all languages l_j for which $\mathcal{D}(l_i, l_j) \in \mathcal{D}$. The translation is done by MMT models which are obtained by training Transformer models from scratch on $\mathcal{D}$, described in Section 5.1. Lets $M_j(s_i) = t'_j$ is the translation of s_i into language l_j. For the pair (s_i, t'_j), either translation only, or denoising + translation is selected with probabilities p and $1-p$ respectively. If translation is chosen, s_i must be reconstructed from t'_j, following traditional back-translation (Sennrich et al., 2016). If denoising + translation is selected, then s_i must be reconstructed from the noised version $N(t'_j)$. In this manner, the pre-training also incorporates back-translation for utilizing monolingual data.

3.1.2 Bitext Data

Figure 2b shows the bitext data usage in pre-training. Given a pair of sentences (s_i, t_j), the pre-training procedure treats s_i as source and t_j as target, and vice versa. Therefore, two pre-training examples are generated for each example in the bitext data. This is in contrast to pre-training with monolingual data described above, where only one pre-training example was generated per input example. Having designated either s_i or t_j as source, the pre-training procedure follows a path similar to that of monolingual pre-training with backtranslation.

3.1.3 Noising Function

The noising function $N(\cdot)$ largely follows the noising techniques used in Liu et al. (2020). Given an input sentence s, $N(s)$ randomly selects a noising type and applies it on s.

Mask only: With probability p_m, $N(s)$ applies span masking on s. It randomly samples spans of tokens from s, with length of the span drawn from a geometric distribution with parameter m_{sl}, and clipped at 3. The fraction of tokens thus masked is at most m_{sr}. Each masked span is either replaced by a single <MASK> token, or deleted, or replaced by randomly selected word in another language with equal probabilities.

Shuffle only: With probability p_s, $N(s)$ applies shuffling to s. An s_r fraction of tokens are selected at random from tokens in s, and permuted among each other, leaving the unsampled tokens intact.

Mask and Shuffle: With probability p_{ms}, $N(s)$ applies both masking and shuffling to s. First, masking is applied as described above. During the shuffling step, <MASK> tokens are excluded from the tokens to be sampled for shuffling.

None: With probability $1 - p_m - p_s - p_{ms}$, no noising is applied on the input.

3.1.4 Combining Datasets

We combine both $\mathcal{D}$ and $\mathcal{M}$ in pre-training. In order to balance the training dataset across language pairs, we apply temperature based sampling following (Fan et al., 2021) with one major change. Since we are operating in a data constrained setting, we do not reduce the size of any dataset.

Let $N_{(i,j)} = |\mathcal{D}(l_i, l_j)|$ the size of the bitext $\mathcal{D}(l_i, l_j)$, and $N_{\mathcal{D}} = \sum_{(i,j)} N_{(i,j)}$. Then the scaled proportion of language pair (l_i, l_j) is $\alpha'_{i,j} = \frac{\alpha_{(i,j)}}{\sum_{(i,j)} \alpha_{(i,j)}}$ where $\alpha_{(i,j)} = \left(\frac{N_{(i,j)}}{N_{\mathcal{D}}}\right)^{\alpha}$. The rescaled size of language pair (l_i, l_j) is then $R_{(i,j)} = max(N_{(i,j)}, \alpha'_{(i,j)} N_{(i,j)})$

We train the transformer network on the combined dataset until convergence, and then select the best checkpoints for further fine-tuning.

3.2 Fine-tuning

For fine-tuning our pre-trained models, we use bitext data $\mathcal{D}$. Unlike pre-training, we don't noise the source side at all. We apply fine-tuning in 1→M and M→1 settings. Following the pre-training setup, we continue to prefix the tag for the target language in the source side, and also rebalance the datasets as in Section 3.1.4. The checkpoint with best BLEU score on validation set is used for final translations. After fine-tuning, we have the following models. (i) eng→{afs}, (ii) {afs}→eng, (iii) fra→{afs}, and (iv) {afs}→fra. For the remaining pairs, i.e. between African languages, we use DENTRA directly.

4 Datasets and Pre-processing

For all experiments, we employ the datasets provided by the organizers, which mainly consist of datasets from Opus (Tiedemann, 2012), Mafand (Adelani et al., 2022a) and Web crawled aligned through LASER (Heffernan et al., 2022). It is worth mentioning that, in all pre-training and fine-tuning we only used a monolingual corpus of 26 languages and English and French-centric bitext. We have not used any African to African bitext in our experiments. Prior to using for pre-training or fine-tuning, datasets were filtered, cleaned, and preprocessed.

4.1 Data Filtering

Based on characteristics of the dataset and a few observed issues, we employed several heuristics to reject highly noisy examples from $\mathcal{D}$ and $\mathcal{M}$. Given an example $(s_i, t_j) \in \mathcal{D}(l_i, l_j)$, we reject it if (i) $|s_i| < 3$ or $|t_j| < 3$, (ii) $|s_i| > 1000$ or $|t_j| > 1000$, (iii) a character other than . appears at least 5 consecutive times in either s_i or t_j, (iv) a word other than . appears at least 3 consecutive times in either s_i or t_j, (v) s_i is identical to t_j, (vi) $|s_i|/|t_j| < 0.2$ or > 5, (vii) langid of s_i or t_j is not the expected langid with a confidence of at least 80% (where langid is computed using fasttext[2]), (viii) the fraction of characters not belonging in this language are more than 50% [3]. For monolinugal data $\mathcal{M}$, we apply rules corresponding to (i)-(iv) , and (vii)-(viii) above.

After filtering and pre-processing the size of the datasets (combined by English centric, French centric, or monolingual) obtained are shown in Table 1[4]. Full list is shown in Appendix A.2.

Dataset	# Datasets	Total Size	Min	Max	Δ
eng-{afs}	22	109.36	0.21	32.01	21.32 %
fra-{afs}	4	13.40	0.22	11.51	3.96 %
Mono	26	34.17	0.0	12.73	0.58 %

Table 1: Data set sizes specified in Million sentence pairs (or sentences). Δ refers to the percentage of sentence pairs (or sentences) rejected after filtering and pre-processing

Param	p	q	p_m, p_s, p_{ms}	m_{sl}	m_{sr}	s_r	α
Value	0.25	0.66	0.25	0.15	0.2	0.05	0.7

Table 2: Hyper-parameter values used in our data preparation

5 Experimental Setup

Table 2 specifies the hyperparameters we have used in pre-training (Section 3.1). We train the model for 6 epochs and select the best checkpoint based on pre-training task performance on a held out validation set.

The best pre-training checkpoint was subsequently fine-tuned for various tasks where we consider the concatenation of all FLORES 200 *dev sets* for the relevant translation directions as validation set. The FLORES *dev sets* have 997 examples for all language pairs.

For evaluation, we use two test sets. The FLORES *devtest* set (subsequently, we refer to it as FLORES *test set*), which has 1012 examples for all language pairs, and an in-domain test set, which is randomly sampled from the provided bitext data and has about 5000 examples from each language pair. Unless otherwise specified, we report performances on the FLORES *test set*.

We use tokenized BLEU from Moses[5] to measure the performance of all translations. Prior to computing BLEU we word tokenize all translations, also using Moses.

5.1 Models

We prepared following baselines for the comparison of our pre-trained and fine-tuned models:

MMT[6] is trained from scratch separately for four tasks with their corresponding bitext: eng→{afs}, {afs}→eng, fra→{afs} and {afs}→fra. We evaluate it in 1→M and M→1 setups.

M2M-100 is trained on many-to-many datasets of 100 languages. We use the trained version provided by the authors (Fan et al., 2021) and evaluate it in all setups, 1→M, M→1, and M→M. Note that M2M-100 does not support all language pairs in this task and thus, we report performance on only the common language pairs. In particular, M2M-100 includes 14/22 languages in eng↔{afs}, 3/4 in fra↔{afs} and 22/48 in {afs}→{afs}. In all M2M-100 experiments, we employ its 418M parameters checkpoint.

M2M_FT employs the pre-trained checkpoint of M2M-100 and fine-tunes it with bitext data. Similar to Adelani et al. (2022a), unseen African languages {*kam, kin, luo, nya, orm, sna, tso, umb*} are mapped to {*km , ht, lo, yi, fy, ba, kk, uz*} respectively for fine-tuning M2M-100. M2M_FT is used for evaluations in 1→M and M→1 setups only.

The following are the models trained in this work for demonstrating the importance of our pre-training and fine-tuning strategies.

DENTRA is the pre-trained model described in Section 3, which we train using (i) monolingual data in 26 languages and (ii) bitext data for only English and French centric directions. We compare DENTRA against the corresponding baselines in all setups, 1→M, M→1, and M→M.

DENTRA_FT uses bitext data for English and French centric directions to fine-tune the DENTRA

[2] https://fasttext.cc/docs/en/python-module.html

[3] Character sets for each language are built by manually curating distinct characters obtained from $\mathcal{D}$

[4] For the Kinyarwanda language, no monolingual data was provided. We reused the Kinyarwanda side from the Kinyarwanda-English bitext for this purpose. For English and French, we randomly sampled 1 million sentences from the combined English/French sides of the bitext datasets provided.

[5] https://github.com/moses-smt/mosesdecoder

[6] These models are also used for backtranslation described in Section 3.1.1

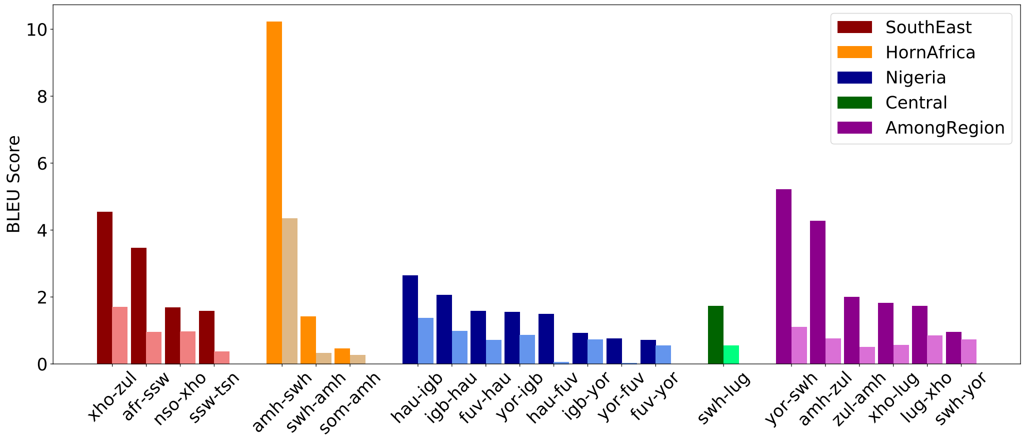

Figure 3: BLEU scores for M2M-100 and DenTra (zero-shot) among African languages on the Flores 200 test set. Dark colors represent DenTra and light colors represent M2M-100.

Tasks	M2M-100	DenTra
eng→{afs}	4.51	9.13
fra→{afs}	4.74	9.48
{afs}→eng	9.13	22.63
{afs}→fra	8.21	15.28

Table 3: Average performance for common languages of DenTra and M2M-100 before fine-tuning

model. DenTra_FT is trained and evaluated against the baselines in only the 1→M and M→1 setups.

6 Comparisons with Baselines

6.1 Without Fine-tuning

In this section, we will show the advantage of DenTra over M2M-100 for the 26 languages in the task without any fine-tuning on either models. As DenTra and M2M-100 both include bitext in their training, we can directly use them for translation.

Table 3 shows the average performance of M2M-100 and DenTra for the 14 English and 3 French centric tasks in M→1 and 1→M setups. In all four tasks, DenTra outperforms M2M-100 by significant margins.

Furthermore, in Figure 3 we display the performance of M2M-100 and DenTra on {afs}→{afs} tasks, i.e. translation between African languages. Similar to M→1 and 1→M setup, we include only the 22 common directions of DenTra and M2M-100 (Full performance list for DenTra is provided in Appendix A.3). Note this is the *zero-shot setting* (Johnson et al., 2017) for both[7]. However, in all translation directions, DenTra outperforms M2M-100 by large margins. These results shows the advantage of pre-training with combined monolingual and bitext data for only the desired set of languages, over pre-training with a large number of additional languages. This confirms our hypothesis discussed in Section 1.

6.2 With Fine-tuning

We evaluate DenTra after it is fine-tuned on the four M→1 and 1→M tasks. Tables 4, 5, 6, and 7 show the BLEU scores for DenTra_FT along with all baselines. Following conclusions may be drawn:

All model variants including DenTra_FT, M2M_FT and DenTra are significantly better than M2M-100 across all language pairs. The general trend of performance comparison in best to worst order is DenTra_FT, M2M_FT, MMT, DenTra, M2M-100, except {afs}→fra where M2M_FT outperforms DenTra_FT.

Improvement of M2M_FT and DenTra_FT over MMT shows the advantage of fine-tuning after pre-training in general. Moreover, since DenTra_FT typically outperforms M2M_FT also, this demonstrates the advantage of including the monolingual corpora and denoising objectives in the pre-training phase.

Generally, it has been shown that combining low resource and high resource languages in a single translation model benefits the low resource languages. We also observe similar behavior as shown by our MMT model. However, we find that extreme multilingual models like M2M-100 must necessar-

[7] Our assumption is that M2M-100 is zero shot in these settings.

ily have larger capacity to represent all languages in its corpora. In particular, if the languages of interest are restricted, it is better to also restrict pre-training to these languages only (Adelani et al., 2022a).

Finally, we note that the performance of translation models where African languages are the target language are generally lower than those where English or French are the target language. This is expected, since the volume of data where each individual African language appears on the target side is much lower than English or French.

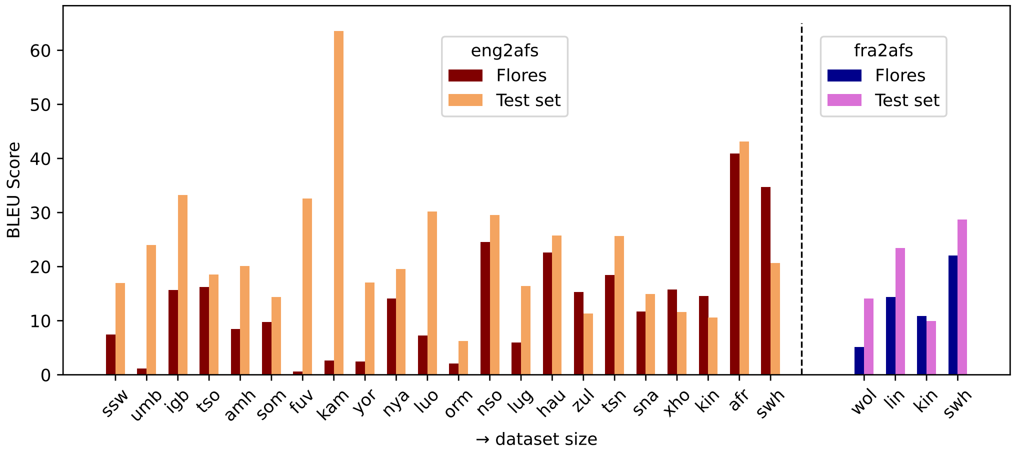

Figure 4: BLEU score comparison of the DENTRA_FT model for FLORES 200 and in-domain test set (isolated from bitext training data $\mathcal{D}$ for English/ French to African languages.

7 Analysis

In this section, we conduct a set of analytical experiments to better understand the datasets and what contributes to performance gains.

Figure 4 shows the BLEU scores of the DenTra_FT model on {eng,fra}→{afs} translation directions, on the both FLORES 200 test set and the in-domain test set sampled from the bitext data prior to training. The language pairs on the horizontal axis are ordered by the dataset size (left to right in increasing order) independently for English and French centric directions. For the English centric translation (eng→{afs}), the BLEU scores on both test sets have little correlation with the dataset size, indicating noisy data. Some languages, such as *umb, fuv, kam,* and *yor* have stark difference between FLORES and in-domain test sets, indicating that these datasets may have predictable patterns that have no relevance to the translation of these languages. This is further exemplified by the comparison to *tso*, which has a smaller dataset yet exhibits better generalization.

Further investigations reveal two primary problems with the bitext data. First, some of these languages have several duplicates in the African side of the data. For example, for Kamba-English (*kam-eng*) dataset, the distinct number of Kamba sentences is less than 5% of the total dataset size. However, this is not consistent across all languages exhibiting overfitting on the training data, as the number of distinct Yoruba (*yor*) sentences in its bitext is about 95% of the total dataset.

Second, the African side of many datasets contain a large fraction of Indic languages from the Social Media domain. Strict heuristics designed based on manual inspection by the authors rejected about $637,000$ examples as being clearly in the Hindi language. Clearly, neither langid nor the LASER encoder (Schwenk and Douze, 2017) are able to reliably detect and align data for these languages. We postulate that low resource languages form a vicious cycle for MT systems trained on bitext data created using multilingual encoders. This opens avenues for future work to explore bitext creation for low resource languages.

8 Conclusion

DenTra has shown significant performance gains in Multilingual Machine Translation for African languages as demonstrated in this paper. DenTra integrates denoising, backtranslation, and translation into the same pre-training setup, and has helped to improve MT performance after fine-tuning for both English and French centric translation. We have shown that massively multilingual models like M2M-100 may not be a good choice for fine-tuning when the languages to be translated from/to are restricted to a small set. Finally, we have studied the variation in performance and reported issues seen in heuristically created bitext data. While this is a known issue, we show this problem to be exacerbated for low-resource languages that share the alphabet with high-resource ones.

Abstract

This report describes our VolcTrans system for the WMT22 shared task on large-scale multilingual machine translation. We participated in the unconstrained track which allows the use of external resources. Our system is a transformer-based multilingual model trained on data from multiple sources including the public training set from the data track, NLLB data provided by Meta AI, self-collected parallel corpora, and pseudo bitext from back-translation. A series of heuristic rules clean both bilingual and monolingual texts. On the official test set, our system achieves 17.3 BLEU, 21.9 spBLEU, and 41.9 chrF2++ on average over all language pairs. The average inference speed is 11.5 sentences per second using a single Nvidia Tesla V100 GPU. Our code and trained models are available at https://github.com/xian8/wmt22

1 Introduction

Multilingual Machine Translation attracts much attention in recent years due to its advantages in sharing cross-lingual knowledge for low-resource languages. It also dramatically reduces training and serving costs. Training a multilingual model is much faster and simpler than training many bilingual ones. Serving multiple low-traffic languages using one model could drastically improve GPU utilization.

The WMT22 shared task on large-scale multilingual machine translation includes 24 African languages (Adelani et al., 2022b). Inspired by previous research works, we train a deep transformer model to translate all languages since large models have been demonstrated effective for multilingual translation (Fan et al., 2021; Kong et al., 2021; Zhang et al., 2020). We participated in the unconstrained track that allows the use of external data. Besides the official dataset for the constrained track, and the NLLB corpus provided by MetaAI (NLLB Team et al., 2022), we also collect parallel and monolingual texts from public websites and sources. These raw data are cleaned by a series of commonly used heuristic rules, and a minimum description length (MDL) based approach to remove samples with repeat patterns. Monolingual texts are used for back translation. For some very low-resource languages such as Wolof, iterative back-translation is adopted for higher accuracy.

We compare different training strategies to balance efficiency and quality, such as streaming data shuffling, and dynamic vocabulary for new languages. Furthermore, we used the open-sourced LightSeq toolkit [1] to accelerate training and inference.

On the official test set, our system achieves 17.3 BLEU, 21.9 spBLEU, and 41.9 chrF2++ on average over all language pairs. Averaged inference speed is 11.5 sentences per second using a single Nvidia Tesla V100 GPU.

2 Data

2.1 Data Collection

Our training data are mainly from four sources: the official set for constrained track, NLLB data provided by Meta AI, self-collected corpora, and pseudo training set from back translation.

For each source, we collect both parallel sentence pairs and monolingual sentences. A parallel sentence pair is collected if one side is in African language and the other is in English or French. We did not collect African-African sentence pairs as we use English as the pivot language for African-to-African translation. Instead, they are added to the monolingual set. More specifically, we split every sentence pair into two sentences and add them to the monolingual set accordingly. For example, the source side of a fuv-fon sentence pair is added to the fuv set. This greatly enriches the monolingual dataset, especially for the very low-resource

December 7-8, 2022 ©2022 Association for Computational Linguistics

languages.

We merge multiple corpora from the same source into one and use bloom filter [2](Bloom, 1970) for fast deduplication. To reduce false positive errors which over delete distinct samples, we set the error rate $1e-7$ and capacity of $4B$ samples which costs $100G$ host memory.

The official set includes the data from data track participants, OPUS collections, and the NLLB parallel corpora mined from Common Crawl (com) and other sources. All domains in OPUS collections are involved, such as Mozilla-I10n, which could introduce many noises such as programming languages, and needs extra rules to clean.

NLLB data provided by Meta AI has three subsets: primary bitext including a seed set that is carefully annotated for representative languages and a public bitext set downloaded from open sources and mined bitexts that are automatically discovered by LASER3 encoder in a global mining pipeline, back-translated data from a pretrained model. We add the first two subsets in our training set.

Some public bitext data that are no longer available or require authorization such as JW300 (Agić and Vulić, 2019), Lorelei[3] and Chichewa News [4] are not included. We noticed that the NLLB team released another version of mined data recently in hugging-face [5], which is different from the version on the WMT22 website. We merge the new version into the old one and remove duplicates.

We collected additional bitexts in two ways: large-scale mining from general web pages, and manually crawling from specific websites and sources.

Large-scale mining focused on two scenarios, parallel sentences appearing on a single web page such as dictionary web pages that use multiple bilingual sentences to exemplify the usage of a word, and parallel web pages that describe the same content but are written in different languages. We extract these pages from the Common Crawl corpus. Then we utilized Vecalign (Thompson and Koehn, 2019), an accurate and efficient sentence alignment algorithm to mine parallel bilingual sentences. We use LASER (Schwenk and Douze, 2017) encoders released by WMT to obtain multilingual sentence embeddings and facilitate the alignment work. We collected about 3 million sentence pairs namely LAVA corpus and submitted them to the data track. And another $150M$ pairs for the unconstrained track.

Specific websites and sources have fewer but higher-quality sentence pairs. For example, the bible website[6] labels the order of sentences across languages so we can align them easily without sentence segmentation. Since JW300 is not publicly available, we crawled pages from Jehovah's Witnesses[7] to recover the dataset.

Monolingual texts have richer sources such as VOA news in Amharic [8] and OSCAR (Abadji et al., 2022), which improve English/French → African translation using back-translation. Monolingual texts from parallel data are also collected as described above. For African → English/French translation, we clean Wikipedia pages in English/French to get monolingual texts. For languages that gain significantly from back-translation such as Wolof, we run another round of back-translation to generate high-quality pseudo data.

2.2 Data Cleaning

We used the following rules to clean parallel datasets, except the NLLB mined bitext.

- Filter out parentheses and texts in between if the numbers of parentheses in two sentences are different.
- Filter out sentence pairs if numbers mismatch or one sentence ends with punctuation *: ! ? ...* and the other mismatches.
- Filter out sentences shorter than 30 characters, sentences having URLs or emails, or words longer than 100 characters.
- De-duplication: remove sentence pairs sharing the same source or target but having different translations.
- Sentences having programming languages are removed. We manually create a set of keywords to detect programming languages, such as *if (* , *==* and *.getAttribute* .
- Language identification using the NLLB language identification model trained by fastText (Joulin et al., 2017)

[7] https://www.jw.org

[8] https://amharic.voanews.com/

One type of noisy text could survive the rules above, which has repeat patterns and commonly exists in many datasets. Here are some examples,

Download Bongeziwe Mabandla mini esadibana ngayo (#001) Mp3 Bongeziwe Mabandla - mini esadibana ngayo (#001).

Coaster Gift,Paper-Cut Coaster Zodiac,Red Coaster Cute,Paper-Cut Zodiac Coaster

mm mm mm MPEE(um) MPEP(um) mm mm mm mm mm mm kg kg

A natural choice to detect these repeating patterns is the minimum description length (MDL) which finds the optimal compression by encoding frequent substrings with shorter codes.

Specifically, given a sentence $\mathbf{s}$, our MDL objective minimizes the length of the codebook plus the bits to encode the sentence:

$$\mathrm{MDL}(\mathbf{s}) = \min_{\mathbf{s}=w_1 w_2 \ldots w_n} \left(C \sum_{\text{distinct } w} |w| - \sum_i \log \left(p(w_i | w_{i-1}) \right) \right)$$

where $w_1, w_2, \ldots w_n$ is the word (coding entry) sequence, C is a positive constant, which balances the contribution of the codebook and length of the encoded sequence. $|w|$ is the length of word w. In our experiments, we set $C = 2$. $p(w_i|w_{i-1}) = \frac{\#w_{i-1}w_i}{\#w_{i-1}}$ is the conditional probability of word bigrams in the sequence.

A sentence is noisy if the ratio of MDL over sentence length is less than a predefined threshold:

$$\mathbf{s} \text{ is noisy if } \quad \frac{\mathrm{MDL}(\mathbf{s})}{\mathrm{len}(\mathbf{s})} < T$$

If a sentence has no repeat patterns at all, then the length of the codebook should be $C\mathrm{len}(\mathbf{s})$, and $\mathrm{MDL}(\mathbf{s}) \geq C\mathrm{len}(\mathbf{s})$. Thus we choose $T = C$.

For the NLLB mined corpus, we remove pairs with laser score < 1.06 or language score < 0.95 provided by LASER. Monolingual texts are cleaned using language scores only.

Table 1 and Figure 1 summarize the size of our training data after data cleaning and deduplication.

2.3 Preprocessing and Post Processing

There are thousands of languages in the world, thus statically training a tokenizer on a predefined list of languages is not flexible for new languages. There are several studies on dynamic vocabulary for new language adaption, the general principle is to maximize the overlap with the old vocabulary. (Lakew et al., 2018, 2019)

Source	Sentence Pairs
Constrained Track	$50.5M$
NLLB	$29.1M$
Self Collected	$151.6M$
Back Translation	$1.41B$
Total	$1.64B$

Table 1: Number of sentence pairs from different sources after data cleaning.

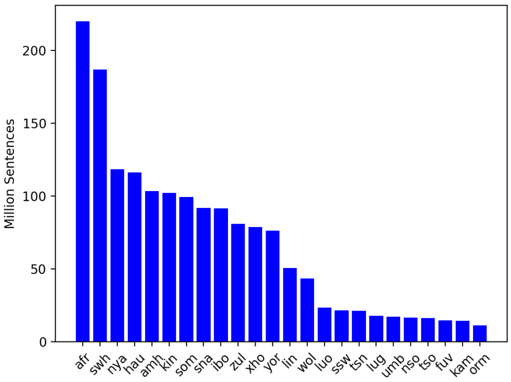

Figure 1: Number of sentences (in millions) in different African languages after data cleaning.

We reuse the mRASP2 tokenizer, a unigram model trained on 150 languages using SentencePiece (Pan et al., 2021). To support new African languages, we train another tokenizer for new languages and merge it to the mRASP2 tokenizer. To ensure that the merged tokenizer produces the same segmentation for old languages, new words that can be made by joining two or more old words are removed and the rest new words' probabilities are scaled down.

We notice that the Yoruba text in FLORES200 has more accented characters than other corpora. According to NLLB team's report, the way FLORES200 marks the tone of vowels is similar to MAFAND dataset (Adelani et al., 2022a). Thus, we use the MAFAND data to train an accent model to post-process the translated sentences for $X \rightarrow$ Yoruba translation. It takes the Yoruba character sequence with accents removed as the input and outputs the accented characters. The structure of the model is a two-layer bidirectional LSTM having 50 hidden units in each layer. Correspondingly, we train another accent model using non-MAFAND datasets to preprocess source text for Yoruba$\rightarrow X$ translation.

3 Model

3.1 Model Architecture

Existing research works demonstrate that small models suffer from the underfitting problem for multilingual machine translation. On the other hand, training and serving large models are expensive. Sometimes model parallelism or pipeline parallelism is necessary if it is impossible to run training on a single GPU due to memory constraints. And quantization is required to reduce the latency of inference. Our compromised model is a pre-layer norm transformer with $2.1B$ parameters which can be trained using $A100$ GPUs with $80G$ memory without parallelism. Details of the model are described in Table 2

Parameter	Value
Encoder Layer	64
Decoder Layer	64
Hidden Size	1024
FFN dimension	4096
Max Length	512
Shared Embedding	Decoder input output
Positional Embedding	Learned

Table 2: Architecture of our transformer model

3.2 Language Tag

There are two popular language tag strategies for multilingual MT: S-ENC-T-DEC which adds source language token to encoder input and target language token to decoder input (Fan et al., 2021; Liu et al., 2020; Wu et al., 2021), and T-ENC which adds target language token to encoder input (Yang et al., 2021; Wu et al., 2021). Our system uses T-ENC-T-DEC which adds the target language token to both encoder and decoder inputs. We did not use source language information for two reasons. First, most translation engines detect input languages automatically, which may introduce incorrect source language tokens. Second, a source sentence may be written in mixed languages.

4 Training and Optimization

4.1 Platform

Our models are trained on 6 machines each equipped with 8 Nvidia $A100$ $80G$ GPUs. We use our internal version of ParaGen [9] (Feng et al., 2022) , a self-developed text generation framework, to train the model. For back-translation, monolingual data are split and translated in parallel using 50 Nvidia Tesla $V100$ GPUs.

To accelerate training, LightSeq is integrated. Unlike approaches that proposed alternative model structures to trade quality for speed, LightSeq used a series of GPU optimization techniques tailored to the specific computation flow and memory access patterns of transformer models. It has been demonstrated 50% to 250% faster than Apex [10] on machine translation tasks. (Wang et al., 2021, 2022) Its inference speed is about 11.5 sentences per second using a single Nvidia Tesla $V100$ GPU, which allows us to translate all monolingual texts within a month.

As the training set's size exceeds the local disk's capacity, it is stored on a remote Hadoop file system.

4.2 Hyper-parameter Tuning

We tune the hyperparameters using a hill climbing approach where each iteration searches along one direction with a different value in the hyperparameter space while keeping the others constant in order to converge to the locally optimal solution on the validation set. To search efficiently, we fix a small batch size and tune other parameters, then increase the batch size after the other parameters have been tuned.

The final configuration is listed in Table 3.

Hyperparameter	Value
Initial Learning Rate	0.001
Warmup Steps	1000
Learning Rate Scheduler	Inverse Square Root
Dropout Rate	0.1
Sampling Temperature	5
Label Smoothing	0.1
Optimizer	AdamW$(0.9, 0.98)$
Activation Function	ReLU
Batch Size	$21M$ tokens

Table 3: Hyperparameters for training.

4.3 Streaming Data Shuffling

Data Shuffling reduces the variance of mini-batches and lowers the risk of local optimum. However, it is challenging to shuffle a Terabyte-scale dataset

[9] https://github.com/bytedance/ParaGen

[10] https://github.com/NVIDIA/apex

dynamically. Our system uses multi-source streaming data based shuffling, which maintains a small in-memory buffer and a set of file pointers that point to random offsets of the training set. Each time a file pointer is selected randomly and loads the next sample to the buffer. A batch of samples is drawn from the buffer randomly once the buffer is full. This approach takes the advantage of data prefetching for sequential access in the Hadoop file system. The randomness of the sampling is controlled by the number of file pointers and the size of the buffer. In our experiments, we use about $5k$ file pointers and $300G$ host memory for the buffer.

To compare with global dynamic shuffling, we run a simulation experiment. We train a model until convergence, then shuffle the full dataset statically, and continue training on the shuffled data. Repeat shuffling until no significant change in loss or performance. For clarity, the original model is named as M_0, and the model trained with $i-th$ round of shuffled data is named as M_i.

Table 4 shows the averaged per token loss of the last 100 training steps and averaged BLEU of M_i on English ↔ African language translations. We observed a slight improvement in the first round, but no significant change in the second round. This experiment suggests that our shuffling method combined with a limited number of static shuffling is a good approximation of global dynamic shuffling.

	M_0	M_1	M_2
Averaged Loss	1.95	1.91	1.91
Averaged BLEU	21.39	21.48	21.49

Table 4: Simulation Experiment of global dynamic data shuffling: M_0 is the model trained on original training data. M_i is the model trained on the $i-th$ round of statically shuffled data using M_{i-1} as the initial point. The averaged training loss over the last 100 steps and averaged BLEU of English ↔ African translations are reported.

4.4 Small Dynamic Vocabulary vs Large Static Vocabulary

Existing studies on vocabulary size do not reach a consensus. Large vocabularies often outperform small ones (Gowda and May, 2020), but not always (Liao et al., 2021)

Our vocabulary has $100k$ words, smaller than most of the other systems. Another difference is that our vocabulary is incrementally built for more than 150 languages, it may miss important words in new languages.

To understand the impact of vocabulary, we train another large unigram model with $200K$ words on the 26 languages in this shared task. Table 5 shows the performance with different vocabularies. It is obvious that the $100K$ vocabulary outperforms the $200K$ vocabulary, about 0.3 improvement in BLEU on average.

Vocabulary Size	Languages	BLEU
$100k$ words	173	21.97
$200k$ words	26	21.64

Table 5: Average BLEU of English ↔ African translations on the FLORES200 devtest set for the models with different vocabularies.

4.5 Pivot vs Direct

As reported in Microsoft's work, pivot-based translation is more robust, especially for directions between low-resource languages since corpora of $X \leftrightarrow Y$ are commonly sparser than $X \leftrightarrow$ English. (Yang et al., 2021) Therefore we use English as the pivot language for African-African translation. For French-African translation, the size of $X \leftrightarrow$ French data is comparable to $X \leftrightarrow$ English. Thus, we train a model for both English and French and choose the better one during inference time.

4.6 Model Averaging

As suggested by other works, model averaging is a simple trick that could significantly improve the performance without changing the model structure or slowing the inference speed. The only cost is the external disk spaces to save intermediate checkpoints, which is trivial compared with GPU and memory costs.

We save the checkpoints every 100 updates of gradients and average the last K checkpoints. By enumerating K from 1 to 20, we find that $K = 10$ is large enough to capture most of the gains.

5 Results

5.1 System Tuning

We tune our model on the FLORES200 devtest dataset, starting with a base model trained on the official data for the constrained track. Then we add more datasets and apply the optimization described above to boost performance. Table 6 reports the averaged BLEU over 56 directions including 24 African languages from and to English and 4 African languages from and to French.

Model Description	BLEU
Base model	16.92
+ NLLB and self-collected data	18.89
+ Data cleaning	19.64
+ Back-translation data	22.85
+ X → English → French	22.95
+ French → English → X †	22.90
+ Yoruba Accent for X → Yoruba	23.20
+ Yoruba Accent for Yoruba → X †	23.17
+ Model Averaging	23.35

Table 6: System tuning on FLORES200 devtest set, averaged BLEU over 56 directions is reported. Superscript † means the modification is not included in the final submission.

We can see that the amount of training data is proportional to the performance of the model, especially when back-translation data is added. For some very low resource languages such as Wolof, back-translation improves Wolof → English from 11.1 to 19.3, and English → Wolof from 4.17 to 7.07.

Another observation is that pivot translation outperforms direct translation for X → French directions, but underperforms for French → X, which indicates that the final step in pivot translation dominates the overall performance.

The impact of Yoruba accent models also shows mixed results. There is a significant improvement for X → Yoruba translation, but a little damage to Yoruba→ X translation. One possible reason is that the non-MAFAND dataset has multiple sources with different accent annotation standards, making the accent model confused. Therefore we only apply post-processing for X → Yoruba translations.

5.2 Final Result

Official evaluation metrics include BLEU, sentence-piece BLEU (spBLEU) score, and chrF++. Table 7 shows the results of our primary submission on FLORES200 dev, FLORES200 devtest set, and hidden test sets respectively. The sentence-piece model for calculating spBLEU is SPM-200 provided by Meta AI [11]

Dataset	BLEU	spBLEU	chrF++
FLORES dev	17.41	21.70	42.01
FLORES devtest	17.43	21.71	41.99
Official test	17.30	21.90	41.87

Table 7: Results of our primary submission on FLORES200 dev, FLORES200 devtest and official test datasets respectively. Metrics are averaged over 100 language pairs.

6 Conclusion

This paper presents our system for the WMT22 shared task on Multilingual Machine Translation for African Languages. We focus on data collection, augmentation, and cleaning. Due to the limited time, we did not try modeling tricks such as reranking and ensemble. Our finding is that the amount of data is crucial for translation quality, especially monolingual data in low-resource languages.

Acknowledgements

We thank Ying Xiong and Yang Wei for building the LightSeq package for this submission. We also thank the GMU-eval team for their effort to make our system work on the evaluation platform.

Abstract

WebCrawl African is a mixed domain multilingual parallel corpora for a pool of African languages compiled by ANVITA machine translation team of Centre for Artificial Intelligence and Robotics Lab, primarily for accelerating research on low-resource and extremely low-resource machine translation and is part of the submission to WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages under the data track. The corpora is compiled through web data mining and comprises 695K parallel sentences spanning 74 different language pairs from English and 15 African languages, many of which fall under low and extremely low resource categories. As a measure of corpora usefulness, a MNMT model for 24 African languages to English is trained by combining WebCrawl African corpora with existing corpus and evaluation on FLORES200 shows that inclusion of WebCrawl African corpora could improve BLEU score by 0.01-1.66 for 12 out of 15 African→English translation directions and even by 0.18-0.68 for the 4 out of 9 African→English translation directions which are not part of WebCrawl African corpora. WebCrawl African corpora includes more parallel sentences for many language pairs in comparison to OPUS public repository. This data description paper captures creation of corpora and results obtained along with datasheet. The WebCrawl African corpora is hosted on GitHub repository [1].

1 Introduction

Parallel corpus play a vital role in the progress of data driven machine translation research and development. Availability of parallel corpora is still a concern for a large collection of world languages. Africa alone is home to an estimated 1200 to 2100 spoken languages[2] and more than 34 languages with 1 Million plus speakers. Many of these 34 languages and associated language pairs fall under the low and extremely low resource categories and machine translation researchers face setbacks due to unavailability of parallel corpus in public domain.

WebCrawl African corpora is a little step put forward towards addressing this issue. Languages covered in WebCrawl African corpora include (1) Afrikaans(afr), (2) Amharic(amh), (3) Chichewa(nya), (4) Hausa(hau), (5) Igbo(ibo), (6) Lingala(lin), (7) Luganda(lug), (8) Oromo(orm), (9) Swahili(swh), (10) Swati(ssw), (11) Tswana/Setswana(tsn), (12) Xhosa(xho), (13) Xitsonga(tso), (14) Yoruba(yor) (15) Zulu(zul) and (16) English and language pairs include African-English and African-African pairs. WebCrawl African is submitted as a part of Large-Scale Machine Translation Evaluation for African Languages shared task(data track) of WMT22 Adelani et al. (2022).

Rest of the paper is organized as follows. Section-2 briefly covers related work on parallel corpora compilation through web data mining. Section-3 covers content collection process followed for WebCrawl African corpora compilation, Section-4 details its alignment processes, Section-5 presents results and analysis. Finally Section-6 presents the datasheet capturing responses to bunch of critical questions capturing many relevant facets of WebCrawl African corpora ranging from motivation, composition, collection process, processing, users, distribution, maintenance and Section-7 conclusion.

2 Related Work

A good amount of translated text are available on the web. However compilation of parallel corpora from web which involves suitable source discovery, sentence extraction, sentence alignment and quality assessment, control is not trivial. Sentence

alignment is the most critical part and alignment techniques range from simple heuristics to neural sentence embedding. Bañón et al. (2020) compiled ParaCrawl corpora from selected websites comprising of 41 languages and Vec/Hun/BLEU-Aligned techniques were used for sentence alignment. Schwenk et al. (2021a) compiled WikiMatrix corpora from Wikipedia articles comprising of 85 languages and used cross-lingual LASER embeddings, distance based measures and FAISS library for fast sentence alignment. Schwenk et al. (2021b) created CCMatrix corpora from snapshots of CommonCrawl comprising of 137 languages and used cross-lingual LASER embeddings, distance based measures, FAISS library and vector compression for fast, storage efficient sentence alignment. Ramesh et al. (2022) compiled Samanantar corpora from selected websites comprising of 11 Indian languages and used LaBSE cross-lingual embeddings, cosine similarity and FAISS library for fast sentence alignment. Philip et al. (2021) proposed an iterative alignment-training-alignment method for expanding corpora of Indian languages.

3 Content Collection through Web Crawling

Creation of parallel corpora through web data mining, by making use of sources of multilingual translated text present on the web has almost became the de-facto technique for its cost effectiveness and scaling advantages. WebCrawl African corpora creation followed similar strategy. As a first step, search has been carried out to discover potential websites having the following characteristics.

- Source website preferably should comprise of large number of text articles published in more than one African languages or/and English.
- Source website should have permissive Copyright T&C and favourable content usage policy.
- Source website should aid in covering diverse information domains, writing styles, genre and contains text covering contemporary language usage etc.
- Source website should have reasonable credibility for ensuring content quality in terms how contents are populated, content review mechanism followed, chances of biases of various forms in hosted content etc.

We ended-up finding four websites namely (1) South African Government[3] comprising of Government communication, (2) Nalibali [4] comprising of multi-genre short stories, (3) Gotquestions[5] comprising of spiritual Q&A and (4) African gospel[6] comprising of song lyrics.

Text content is mined from these four identified websites following four step process.

- Analyze website layout and collect relevant content through suitable web crawler
- Preserve alignment supervision signals such as web-page/document level hyperlinks across languages etc, wherever available
- Extract plain text by stripping of html tags
- If script is latin then apply nltk English sentence tokenizer else manually check sentence delimiter and apply delimiter to tokenize sentences
- Further align sentences following alignment algorithms-1, 2, 3

A relative comparison of 4 websites in terms of their contributions to the WebCrawl African corpora is shown in Figure-1

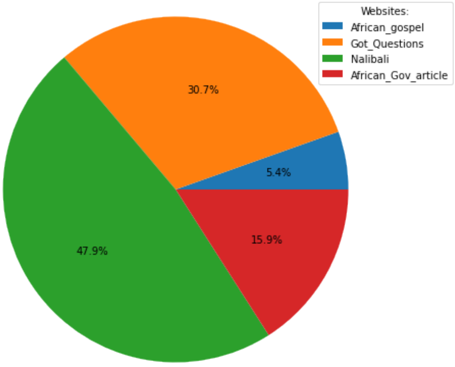

Figure 1: Source wise contributions in the WebCrawl African corpora

4 Alignment of Parallel Sentences

A good alignment strategy is expected to leverage alignment supervision signals available at the source websites. Since hyperlinks connecting

[3] https://www.gov.za/
[4] https://nalibali.org/
[5] https://www.gotquestions.org/
[6] https://africangospellyrics.com/

African and English language web-pages are available in the websites selected, the same is exploited for web-page level alignment and consequently search space for sentence alignment reduced significantly. Two different strategies are employed for sentence alignment duly leveraging the source websites information structure. Algorithm 1 is used for English-African parallel sentence alignment using cross-lingual embeddings and Algorithm 2 3 is used for fast African-African parallel sentence alignment based on common English sentences without using computationally expensive cross-lingual embeddings approach.

4.1 African-English Sentence Alignment

On an average, each web-page is having 200 to 250 sentences and hyperlinks to other language translated pages. Sentences from web-page aligned sources are extracted and segregated into source and target languages. Though web-pages are aligned, this unfortunately does not assure sentence level alignment due to improper sentence tokenization or even translation and format errors at the source. So a distinct need exists for carrying out sentence alignment exercise post segregation. Hence sentences are further aligned based on multilingual sentence encoders LASER[7] provided by the organizer of WMT22 Large-Scale Machine Translation Evaluation for African Languages shared task Adelani et al. (2022) and also heuristics. For a given row/sentence in source side, embeddings of all the target rows/sentences within a dynamic window around the source row is computed and the target row having maximum cosine similarity is selected as the source aligned sentence. Details are described in Algorithm 1. Time complexity of this African-English alignment algorithm depends on window-size. In worst case scenario, window-size can go up to number of source/target sentences and time complexity O(n^2), where n is max(#source sentences, #target sentences). Typically for the web-page aligned sources used, #source sentences or #target sentences range from 200 to 250.

4.2 African-African Sentence Alignment

The strategy employed for aligning African-African parallel sentences utilizes aligned African-English parallel sentences and does a fast alignment based on common English sentences without utilizing expensive cross-lingual embeddings.

5 Results and Analysis

We propose to evaluate the compiled WebCrawl African corpora in three ways. First, we present the distribution of extracted parallel sentences across language pairs. We then assess its usefulness by training a MNMT system for 24 African→English directions and finally compare it with resources available on public domain like OPUS.

5.1 Statistics of WebCrawl African Corpora

WebCrawl multilingual parallel corpora comprises a total of 695K mixed domain parallel sentences distributed non-uniformly over 74 language pairs. The parallel sentences are mined from web-pages/documents such as government notifications, short stories, descriptive answers to spiritual questions and lyrics. The range of sentences varies from around 85 sentences (Hausa-Swati) to 64500 sentences (Swahili-English). For the monolingual corpora, the range varies from around 1,300 sentences for Igbo to 64,500 sentences for Swahili. Primary reason which influenced the number of parallel sentences is non-uniform coverage of text across languages on the websites sourced for the corpora compilation. Number of parallel sentences per language pair is captured in Table-1.

As per Table 1, African languages are relatively rich in vocabulary as compared to English. However this trend is not observed in case of Amharic, Hausa languages. Also its interesting to observe that even though Xhosa is not having the highest number of sentences, but has the highest vocabulary(xho-eng) among all pairs.

5.2 Usefulness of WebCrawl African Corpora

As a measure of corpora usefulness, two MNMT models for 24 African languages to English are trained. First one with the existing corpus and second one by combining WebCrawl African corpora with the existing corpus and both are evaluated on FLORES200 Costa-jussà et al. (2022). Results as shown in Table 2 show that inclusion of WebCrawl African corpora could improve BLEU score by 0.01-1.66 for 12 out of 15 African→English translation directions and even by 0.18-0.68 for the 4 out of 9 African→English translation directions which are not part of WebCrawl African corpora, in spite being a tiny fraction as compared to the existing corpus. Potential reason could be WebCrawl African provides complimentary data to that of available

[7] https://github.com/facebookresearch/LASER/tree/main/tasks/wmt22

Algorithm 1 Algorithm for sentence alignment: African-English languages

```
Input: Tokenized sentences of srcLang(srcSentTok) and tgtLang(tgtSentTok), language encoder provided by organizers(src-lang-encoder),tgt-lang-encoder
Output: Aligned senteces for $srcSentTok$
$nsrc \leftarrow len(srcSentTok)$ , $ntgt \leftarrow len(tgtSentTok)$
$windowSize \leftarrow abs(nsrc - ntgt) + 2$    ▷ abs: absolute value, 2 is added to windowSize as an additional margin to error i.e tokenization error, translator error
$i = 0$
while $i > nsrc$ do
    if $i - windowSize > 0$ and $i + windowSize < nsrc$ then
        $windowSent \leftarrow tgtSentTok[i - windowSize : i + windowSize]$
    else if $i - windowSize > 0$ and $i + windowSize >= ntgt$ then
        $windowSent \leftarrow tgtSentTok[i - windowSize : ntgt]$
    else if $i - windowSize < 0$ and $i + windowSize <= ntgt$ then
        $windowSent \leftarrow tgtSentTok[0 : i + windowSize]$
    else if $i - windowSize < 0$ and $i + windowSize >= ntgt$ then
        $windowSent \leftarrow tgtSentTok[0 : ntgt]$
    end if
    compute vector embedding of $srcEmbed[i] \leftarrow srcLangEncoder(i)$
    for all $j \in windowSent$ do
        compute vector embedding of $windowEmbed[j] \leftarrow tgtLangEncoder(j)$
        compute similarity $cosSimScore[j] \leftarrow cosine\_sim(srcEmbed[i], windowEmbed[j])$
    end for
    $maxind \leftarrow indexofmax(cosSimScore)$
    Required aligned sentence is $srcSentTok[i]$ with $windowSent[maxind]$
    $i = i + 1$
end while
```

Algorithm 2 Algorithm for sentence extraction/alignment: African-African languages

```
Input: parallel sentences of African-lang, English and Other-African-lang, English sentence pairs of all articles
Output: African-African-lang-p-sent, Other-African-African-lang-p-sent
j=0
while $j < len(articles)$ do
    sentence pairs in $j^{th}$ article African-lang-en-p-sent,eng-p-sent and Other-African-lang-en-p-sent,eng-other-p-sent(afr-en pairs extracted from 1)
    Matching_indices = Compute_intersection(eng-p-sent, eng-other-p-sent)
    Align African-African-lang-p-sent, Other-African-African-lang-p-sent based on Matching_indices
    $African - African - lang - p - sent, Other - African - African - lang - p - sent$ are required gold parallel sentence pairs
    $j = j + 1$
end while
```

Algorithm 3 Algorithm for Compute_intersection

```
Input: Sentences of eng-p-sent, Sentences of eng-other-p-sent
edit_threshold = 4
Output: Returns list of tuples. for example [(1,1),(2,4)..] , means edit_distance(eng-p-sent[2], eng-other-p-sent[4]) <=edit_threshold
index1=0
index2=0
while $index1 < len(eng - p - sent)$ do
    while $index2 < len(eng - other - p - sent)$ do
        if edit_distance($eng-p-sent[index1], eng-other-p-sent[index2]) < edit\_threshold$ then
            tuple1 = $(index1, index2)$
            Matching_indices.append(tuple1)
        end if
        $index2 = index2 + 1$
    end while
    $index1 = index1 + 1$
end while
Return Matching_indices
```

in the existing corpus. Both the experiments used identical parameters and corpora used are only the only difference. For training, both WMT22 and WebCrawlAfrican+WMT22 corpus are further filtered using heuristics: (1) either source or target sentence is empty, (2) either source or target sentence length greater than 800 characters, (3) length of source and target sentence ratio is greater than 2.5 or length of source and target sentence ratio is less than 0.4 and (4) source or target sentence contains word having length greater than 10, (5) source or target sentence length is less than 4 and (6) source and target sentences are equal. Transformer with 24 layers of encoder and 6 layers of decoder are used for training both the models.

5.3 Comparison of WebCrawl African with OPUS Repository

A large part of African languages fall under the low and extremely low resource categories and do not have availability of parallel corpus of reasonable size in the public domain. A comparison of WebCrawl African corpora is carried out with the publicly available African parallel corpus listed on OPUS[8] repository in terms of parallel sentences.

Comparison results as captured in Figure-2 shows that out of 15 African-English language pairs compared, WebCrawl-African corpora has more number of parallel sentences for 7 African-English language pairs namely Chichewa-English, Lingala-English, Luganda-English, Oromo-English, Swati-English, Tswana-English, Tsonga-English languages as compared to OPUS public repository at the time of writing this paper. In fact WebCrawl-African corpora has 4 languages namely Chichewa, Luganda, Swati, and Tswana for which OPUS repository doesn't have even a single parallel corpora with any languages. Same goes for a few other African-African language pairs as well.

5.4 Corpora Quality

Though parallel corpora using web data mining approach can be created at scale, controlling quality of such corpora throws a major challenge. Noises ranging from source side errors such as incorrect translation, misspelling, incorrect grammar, biases of various forms and processing errors such as improper sentence tokenization, sentence alignment, additions, deletions etc often are of concern. In case of WebCrawl African corpora, the first choice made is to source content from credible websites, where website content is mostly generated in a controlled manner and contents are further reviewed. Also since the sources used have aligned web-pages so extracted sentence qualities are expected to be relatively better.

However, the authors could not analyze the corpora for translation correctness, biases and other quality metrics due to lack of knowledge on African

[8] https://opus.nlpl.eu/

Table 1: Statistics of WebCrawl African Parallel Corpora. (a,b,c) values in each box represents: $a = sentence\_count * 1000$, $b = unique\_source\_tokens * 1000$ and $c = unique\_target\_tokens * 1000$)

languages. Further human evaluation by language experts could not be carried out due to shortage of time and resources. As far as diversity of domains, genre, writing style and contemporary use of languages are concern, the source websites selected are expected to address them reasonably well. The details are covered in the datasheet presented in the next section.

6 Datasheets for WebCrawl African Corpora

Toward the growing consensus of having systematic dissipation of information on dataset to all its stakeholders by capturing all relevant facets, we followed Gebru et al. (2021) the idea of datasheets for datasets and further its adaptation by Costa-jussà et al. (2020) for MT taks. Datasheet for the WebCrawl African corpora is given below.

6.1 Motivation

(a) Who created the dataset(e.g., which team, research group) and on behalf of which entity (e.g. company, institution, organization)?

WebCrawl African corpora is compiled by ANVITA machine translation team of Centre for Artificial Intelligence and Robotics Lab based in Bangalore.

(b)Did they fund it themselves? If there is an associated grant, please provide the name of the grantor and the grant name and number

WebCrawl African corpora compilation work is fully supported by the Centre for Artificial Intelligence and Robotics Lab. No external grants are received or used for this work.

(c) For what purpose was the data set created?

Table 2: MT performance (BLEU, CHRF2++) with and without WebCrawl African Corpora.[*] Filtered

Was there a specific task in mind? If so, please specify the result type (e.g. unit) to be expected

WebCrawl African corpora is created primarily for accelerating research on low resource and extremely low resource machine translation. This corpora is also part of the submission to WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages under data track.

(d) Could any of these uses, or their results, interfere with human will or communicate a false reality?

No such thing is communicated to the authors. However, as machine translation is not free from biases, errors and may fail to portray actual essence of the translation or portray false, unfair realities, so such things can not be ruled out for WebCrawl African corpora and its usage as well.

(e) What is the antiquity of the file? Provide, please, the current date. The first version of WebCrawl African corpora was released on 10 May 2022. There was no further release till the time of writing this response.

(f) Has there been any monetary profit from the creation of this dataset?

The dataset is created and released mainly to aid research in MT and hoping to be useful for other NLP research as well. It's not for any monetary profit in the past, present and future as well.

6.2 Composition

(a) Is there any synthetic data in the dataset? If so, in what percentage?

WebCrawl African corpora does not contain any synthetic data.

(b) Are there multiple types of instances or is there just one type? Please specify the type(s), e.g. Raw data, preprocessed, symbolic.

WebCrawl African corpora comprises 695K parallel sentences spanning 74 language pairs from 15 African languages and English. African languages covered include Afrikaans(afr), Lingala(lin), Swati(ssw), Amharic(amh), Luganda(lug), Tswana/Setswana(tsn), Chichewa(nya), Hausa(hau), Oroma(orm), Xhosa(xho), Igbo(ibo), Xitsonga(tso), Yoruba(yor), Swahili(swh), and Zulu(zul). Source and Target parallel sentences are part of two separate files having the following naming convention.

Source file : webcrawl-african-{src-lang}-{tgt-lang}.{src-lang}

Target file : webcrawl-african-{src-lang}-{tgt-

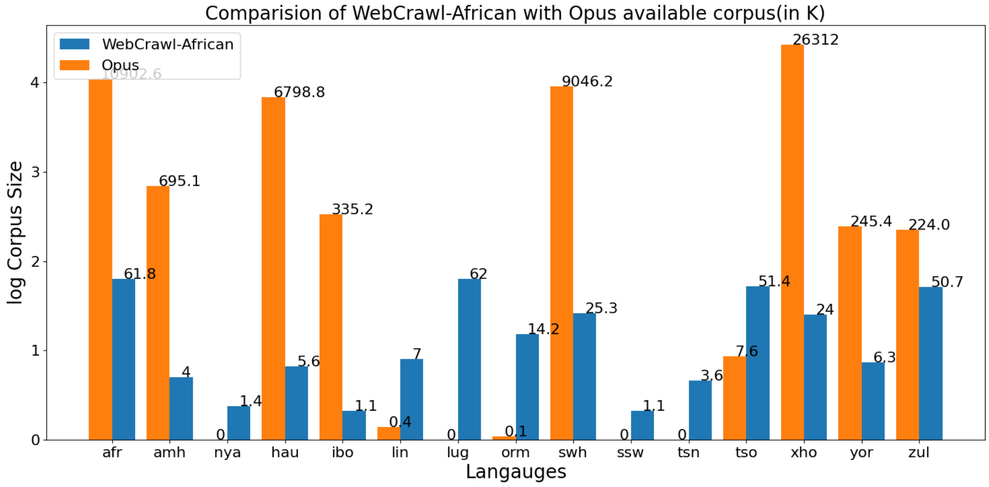

Figure 2: Comparison of WebCrawl-African corpora with the parallel corpus listed on OPUS repository

lang}.{tgt-lang}

src-lang and *tgt-lang* languages correspond to one of the 15 African languages and English part of WebCrawl African corpora and the whole corpora is spread over 148 files in 2 directories.

Monolingual corpora for language *src-lang* is available at *webcrawl-african-{src-lang}-eng.{src-lang}* file.

(c) What do the instances (of each type, if appropriate) that comprise the data set represent? (e.g. documents, photos, people, countries).

Instances represent parallel sentences aligned between two languages and stored in source and target files, following the naming convention mentioned above.

(d) How many instances (of each type, if appropriate) are there in total?

WebCrawl African parallel corpora comprises a total of 695K sentences (instances) distributed non-uniformly over 74 language pairs from 15 African languages and English. The range of sentences varies from around 85 sentences (Hausa-Swati) to 64,500 sentences (Swahili-English).

For the monolingual corpora available, the range of sentences varies from around 1,300 for Igbo to 64,500 sentences for Swahili. Complete count for each language pairs is available at the corpora hosting page `https://github.com/pavanpankaj/Web-Crawl-African`.

(e) Does the dataset contain all possible instances or is it just a sample of a larger set? i.e. Is the dataset different than an original one due to the preprocessing process? In case this dataset is a subset of another one, is the original dataset available?

WebCrawl African corpora is compiled by mining text from websites mentioned, through crawling and following sentence alignment techniques. Therefore, although the corpora is not a subset of any other corpora, it is limited by the text content crawled till the date of released of this corpora.

(f) Is there a label or a target associated with each of the instances? If so, please provide a description.

For any given language pair, a sentence in line number *i* and *Source language file : webcrawl-african-{src-lang}-{tgt-lang}.{src-lang}* will have an aligned target sentence in line number *i* and *Target language file : webcrawl-african-{src-lang}-{tgt-lang}.{tgt-lang}*. There are no other explicit labels associate with instances.

(g) What is the format of the data? e.g. .json, .xml, .csv .

For all language pairs, the aligned source and target sentences are kept in two seperate files following naming conventions mentioned in Section 6.2.(b) and all files are in UTF-8 plain text format.

(h) Is any information missing from individual instances? If so, please provide a description, explaining why this information is missing (e.g. because it was unavailable). This does not include intentionally removed information, but might include, e.g. redacted text.

No such thing is reported. However, due to the automated techniques employed for corpora creation, some sentences may have missing words. Also there are language pairs for which no parallel sentences are present, for example Lingala does not have any language pairs with all other African languages included in WebCrawl African corpora.

(i) Are there any errors, sources of noise, or redundancies in the dataset? If so, please provide a description. Do not include missing information here.

No such thing is reported. However, due to the automated techniques employed for corpora creation, sentence misalignment error and misalignment induced noises in small proportion can not be ruled out. Additionally, content collected from African Gospel lyrics website where the content is generated through crowdsourcing with not so strict content review mechanism may have noises ranging from misspelling, grammatical errors and use of informal writings.

(j) Is there any verification that guarantees there is not institutionalization of unfair biases? Both regarding the dataset itself and the potential algorithms that could use it.

No such study is carried out or mechanism employed to assess and address corpora biases. Corpora is compiled by mining text from websites mentioned and inherited biases can not be ruled out. So both WebCrawl African corpora and translation algorithms could present biases.

(k) Are there recommended data splits, e.g. training, development/validation, testing? If so, please provide a description of these splits explaining the rationale behind them.

No specific splits are recommended.

(l) Is the dataset self-contained, or does it link to or otherwise rely on external resources? e.g., websites, tweets, other datasets. If it links to or relies on external resources, i) Are there any guarantees that they will exist, and remain constant over time? ii) Are there official archival versions of the complete dataset? i.e. including the external resources as they existed at the time the dataset was created. iii) Are there any restrictions (e.g. licenses, fees) associated with any of the external resources that might apply to a future user? Please provide descriptions of all external resources and any restrictions associated with them, as well as links or other access points, if appropriate.

WebCrawl African corpora is self-contained and hosting page as mentioned contains the complete corpora.

(m) Does the dataset contain data that might be considered confidential? e.g. data that is protected by legal privilege or by doctor patient confidentiality, data that includes the content of individuals non-public communications. If so, please provide a description.

Corpora is compiled by mining text available in the public domain. So such a presence is unlikely.

(n) Does the dataset contain data that, if viewed directly, might be offensive, insulting, threatening, or might otherwise cause anxiety? If so, please describe why.

Website content sourced for compiling corpora is meant for public consumption and genre includes government communication, short children stories, religious text and lyrics. So such anti-social content is unlikely. However, no review of the corpora is carried out from the perspective in question.

(o) Does the dataset relate to people? If so, please specify a) Whether the dataset identifies subpopulations or not. b) Whether the dataset identifies individual people or not. c) Whether it contains information that could vulnerate any individuals or their rights. c) Any other verified information on the topic that can be provided.

WebCrawl African corpora is compiled from open source content meant for public consumption and likely to reference people for the cause that made them appear publicly. Corpora does not include and express anything new which is not there in the public domain. However, no formal review of the corpora is carried out from the perspective in question.

(p) Does the dataset cover included languages equally?

Size of both parallel and monolingual corpora is not same for all the languages and language pairs included. Primary reason is the non-uniform coverage of text across languages on the websites sourced for the corpora compilation.

(q) Is there any evidence that the data may be somehow biased? i.e. towards gender, ethics, beliefs.

No study is carried out or mechanism employed to assess and address corpora biases. The corpora is compiled by mining text content available on the websites mentioned and inherited biases can not be ruled out.

(r) Is the data made up of formal text, informal text or both equitably?

WebCrawl African corpora comprises mostly formal text. However there are instances of informal content primarily coming from lyrics mined from African Gospel Lyrics website.

(s) Does the data contain incorrect language expressions on purpose? Does it contain slang terms? If that's the case, please provide which instances of the data correspond to these.

Given the genre of content hosted by the websites sourced for this corpora mining, such contents are unlikely. However, no review of the corpora is carried out from the perspective in question.

6.3 Collection Process

(a) Where was the data collected at? Please include as much detail; i.e. country, city, community, entity and so on.

WebCrawl African corpora is compiled by mining content hosted by websites (1) South African Government `https://www.gov.za/`, (2) Nalibali `https://nalibali.org/`, (3) Gotquestions `https://www.gotquestions.org/` and (4) African gospel `https://africangospellyrics.com/`. Websites comprise of text content covering government communication, multi-genre short stories, answers to spiritually related questions and gospel lyrics. A large part of it presumably written by the government officials, subject experts and volunteers primarily from the African countries and to some extent may be by the African speaking people from other countries. So data might be considered to have originated primarily from the African countries and other places around the globe as well. However, corpora compilation is carried out by the ANVITA team at Centre for Artificial Intelligence and Robotics, Bangalore.

(b) If the dataset is a sample from a larger set, what was the sampling strategy? i.e. deterministic, probabilistic with specific sampling probabilities.

WebCrawl African corpora is compiled by mining text content available on websites mentioned. The corpora is not a subset of any other corpora and no specific sampling was performed. However content is limited by the text crawled until the date of release of corpora.

(c) Are there any guarantees that the acquisition of the data did not violate any law or anyone's rights?

Websites having permissible copyright T&C and favourable content usage policy are used at the first place for content acquisition. Source websites permit usage and distribution of content for non-commercial, not-for-profit and fair use with due source acknowledgement. WebCrawl African corpora is hence released under CC-BY-NC-SA license for research purpose after intimation and with source acknowledgement. As long as WebCrawl African corpora license and source website copyright T&C and content usage policy is followed, one should safely assume that corpora acquisition and usage are unlikely to violate any laws or rights. Neither ANVITA team nor Centre for Artificial Intelligence and Robotics Lab holds any copyright over the WebCrawl African corpora. However, any derivatives of the corpora must acknowledge all sources including team ANVITA.

(d) Are there any guarantees that prove the data is reliable?

WebCrawl African corpora is created in an automated fashion without human verification like most of the large scale parallel corpora, thereby making it hard to guarantee provable reliability. However, as corpora is compiled by mining websites where content is mostly generated in a controlled manner and reviewed, makes the corpora reasonably reliable.

(e) Did the collection process involve the participation of individual people? If so, please report any information available regarding the following questions: Was the data collected from people directly? Did all the involved parts give their explicit consent? Is there any mechanism available to revoke this consent in the future, if desired?

As stated, content for the corpora compilation is directly sourced from websites mentioned and without direct participation of individual people.

(f) Has an analysis of the potential impact of the dataset and its use on data subjects been conducted? i.e. a data protection impact analysis. If so, please provide a description of this analysis, including the outcomes, as well as a link or other access point to any supporting documentation. Neither such analysis is conducted nor any communication received on the subject.

(g) Were any ethical review processes conducted?

No ethical review processes were conducted.

(h) Does the data come from a single source or is it the result of a combination of data coming from different sources? In any case, please provide references.

WebCrawl African corpora is compiled by mining content hosted by four websites (i) South African Government `https://www.gov.za/`, (ii) Nalibali `https://nalibali.org/`, (iii) Gotquestions `https://www.gotquestions.org/` and (iv) African gospel `https://africangospellyrics.com/`. Websites comprise of text content covering government communication, multi-genre short stories, answers to spiritually related questions and gospel lyrics and contributed in creating mixed domain corpora. However, compilation is carried out by the ANVITA team.

(i) If the same content was to be collected from a different source, would it be similar?

It's likely to be similar if the content collected has a similar topic, genre, writing style and content distributions.

(j) Please specify any other information regarding the collection process. i.e. Who collected the data, whether they were compensated or not, what mechanisms were used. Please, only include if verified.

Content acquisition and corpora compilation is carried out by ANVITA team using a four steps process.

(i) Identification of websites based on content coverage, copyright T&C, usage policy and credibility.

(ii) Analysis of website layout and collection of relevant content through crawling preserving webpage/document level alignment signals, wherever available.

(iii) Extraction of plain text by stripping of html tags and splitting of text at sentence level

(iv) Alignment of parallel sentences across language pairs

6.4 Processing/Cleaning/Labelling

(a) Please specify any information regarding the preprocessing that you may know (e.g. the person who created the dataset has somehow explained it) or be able to find (e.g. there exists and informational site). Please, only include if verified. i.e. Was there any mechanism applied to obtain a neutral language? Were all instances preprocessed the same way?

WebCrawl African corpora is available as sentence aligned files. Preprocessing steps on raw crawled web-pages include striping off html tags, sentence tokenization and sentence alignment. Sentence alignment was carried out based on cross-lingual embeddings using LASER encoder and heuristics to a large extent. The entire corpora is preprocessed in the same way. No word/subword/character level tokenization or other pre-processing like filtering on parallel sentences were carried out. However, further filtering based on heuristics similar to the one used by the authors for training MT models may be carried out for better performance.

6.5 Users

(a) Has the dataset been used already? If so, please provide a description.

WebCrawl African corpora is used as a resource for the WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages Adelani et al. (2022). This corpora is also used by the ANVITA team for training MT model and results are presented in this paper.

(b) When was the dataset first released?

The initial release of WebCrawl African corpora was 10 May 2022.

(c) Is there a repository that links to any or all papers or systems that use this dataset? If so, please provide a link or any other access point.

WMT event is supposed to present a findings paper for the 2022 edition that may include such reference. Also corpora hosting page is likely to maintain such repository.

(d) What (other) tasks could the dataset be used for? Please include your own intentions, if any.

WebCrawl African corpora is primarily intended for machine translation tasks. It can also be used as monolingual corpora for tasks such as language modeling, corpus based language studies and few other NLP tasks with additional annotations.

(e) Are there tasks for which the dataset should not be used? If so, please provide a description.

There is no explicit task where this corpora should not be used. However, use of WebCrawl African corpora is not recommended as a benchmark corpora.

(f) Any other comments? i.e. Do the collection or preprocessing processes impact future uses?)

Like any large parallel corpora, WebCrawl African corpora is created in an automated fashion without human verification.

6.6 Distribution

(a) Please specify the source where you got the dataset from.

As mentioned, WebCrawl African corpora is compiled by mining text from web-pages hosted by (i) South African Government https://www.gov.za/, (ii) Nalibali https://nalibali.org/, (iii) Gotquestions https://www.gotquestions.org/ and (iv) African gospel https://africangospellyrics.com/

(b) When was the dataset first released?

WebCrawl African corpora was first released on 10 May 2022.

(c) Are there any restrictions regarding the distribution and/or usage of this data in any particular geographic regions?

No, there are no such restrictions.

(d) Is the dataset distributed under a copyright or other intellectual property (IP) license? And/or under applicable terms of use (ToU)? Please cite a verified source.

WebCrawl African Corpora distributed under CC-BY-NC-SA license. Barring commercial use, the license allows mostly unrestricted fair usage.

(e) Any other comments? i.e. How has the data been distributed? Who has access to the dataset? When was the dataset first distributed? Are there any other regulations on the dataset?

WebCrawl African Corpora is distributed through GitHub public hosting at https://github.com/pavanpankaj/Web-Crawl-African and also WMT 2022 website at https://www.statmt.org/wmt22/large-scale-multilingual-translation-task.html since 10 May 2022 under CC-BY-NC-SA license.

6.7 Maintenance

(a) Is there any verified manner of contacting the creator of the dataset?

All queries on WebCrawl African corpora should be sent to Pavan Pankaj Vegi at pavanpankaj333@gmail.com and Biswajit Paul at biswajit.cair@gov.in.

(b) Specify any limitations there might be to contributing to the dataset. i.e. Can anyone contribute to it? Can someone do it at all?

Scope exists for extending the corpora with additional parallel sentences and language pairs, specifically involving low and extremely low resource languages. Contribution can be done by contacting ANVITA team members at pavanpankaj333@gmail.com and biswajit.cair@gov.in

(c) Has any erratum been notified?

No erratum has been notified.

(d) Is there any verified information on whether the dataset will be updated in any form in the future? Is someone in charge of checking if any of the data has become irrelevant throughout time? If so, will it be removed or labeled somehow?

WebCrawl African corpora is likely to be updated with additional parallel sentences in future by the ANVITA team. Though chances of corpora becoming irrelevant in near future are less likely, but if it happens, hosting page https://github.com/pavanpankaj/Web-Crawl-African will reflect the right status.

(e) Is there any available log about the changes performed previously in the dataset?

Not applicable, as the current version is the first version. However, log of future changes will be recorded at the corpora hosting page https://github.com/pavanpankaj/Web-Crawl-African

(f) Could changes to current legislation end the right-of-use of the dataset? WebCrawl African corpora is published under CC-BY-NC-SA license. We do not foresee any right-of-use changes in future.

(g) Any other comments? i.e. Is there someone supporting/hosting/maintaining the dataset? If the dataset relates to people, are there applicable limits on the retention of the data associated with the instances?

Webcrawl African corpora is hosted at https://github.com/pavanpankaj/Web-Crawl-African and likely to be maintained by the ANVITA team..

7 Conclusion

This paper presented detailed description of WebCrawl African corpora. The paper also describes approach and design choices to systematically create parallel corpora and extend the WebCrawl African corpora through web data mining and alignment. WebCrawl African corpora compiled comprises 695K parallel sentences spanning 74 different language pairs from English and 15 African languages, many of which fall under low and extremely low resource categories. Webcrawl African corpora is hosted at https://github.com/pavanpankaj/Web-Crawl-African for non-commercial, not-for-profit and fair use. This corpora comprises sentences from multiple domains and includes government communication, short children stories, religious text and lyrics. Though human verification of the corpora was not carried out but favourable characteristics of selected source websites aided to address some of the quality concerns relatively better.

Experiments and evaluation of results show that inclusion of WebCrawl African corpora with WMT 2022 corpus has improved BLEU score by 0.01-1.66 for 12 out of 15 African→English translation directions and even by 0.18-0.68 for the 4 out of 9 African→English translation directions which are not part of WebCrawl African corpora and also it has more parallel sentences for many language pairs in comparison to OPUS public repository.

WebCrawl African corpora is primarily intended for machine translation tasks, specially for accelerating research on low resource and extremely low resource machine translation. It can also be used as monolingual corpora for tasks such as language modeling, corpus based language studies and few other NLP tasks with additional annotations.

Acknowledgements

The authors would like to thank Director, CAIR for his constant encouragement, guidance and enablement.

Abstract

This paper describes ANVITA African NMT system submitted by team ANVITA for WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages under the constrained translation track. The team participated in 24 African languages to English MT directions. For better handling of relatively low resource language pairs and effective transfer learning, models are trained in multilingual setting. Heuristic based corpus filtering is applied and it improved performance by 0.04-2.06 BLEU across 22 out of 24 African→English directions and also improved training time by 5x. Use of deep transformer with 24 layers of encoder and 6 layers of decoder significantly improved performance by 1.1-7.7 BLEU across all the 24 African→English directions compared to base transformer. For effective selection of source vocabulary in multilingual setting, joint and language wise vocabulary selection strategies are explored at the source side. Use of language wise vocabulary selection however did not consistently improve performance of low resource languages in comparison to joint vocabulary selection. Empirical results indicate that training using deep transformer with filtered corpora seems to be a better choice than using base transformer on the whole corpora both in terms of accuracy and training time.

1 Introduction

Africa is very rich in languages, and around 1200 to 2100 languages are spoken in African countries[1], 24 African languages and 100 language pairs were selected for the WMT22 Large-Scale Machine Translation Evaluation for African Languages shared task Adelani et al. (2022b). Selected 24 African languages include Afrikaans(afr), Amharic(amh), Chichewa(nya), Hausa(hau), Igbo(ibo), Kamba(kam), Kinyarawanda(kin), Lingala(lin), Luganda(lug), Luo(luo), Nigerian Fulfulde(fuv), Northern Sotho(nso), Oromo(orm), shona(sna), Somali(som), Swahili(swh), Swati(ssw), Setswana(tsn), Umbundu(umb), Wolof(wol), Xhosa(xho), Xitsonga(tso), Yoruba(yor) and Zulu(zul) and language pairs include African-English, selective African-French, and African-African pairs, where many of the pairs fall under the low resource category. In this task, organizers permitted two submissions, Best scoring submission is considered as Primary model and other one being the Contrastive model. This paper describes our submission to WMT 2022 Large-Scale Machine Translation Evaluation for African Languages shared task where we participated for translation of 24 African languages to English. We are not officially given a rank as we didn't participate in all African MT directions.

2 Related Work

Developing quality machine translation system for low resource languages still remains a major challenge and many of the world languages fall under this category. Some of the recent developments do show that multilingual NMT is a promising direction. In massively multilingual neural machine translation, the authors have shown to train a single model for translating 102 languages to and from English and the results outperformed the strong bilingual baseline MT system especially for low resource languages Johnson et al. (2017). However, it cannot be generalized to all high and medium resource languages. Gowda et al. (2021) built a multilingual neural machine translation system capable of translating from 500 source languages to English which includes medium, low and extremely low resource languages. Zhang et al. (2020a) improved zero-shot translation in multilingual neural machine translation by random back translation. Kudugunta et al. (2019) have shown that represen-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1090 - 1097
December 7-8, 2022 ©2022 Association for Computational Linguistics

tations of high resource and/or linguistically similar languages are more robust when fine-tuning on an arbitrary language pair, which is critical to determining how much cross-lingual transfer can be expected in a zero or few-shot setting.

Zhou et al. (2021) shown deep architectures for neural machine translation and post ensemble have shown improved results on machine translation tasks. Zhang et al. (2020b) presented language independent heuristics for filtering noisy pairs from parallel corpus. Yang et al. (2021) proposed progressive training, in which the MT system is trained from shallow to deep architectures - increasing number of encoder and decoder layers. However, major improvement is observed while increasing encoder layers. Adelani et al. (2022a) created novel African corpus for 16 African languages and finetuned on pre-trained large MT models. Fan et al. (2021) demonstrated massively multilingual machine translation by training a single model that can translate between any pair of 100 languages.

3 Datasets

We used all the parallel corpora provided by WMT 2022 organizer. Corpus contain existing OPUS repository Tiedemann (2012), WMT 2022 novel corpus[2] and comprises of sources such as wikimedia, CCMatrix, CCAligned, bible-uedin, GNOME, XLEnt, QED,KDE4, mozilla-I10n, SPC, TED2020, Tatoeba, ELRC_2922, OpenSubtitles, Ubuntu, LAVA corpus2, MAFAND-MT Adelani et al. (2022a), KenTrans Wanzare et al. (2022), Kencorpus McOnyango et al. (2022), WebCrawl-African[3] and huggingface (provided by organisers) etc. Tiedemann (2012). Combining all a total 140 Million parallel sentences for the 24 African-English language pairs are extracted.

Language wise statistics of corpus used in our system is listed in Table 1.

4 System Overview

ANVITA African MT system comprises of two major sub systems: Data preprocessing and Model training under different strategies and architectural configurations followed by evaluation.

4.1 Data Preprocessing

As part of data preprocessing, we removed potentially noisy sentence pairs using the heuristics presented in Data Filtering subsection. To handle rare words and out of vocabulary words in the corpus we tokenized the training data using sentencepiece Kudo and Richardson (2018).

4.1.1 Data Filtering

As most of the corpora is extracted by automated techniques, there are chances of presence of noisy sentence pairs in the corpus. As transformer is known to be sensitive to corpus noise Liu et al. (2019) rigorous filtering was performed on the corpus based on heuristics adopted from Li et al. (2019), Vegi et al. (2021) and Pinnis (2018). Details of the heuristics used are listed below.

- F0: Filter out sentence pair, in which either source or target sentence is empty.
- F1: Filter out sentence pair, in which either source or target sentence length greater than 800 characters.
- F2: Filter out sentence pair in which length of source and target sentence ratio is greater than 2.5.
- F3: Filter out sentence pair in which length of source and target sentence ratio is less than 0.4.
- F4: Filter out sentence pair, if source or target sentence contains word having length greater than 10.
- F5: Filter out sentence pair, if source and target sentences are equal.
- F6: Filter out sentence pair, if source or target sentence length is less than 4.

Corpus statistics after applying heuristics based filtering is given in Table 1. By applying heuristics, approximately 31% of total parallel sentences amounting to 44802801 are removed as they are potentially noisy pairs. Relative impact of each filter is also captured in Table 1. Heuristics chosen are language agnostic but there is always a room for corpus and language dependent heuristics, specifically the threshold values.

Experiments are carried out to observe the effect of data filtering (Configuration B vs Configuration A). Configuration A and B are discussed in detail in section 5.

4.1.2 Tagging of Source Sentences

As most of the African languages follow Latin script, so as to tag input sentences based on languages we have added special tokens at the source side similar to Vegi et al. (2021). Tokens are generated using special symbols of length 4. Special symbols are used to avoid overlapping of tags with language vocabularies.

4.2 Vocabulary Selection

We experimented with various configurations of source side sentencepiece subword vocabularies. However, for target side we fixed sentence piece subword vocabulary size to 16K for all the configurations.

Source side vocabulary estimation is done based on the work of Gowda and May (2020), where it is shown that for low resource languages optimal BLEU score is obtained for relatively smaller subword vocabulary of size between 4K to 6K. Also as most of the African languages follow Latin script, there are also chance of large vocabulary(subword) overlap among the languages.

1. Source side vocabulary is set to 100K, jointly for all 24 languages and used in Configurations A,B,C and D. Please refer to Section 5 for more details on Configurations.

2. Language wise 4K to 6K subword vocabulary based on language corpus size, where 6K is used for the languages having more than 1 million sentence pairs and 4K for languages having less than 1 million size. Though it is expected a total vocabulary of around 130K but we obtained 75K combined vocabulary as there are many common subword vocabulary among languages. This is used in Configuration E.

3. We experimented with increasing source side joint vocabulary from 100K to 144K in which 120K subword vocabulary for top 18 high resource languages and remaining 24K for the remaining 6 languages.

4.3 Model Training

ANVITA African MT system used base transformer, deep transformer, ensemble techniques and used fairseq framework for training Ott et al. (2019).

4.3.1 Base Transformer: 6x6

Training configuration follows base transformer similar to Vaswani et al. (2017) and used 6 encoder and 6 decoder layers. Base transformer model is trained on all corpora provided by the organizer except WebCrawl African corpora.

4.3.2 Deep Transformer: 24x6

Training used 24 encoder and 6 decoder layers for 10 epochs with batch size 10240, dropout 0.3, word embedding size of 1024, adam optimizer, update-freq 8, heads 8, encoder and decoder feed forward dimension of 4096, batch type tokens, warm-up steps 4000, learning rate $5e^{-4}$. Training configurations are adopted from Yang et al. (2021). Constrained and Primary models are trained on all corpora provided by Organizers except WebCrawl

African corpora.

4.3.3 Ensemble

We ensembled last two epochs of Deep Transformer 24x6 i.e 11,12 and this was our primary submission for the shared task.

5 Experimental Evaluation and Result Analysis

Experiments carried out for 6 distinct configurations to assess effect of filtering, deep transformer and strategies used for vocabulary selection.

5.1 Configurations

- Configuration A: Experiment is carried out for 10 epochs on Base Transformer architecture with 6 encoder and 6 decoder layers with out applying data filtering on all corpus provided by WMT 22 except WebCrawl African corpora.

- Configuration B: Experiment is carried out for 10 epochs on Base Transformer architecture with 6 encoder and 6 decoder layers with heuristic based filtering on all corpus provided by WMT 22 except WebCrawl African corpora.

- Configuration C: Experiment is carried out for 10 epochs on Deep Transformer architecture (as discussed in 4.2.2) with 24 encoder and 6 decoder layers with heuristic based filtering on all corpus provided by WMT 22 except WebCrawl African corpora.

- Configuration D: Experiment is carried out for 10 epochs on Deep Transformer architecture (as discussed in 4.2.2) with 24 encoder and 6 decoder layers with heuristic based filtering on all corpus provided by WMT 22 including WebCrawl African corpora.

- Configuration E: Experiment is carried out for 10 epochs on Deep Transformer architecture (as discussed in 4.2.2) with 24 encoder and 6 decoder layers with heuristic based filtering and language wise subword vocabulary(as discussed in 4.1.2) on all corpus provided by WMT 22 including WebCrawl African corpora.

- Configuration F: Configuration C is carried out for 2 more epochs (i.e. 11 and 12) and applied ensembling of last 2 epochs i.e. 11 and 12.

5.2 Results and Analysis

ANVITA African→English MT system was evaluated on standard Flores200 dataset Costa-jussà et al. (2022) and evaluation was also done by the organizer of Large-Scale Machine Translation Evaluation for African Languages task on blind test sets Adelani et al. (2022b). Results of both the experiments are given below Tables 2 and 3. Configuration-F is our primary submission and Configuration-C is our Contrastive submission to the WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages. Due to computational and time constraints we were not able to submit a model with WebCrawl African corpora as a primary/constrained submission. All the experiments carried out on Nvidia RTX 8000 48GB single GPU system. Training base transformer (6×6) without filtering and with filtering took approximately 400 hours and 80 hours respectively for 10 epochs. Remaining all experiments used deep transformer took around 290 hours for 10 epochs.

Table 2 shows the results obtained when experiments are carried out with configurations A,B,C,D,E, and F.

In the following subsections, key insights obtained using configurations A,B,C,D, and E are presented with respect to effect of filtering, deep transformer, and individual language wise subword vocabulary selections. However Configuration F is not compared against other configurations, as Configuration F is a replica of Configuration C with 12 epochs and did not use WebCrawl African corpora.

5.2.1 Effect of Filtering: Configuration A vs B

1. Heuristic based filtering has shown significant improvement on BLEU and CHRF2++ ranging from 0.04-2.06 and 0.23-1.55 respectively on all 22 out of 24 African → English language directions.

2. Reduced training time from 400 hours (Configuration A) to 80 hours (Configuration B).

3. Decrease in BLEU score and CHRF2++ for two languages namely Nigerian Fulfulde(fuv) and Wolof(wol).

5.2.2 Effect of Deep Transformer: Configuration B vs C

1. Deep transformer architecture (Configuration C) has shown significant improvement on BLEU and CHRF2++ ranging 1.12-7.7 and 2.19-7.89 respectively on all 24 African → English language directions.

2. As expected, it increased training time from 80 hours (Configuration B) to 290 hours (Configuration C), but still less than base transformer training time without filtering.

5.2.3 Effect of inclusion of WebCrawl African: Configuration C vs D

1. Inclusion of Our corpora-3, WebCrawl African (Configuration D) has shown improvement on BLEU ranging 0.01-1.66 for 12 out of 15 African→English translation directions and even by +0.18-0.68 for the 4 out of 9 African→English translation directions. However there is a marginal decrease in remaining African→English directions.

2. Inclusion of Our corpora-3, WebCrawl African (Configuration D) has shown improvement on CHRF2++ ranging 0-1.48 on 19 African → English language directions, however there is a marginal decrease in remaining directions.

5.2.4 Effect of ISV (Individual Subword Vocabulary): Configuration D vs E

ISV (Configuration E) has shown significant improvement on few language directions, however there is a marginal decrease of BLEU and CHRF2++ in majority of the directions and specifically 17 and 19 out of 24 respectively.

It is observed that increase of source side joint vocabulary beyond 100K does not improve performance and in fact decrease in BLEU score is observed for majority of the languages. Also use of language wise vocabulary selection did not consistently improve performance of low resource languages in comparison to joint vocabulary selection.

5.3 Comparison With Available Models

To the best of our knowledge, results using a single multilingual model covering all the 24 African languages to English is not available. Often meaningful comparison becomes hard as not all the reported results use same test-set used here. Yang et al. (2021) trained NMT model for translating

Table 3 Results of African to English models on blind test set from Organizer
Tran: Transformer, (n): refers to n epochs, blind:refers to blind test set used by Organizer for evaluation, prim: primary model submitted to the task, Contras: Contrastive model submitted to the task,

101 languages from any to any directions and 12 out of 24 translation directions part of our submission are in common. Comparison on FLORES shows our model produced an improved results for 7 out of 12 African→English directions namely {Hausa, Chichewa, Swahili, Xhosa, Yoruba, Zulu }→English. Emezue and Dossou (2021) trained many to many models for African languages and 5 out 24 African translation directions part of our submission are in common. Our model showed an improvement for all the common 5 African→English directions namely {Igbo, Kinyarwanda, Xhosa, Yoruba, Swahili}→English.

6 Conclusion

This paper describes our submission to WMT 2022 shared task on Large-Scale Machine Translation Evaluation for African Languages under the constrained translation track. We focused on 24 African languages to English MT directions. Multilingual model with deep transformer showed significant improvement in BLEU and CHRF2++ scores across all 24 African to English MT directions. Vocabulary size of 4K to 6K per language for estimating size of joint source vocabulary seems to be a good choice in a multilingual setup. Heuristic based filtering did improve the BLEU scores. However the biggest gain of filtering observed is in terms of training time speed up by 5x. Empirical results indicate that training using deep transformer with filtered corpora seems to be a better choice than using base transformer on the whole corpora both in terms of MT accuracy and training time.

Abstract

This paper describes the submissions of Huawei translation services center (HW-TSC) to the WMT22 Very Low Resource Supervised MT task. We participate in all 6 supervised tracks including all combinations between Upper/Lower Sorbian (Hsb/Dsb) and German (De). Our systems are build on deep Transformer with a large filter size. We use multilingual transfer with German-Czech (De-Cs) and German-Polish (De-Pl) parallel data. We also utilize regularized dropout (R-Drop), back translation, fine-tuning and ensemble to improve the system performance. According to the official evaluation results on OCELoT[1], our supervised systems for all 6 language directions got the highest BLEU scores among all submissions. Our pre-trained multilingual model for unsupervised De2Dsb and Dsb2De translation also gains the highest BLEU.

1 Introduction

In this paper, we describe our very low resource supervised MT systems for all combinations between Hsb, Dsb and De. We first select a base pre-trained multilingual model and then fine-tune it. As we focus primarily on the supervised task, we only apply our pre-trained multilingual system with zero-shot for unsupervised task submissions.

As show in WMT21 shared task (Libovický and Fraser, 2021), most participants use De-Cs for transfer or combine De-Cs with the low resource pairs to build a multilingual system. Fine-tuning based on a multilingual pre-trained (Fan et al., 2020) model has shown very promising results for low resource tasks. We add De-Pl data and train our multilingual pre-trained model to transfer the low resource pairs.

This paper is structured as follows: we describe our data source and data pre-processing method in section 2. We detail the model structure and method we used in Section 3. We then present the final experiments in Section 4 and Section 5, and finally we conclude our work in Section 6.

2 Dataset

2.1 Data Source

For our base pre-trained multilingual systems, we use all the bilingual data (De-Cs and De-Pl) from the latest version of OPUS. We also sample 20M German monolingual data from news (general) MT task for augmentation. For fine-tuning the systems transfer to our task, we use all the bilingual and monolingual data officially provided without any filtering strategy. We use dev set and test set together for model parameter adjustment and system selection (do not include the blind test data from the previous years).

2.2 Data Pre-processing

For all the data mentioned above, we remove duplicate sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).

For De-Cs and De-Pl, the data pre-processing procedure is as follows:

- Remove sentences with mismatched parentheses and quotation marks.
- Filter out sentences of which punctuation percentage exceeds 0.4.
- Filter out sentences with a character-to-word ratio greater than 12 or less than 1.5.
- Filter out sentences with more than 150 words.
- Apply langid (Joulin et al., 2017, 2016) to filter out sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter out sentence pairs that are poorly aligned.

Table 1: The data sizes of before and after pre-processing in our very low resource supervise MT Task

We sample 3.2M Cs and Pl data from bilingual data and up-sampling 3.2M De, Hsb, Dsb from a combined dataset of all the three languages. We mix the data above and build a joint SentencePiece model (SPM) (Kudo and Richardson, 2018; Kudo, 2018) for word segmentation, with a vocabulary of 40k. We use Moses tokenizer (Koehn et al., 2007) to pre-segment sentences. We also use the combined data to build a joint vocabulary for all of our models. The vocabulary size is slightly larger than SPM vocabulary to cover more tokens, which is set to 41k.

3 System Overview

3.1 Model

Transformer (Vaswani et al., 2017), as the current mainstream architecture of NMT, adopts a fully self-attention mechanism, which can realize algorithm parallelism, speed up model training, and improve model performance. Deep transformer is an variant of Transformer, which increases the number of encoder layers and uses pre-layer-normalization to further improve model performance. Therefore, in all translation tasks, we adopt the following model architecture:

- Deep Transformer (Wei et al., 2021): We refer to the Transformer-big model architecture and decrease the dim for faster training. our Deep Transformer model features pre-layer-normalization, 35-layer encoder, 6-layer decoder, 16-head self-attention, 768-dimension word embedding and 3072-hidden-state.

3.2 Multilingual Transfer

Recent researches have shown that multilingual models outperform their bilingual counterparts, particularly when the number of languages in the system is limited and those languages are related (Lakew et al., 2018). This is mainly due to the capability of the model to learn interlingual knowledge (shared semantic representation between languages) (Johnson et al., 2016) (Ranathunga et al., 2021). Transfer learning using pre-trained multilingual model (Fan et al., 2020) has shown very promising results for low resource tasks. In this task, we first select a multilingual system as the base system, then fine-tune the system with low resource language pairs.

3.3 R-Drop

Dropout (Srivastava et al., 2014) is a powerful and widely used technique for regularizing deep neural networks. Though it can help improve training effectiveness, the randomness introduced by dropouts may lead to inconsistencies between training and inference. R-Drop (Wu et al., 2021) forces the output distributions of different sub models generated by dropout be consistent with each other. Therefore, we use R-Drop to augment the pre-trained multilingual model for each track and reduce inconsistencies between training and inference.

3.4 Back Translation

Back translation (BT) (Edunov et al., 2018) refers to translating the target monolingual data into the source language, and then using the synthetic data to increase the training data size. This method has been proven effective to improve the NMT model performance. We apply sampling(Graça et al., 2019) back-translation for all language directions.

4 Experimental Settings

During the training phase, we use Pytorch-based Fairseq[2] (Ott et al., 2019) open-source framework. Each model is trained using 8-V100 with a batch size of 2048 tokens for each GPU. Dropout was set to 0.1 for pre-train multilingual model, and 0.3 for fine-tuning model. The label smoothing rate (Szegedy et al., 2016) is 0.1. Adam optimizer (Kingma and Ba, 2015) with $\beta 1$=0.9 and $\beta 2$=0.98 is also used. Furthermore, we use reg_label_smoothed_cross_entropy as the loss function and set reg-alpha to 5 when applying R-

Table 3: Avg. scores on WMT21 dev set, test set and WMT22 dev set for De↔Dsb.

Drop training strategy. For pre-training the multilingual model, the update frequency, the learning rate and warm-up steps are 4, 5e-4 and 4000 respectively; for fine-tuning the model, the update frequency and the learning rate is 1 and 1e-4 without warm-up. In the evaluation phase, we use Marian[3] (Junczys-Dowmunt et al., 2018) for decoding and then calculate the sacreBLEU[4] (Post, 2018) on the WMT21 dev set, test set and WMT22 dev test to measure the performance of each model.

5 Experimental Result

First of all, we test pre-trained multilingual models without fine-tune and get quiet low scores. Next, we fine-tune all of our pre-trained models with bitext and then select a best one according to the BLEU scores for every task.

5.1 De↔Hsb

Table 2 shows the results of using the selected pre-trained multilingual model to improve the De↔Hsb model performance.

System	Hsb2Dsb	Dsb2Hsb
Pre-trained model	1.1	1.0
Bitext finetune	62.9	65.3
Multilingual finetune	67.6	72.0
Sampling BT	69.6	74.2
Ensemble	70.0	74.7
WMT22submission	**88.0**	**86.8**

Table 4: Avg. scores on WMT22 dev set for Dsb↔Hsb.

In De2Hsb, we adopt the strategy of noised ST (Imamura and Sumita, 2018) because we have a large amount of German monolingual data. We sample 20M German monolingual for noised ST. We find that this strategy can bring an additional 0.2 BLEU improvement. At the same time, we use all the Hsb monolingual data (including the Hsb side of Dsb-Hsb) for sampling BT, which brings an increase of 3.4 BLEU. BLEU increases by 0.2 after ensemble.

In Hsb2De, We find that both sampling BT and forward translation + sampling BT (FT+ST) (Wu et al., 2019) can bring certain improvement, but sampling BT outperforms the FT+ST strategy (0.7 BLEU vs 0.1 BLEU). After ensemble, model performance continues improving by 0.4 BLEU.

5.2 De↔Dsb

Table 3 shows the results of using the selected pre-trained multilingual model to improve the De↔Dsb model performance. We follow the same strategy as that of De↔Hsb.

In De2Dsb, we adopt noised ST with the same data as De2Hsb. We use 20M German monolinguals for noised ST. We find that this strategy can bring an additional 0.5 BLEU improvement. At the same time, we use all the Dsb monolingual data (including the Dsb side of Dsb-Hsb) for sampling BT, which brings an improvement of 7.4 BLEU. Finally, BLEU increases by 0.2 after ensemble.

In Dsb2De, Sampling BT and FT+ST can bring certain improvement (2.6 BLEU vs 0.1 BLEU). After ensemble, model performance continues improving by 0.2 BLEU.

5.3 Hsb↔Dsb

Table 4 shows the results of using the selected pre-trained multilingual model to improve the Hsb↔Dsb model performance.

Regarding the Hsb2Dsb task, we first fine-tune the many-to-many pre-trained model with bitext, and then combine the De2Hsb, De2Dsb, Hsb2De, Dsb2De multilingual to continue fine-tuning both Hsb2Dsb and Dsb2Hsb models. This strategy gets improvements of 5+ BLEU. Then, we perform one

w/ R-drop	**65.6**	**50.1**	**66.3**	**55.2**	**62.9**	**65.3**

Table 6: Avg. scores of WMT21 dev set, test set and WMT22 dev set for each track without or with R-drop.

round of sampling BT for optimization.

After we ensemble the latter two models, the model performances significantly increase by 7.1 and 9.4 BLEU respectively when comparing with the base many-to-many fine-tuning model, which also proves the advantages of the multilingual model in low-resource tasks.

5.4 Unsupervised Submission

We conduct an unsupervised experiment with our many-to-one and one-to-many pre-trained model. For Hsb2De and Dsb2De, we add tags to the Hsb/Dsb monolingual data and get the German result from many-to-one model for zero-shot. Then we fine-tune the best one-to-many model with the zero-shooting translations, and get the Hsb2De, Dsb2De models, which obtains 11.5 BLEU on the Hsb2De track and 13.5 BLEU on the Dsb2DE track. Based on the two base models, we continue conducting a round of BT with 2M German monolingual data, and then train the De2Hsb and De2Dsb models for submission. The BLEU scores are 10.4 (De2Hsb) and 9.0 (De2Dsb). As we have not invested much efforts in the unsupervised task, more experiments need to be done in the feature.

6 Analysis

6.1 Pre-trained Model

Due to the availability of large amount of De-Cs and De-Pl data and the similarities between Hsb/Dsb and Cs/Pl, we pre-train several multilingual models with different strategies, and then fine-tune with very low resource bilingual data. We choose the best strategy for every language direction for further fine-tuning. Specifically, we design three pre-trained multilingual models: a one-to-many model trained with the De2Cs and De2Pl bilingual data, a many-to-one model trained with the Cs2De and Pl2De bilingual data, and a many-to-many model trained with the Cs2De, De2Cs, Pl2De and De2Pl bilingual data. For each corpus we use a different tag to differentiate. Furthermore, we train a De-Cs model as done by last year's participants, in order to get better comparison results.

Table 5 shows that data selection for the pre-trained model is closely related to the task requirements. For tasks of translating other languages into De, the many-to-one model trained with Cs2De and Pl2De corpora performs the best. For tasks of De2Hsb/Dsb, the one-to-many model trained with De2Cs and De2Pl corpora works the best. In general, the many-to-many model is more suitable for the Hsb2Dsb and Dsb2Hsb task, because the many-to-many model is trained with Cs and Pl data at both the source and target sides. With large amount of Cs/Pl data for transfer, both the encoding and decoding layers can benefit transfer for the Hsb2Dsb and Dsb2Hsb embeddings. Multilingual pre-trained models have better performance than bilingual pre-trained models in all directions. Besides, the unsupervised results also show the transfer capability of our pre-trained multilingual models.

6.2 The Effect of R-drop

Considering the limited sources and the large size of the multilingual model, we try the R-drop strat-

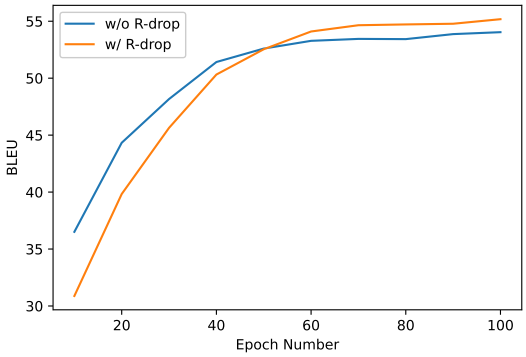

Figure 1: BLEU curves along with or without R-drop

egy to see whether the R-drop strategy is effective on multilingual models. Based on the optimal multilingual model for each task selected in the previous step, we compared whether the use of the R-drop strategy in the training process can lead to further improvements. It can be seen from Table 6 that after using the R-drop strategy for training, the BLEU of each track further improves by at least 1 point, indicating that R-drop does have a good effect in low-resource scenarios with large models. Therefore, we adopt the R-drop strategy for further training. In addition, Figure 1 is a graph depicting the BLEU convergence curves on the Dsb2De track. From the figure we can find that when the BLEU value increases by using R-drop, the convergence time also increases by about ten epochs.

7 Conclusion

This paper presents our translation systems for the WMT22 very low resource supervised MT task. During the experiment, We use multilinguals to build our base translation system, and then use forward translation and back translation methods to expand the size of training data for a better translation system. We also adopt test set fine-tuning and ensemble to further improve the system performance. Finally, according to the official evaluation results on OCELoT, our submission achieves the highest BLEU scores in all 6 language directions in the supervised task, and our submission of De2Dsb and Dsb2De also gains the highest BLEU in unsupervised task.

Abstract

This paper presents the work of team PICT-NLP for the shared task on unsupervised and very low-resource supervised machine translation, organized by the Workshop on Machine Translation, a workshop in collocation with the Conference on Empirical Methods in Natural Language Processing (EMNLP 2022). The paper delineates the approaches we implemented for supervised and unsupervised translation between the following 6 language pairs: German-Lower Sorbian (de-dsb), Lower Sorbian-German (dsb-de), Lower Sorbian-Upper Sorbian (dsb-hsb), Upper Sorbian-Lower Sorbian (hsb-dsb), German-Upper Sorbian (de-hsb), and Upper Sorbian-German (hsb-de). For supervised learning, we implemented the transformer architecture from scratch using the Fairseq library. Whereas for unsupervised learning, we implemented Facebook's XLM masked language modeling approach. We discuss the training details for the models we used, and the results obtained from our approaches. We used the BLEU and chrF metrics for evaluating the accuracies of the generated translations on our systems.

1 Introduction

Neural machine translation has witnessed significant progress in the case of highly spoken languages such as English (Bahdanau et al., 2015), Mandarin (Li et al., 2022), French (Emezue and Dossou, 2020), etc. However, in many cases, it becomes challenging to develop a robust bilingual machine translation system, especially with limited resources (Dong et al., 2015). There are big-tech companies such as Google[1] and Bing[2], which have taken initiatives to build translation systems for multiple languages. Still, languages that are low-resource in nature, such as the Sorbian family of languages (Howson, 2017), have gotten lesser attention in terms of research. The paper focuses on the development of machine translation systems between pairs of languages from German, Lower Sorbian, and Upper Sorbian, using both supervised and unsupervised approaches.

In the Indo-European language family, German (Deutsch) belongs to the western Germanic branch (Durrell, 2006). Approximately 95 million people speak it natively; 28 million speak it as a second language in more than 40 countries. Due to a phonetic mutation called High German Consonant Shift (Vennemann, 2008), German moved away from other Germanic languages. This shift in German consonants occurred between the 3rd and 5th centuries, and probably ended in the 9th century AD.

Lower Sorbian (dolnoserbska rěc) and Upper Sorbian (hornjoserbska rěč) are western Slavonic languages spoken in the region of Lower and Upper Lusatia in the southeast of Germany respectively. They are closely related to other West Slavonic languages, including Polish, Czech, Slovak, and Kashubian. There are seven recognized autochthonous minorities and regional languages in Germany, including Danish, Saterfrisian, North Frisian, Romanes, and Lower German.

We aimed to carry out research in neural machine translation between German, which is high-resource in nature, and Lower and Upper Sorbian, which are low-resource languages. We implement supervised and unsupervised methods for the same. For the supervised approach, we trained transformer (Vaswani et al., 2017) models from scratch using the bilingual data provided by WMT in the 2022 workshop edition. We used the Fairseq[3] (Ott et al., 2019) library for the same, which is a sequence-to-sequence learning toolkit for neural

machine translation. Transformer(Vaswani et al., 2017) is a Seq2Seq (Sutskever et al., 2014a) model that uses self-attention to train on input data. The encoder part of the transformer model consists of a self-attention layer and a feed forward neural network (Bebis and Georgiopoulos, 1994). The encoder of the transformer reads the input sequence, one word at a time to produce a hidden vector. The decoder produces the output sequence from the vector received from the encoder. Being part of recent NMT research, transformers perform well compared to baseline models such as CNNs (Albawi et al., 2017) and LSTMs (Hochreiter and Schmidhuber, 1997).

For the unsupervised approach, implemented Facebook XLM's[4] masked language model (cross-lingual language model) for unsupervised learning (Chronopoulou et al., 2021). Training data used for the same was monolingual data provided by the organizers and the OPUS project[5]. We preprocessed the data, and also applied byte-pair encoding (BPE) (Sennrich et al., 2016) to the input and target data. We made use of the fastBPE[6] library for the same. Finally, we applied XLM preprocessing on the data before training.

We experimented our approaches on six language pairs between German, Lower Sorbian and Upper Sorbian. We have used the BLEU (Papineni et al., 2002) and chrF (Popović, 2015) evaluation metrics for computing accuracy, which have been discussed in this paper.

2 Dataset Description

We used the data provided by the WMT22 organizers, and from the OPUS project, recommended by the organizers. The statistics of the training data for both supervised and unsupervised approaches is given in Table 2. For the supervised training, we used the parallel data provided by the organizers, for each language pair. We used the 2022 version of the data itself, as training for larger corpora was proving computationally expensive at our end. For translations between German and Lower Sorbian, validation data size was 1353, whereas for Upper Sorbian-Lower Sorbian and German-Upper Sorbian, validation data sizes were 709 and 2000 for each language respectively.

For unsupervised learning, we used the monolingual data for Lower Sorbian provided by the organizers. For Upper Sorbian, we used the monolingual data provided by the Witaj Sprachzentrum[7]. Whereas for German, we used the monolingual data provided by the OPUS project. The quantitative statistics of these datasets is given in Table 2.

The blind test data provided by the organizers contained 1000 sentences each for translations between Lower Sorbian and German, 1000 sentences each for translations between Lower Sorbian and Upper Sorbian, and 1621 sentences each for translations between Upper Sorbian and German. We submitted the inferences on the blind test data to the shared task leaderboard.

3 Data Preparation

The data preprocessing step was crucial in determining the accuracies of our translations. The goal was not to waste resources (compute power, time) in processing things that don't add much value to extracting the semantics and understanding the text. (Tabassum and Patil, 2020)

For supervised learning, we preprocessed the source and target text using fairseq-preprocess[8], an inbuilt preprocessing script provided by Fairseq. We set the number of parallel workers for preprocessing the text as 20, so as to achieve faster preprocessing. Normalization (Mansfield et al., 2019) and pre-tokenization of the text is done before passing the to fairseq-preprocess. We used sacremoses[9]

[4] https://github.com/facebookresearch/XLM

[5] https://opus.nlpl.eu/

[8] https://fairseq.readthedocs.io/en/latest/command_line_tools.html

[9] https://github.com/alvations/sacremoses

tokenizer, which helps us to tokenize and normalize text according to our needs. fairseq-preprocess binarizes the training data and builds vocabularies from the text of that particular language.

For unsupervised learning, we applied some additional preprocessing, which consisted of using XLM-Moses tokenizer. The XLM-Moses tokenizer performs the following steps: removing unicode punctuations, normalizing punctuations (punctuations will be removed from the utterances during training) and removing any non-printing characters. We also applied byte-pair encoding (Sennrich et al., 2016) to our data, where we use the inbuilt script provided by fastBPE[10]. Byte-pair encoding algorithm computes the unique set of words used in the corpus (after the normalization and pre-tokenization steps are completed), and then builds the vocabulary by taking all the symbols used to write those words. Byte-pair encoding algorithm application includes learning the BPE codes from the training dataset, then applying the same on the training, validation and test datasets. Also, we get the training vocabulary once we have obtained the codes after training. Finally, we apply XLM preprocessing provided by Facebook XLM, to get the final preprocessed data.

4 Model Description

4.1 Supervised Training

We trained transformer models from scratch using the 'transformer' architecture provided by open-source toolkit Fairseq. Fairseq provides multiple state-of-the-art architectures to build translation models. Transformers use self-attention along with an encoder-decoder approach to train (Sutskever et al., 2014b). Encoders extract features from input sentences, and decoders use those features to produce output translations. The encoder in the transformer consists of multiple encoder blocks. Input sentences pass through encoder blocks, and the outputs of the last encoder block become the inputs to the transformer decoder. The decoder also consists of multiple decoder blocks, and feature information is received from the encoder by each block of the decoder.

4.2 Unsupervised Training

For unsupervised training, a masked language model (MLM) is implemented using data from both languages (source and target). We use the XLM model for easier implementation of the MLM objective. Masked prediction is implemented during the training steps, along with denoising autoencoding (Vincent et al., 2008), which involves reconstructing the original text data from a corresponding noisy version. We use an encoder-decoder transformer model, consisting of 12 layers in total (6 each to encoder and decoder), and is similar to the XLM architecture. We transfer the masked language model trained encoder transformer to the aforementioned encoder-decoder translation model.

5 Experiments

5.1 Training Details

For training the models we used the fairseq, a sequence model toolkit written in Pytorch (Paszke et al., 2019) developed by Facebook Artificial Intelligence Research (FAIR) team. We trained our models on the Nvidia Tesla K80 GPU, which has a 13GB RAM capacity.

For supervised learning, we trained our models on 50 epochs, and the total training time for every model was around 2 hours. We used the Adam optimizer (Kingma and Ba, 2014) for enhancing training performance, with corresponding beta coefficients set to 0.9 and 0.98. Label smoothing rate (Paszke et al., 2019) for the model is set to 0.1 (Label smoothing encourages the model to produce a finite output, which may lead to better generalization and prevent overfitting). Clip threshold of gradients is set to 0 (Zhang et al., 2019). A dropout (Srivastava et al., 2014) of 0.2 for input features is specified in the architecture. Maximum number of tokens in a batch is set to 4096 during training. Learning rate (Igiri et al., 2021) for the model is set to 0.0005.

For the unsupervised training, we train our models on 20 epochs, taking about five hours to train. Input words to the model are randomly shuffled during training, 3 at a time (Malkin et al., 2021). A word dropout of 0.1 is specified. 8 attention heads are taken in each layer of the encoder. Overall dropout and attention dropout of 0.1 is specified. 1000 tokens are taken per batch, and a batch-size of 32 is taken for training the models. Dimension of the embedding layer in the model was set to 1024. Sequence length of 256 is specified during training. We use the GeLU activation function (Hendrycks and Gimpel, 2016) in this model, instead of the typi-

cal ReLU function used. Here too, Adam optimizer was used, with corresponding beta coefficients set to 0.9 and 0.98.

5.2 Evaluation Metrics

The BLEU (Papineni et al., 2002) and chrF (Popović, 2015) metrics were used for evaluation of the generated translations. The same metrics were used for evaluation on the shared task leaderboard.

BLEU stands for Bilingual Language Understudy. BLEU algorithm is used to evaluate machine translation quality. BLEU metric is language independent, and is easy to understand and compute. Higher the BLEU, better are the translations.

chrF stands for "character n-gram F-score". Informally, it measures the amount of overlap of short sequences of characters (n-grams) between the MT output and the reference. According to (Mathur et al., 2020) , chrF is "is technically the macro-average of n-gram statistics over the entire test set".

6 Results

For the results, please refer to Table 3. Table contains the BLEU and chrF scores to the translations that we obtained on all six language pairs (de-dsb, dsb-de, dsb-hsb, hsb-dsb, de-hsb, hsb-de), by both supervised and unsupervised approaches. These scores are obtained from our submissions to the leaderboard for the Unsup-Very Low Sup Shared task.

7 Related Work

Machine translation has been a pivotal field of research in the natural language processing domain. With rule-based and statistical machine translation methods proposed in the past decades, neural machine translation has surpassed these conventional methods by achieving state-of-the-art accuracies with each year. In 2014, Bahdanau (Bahdanau et al., 2015) proposed the base paper for neural machine translation. According to the paper, the encoder part of the model encodes the input sentence into a fixed length vector, from which the decoder generates the translation. The encoder and decoder parts could be neural architectures such as a simple RNN, LSTM (Sherstinsky, 2020), Bidirectional RNN (Schuster and Paliwal, 1997), GRU (Chung et al., 2014), etc. With the introduction of transformers (Vaswani et al., 2017) and self-attention in training neural networks, NMT research got a substantial boost.

German, being pretty high resource in nature; there has been significant work carried out in German in NMT. The Workshop on Machine Translation (WMT) has a significant contribution to the same. Minh-Thang Luong (Luong et al., 2015) demonstrate two seperate attention mechanisms (global and local attention) for bidirectional translations between English and German, gaining an increase of 5.0 in the BLEU score over non-attention based techniques. Macketanz (Macketanz et al., 2021) present the result of applying a fine-grained test suite on the outputs of 36 state-of-the-art machine translation systems between English and German, which were submitted to the Sixth Conference on Machine Translation. Xu (Xu et al., 2021) proposed BiBERT, a bilingual BERT model which helped in achieving state-of-the-art translation performance compared to other published papers till date, and that too without implementing backtranslation (Edunov et al., 2018). The paper also proposes a stoicastic layer selection method which helps in improving translation performance.

Sorbian family of languages have started receiving attention with regards to NMT research in the past few years. Li and team (Li et al., 2020) worked on supervised machine translation for a few language pairs, which included German-Upper Sorbian translations. They experimented with document-enhanced NMT, XLM pretrained language model enhanced NMT, etc. Their primary submissions won the first place in the German to Upper Sorbian Translation directions.

Knowles and team (Knowles et al., 2020) worked on implementing ensemble learning in transformer models for German-Upper Sorbian, built using BPE-dropout, lexical modifications and backtranslation.

Pertaining to unsupervised learning: Chronopoulou (Chronopoulou et al., 2020) propose the LMU Munich System for the WMT 2020 Unsupervised Machine Translation task, which involves using a pretrained monolingual model and finetuning it on both German and Upper Sorbian. Finally, the system uses backtranslation, and uses the pseudo-parallel data obtained to finetune the model further. Finally, the paper ensembles the best best-performing systems and give state-of-the-art scores on unsupervised translations between German and Upper Sorbian. Edman (Edman et al., 2021) implement transformer encoder-decoder architectures for unsupervised NMT from German to Lower Sorbian. The system has three modifications from the conventional methodology- training followes a bilingual approach, instead of a multilingual system approach. Secondly, a novel method is introduced for building the vocabulary of an unseen language. Finally, experimentation is done with the order of implementation of online and offline backtranslation. The paper received first place in the Unsupervised Machine Translation Task for WMT 2021.

8 Conclusion

Thus, we have implemented supervised and unsupervised neural machine translation approaches for translation between language pairs consisting of German(de), Lower Sorbian(dsb), and Upper Sorbian(hsb). We utilized different architectures for implementing the same. Our future plans include training these models with much larger corpora on computationally-efficient machines to obtain better evaluation metric scores and use high-end GPUs for practical training. We plan to use better preprocessing techniques and linguistic methods to improve the usefulness of the final training data to be fed to the models. We plan to implement backtranslation to improve current translation accuracy, have longer pre-training, and implement other pretrained models such as mBERT and XLM.

MUNI-NLP Systems for Lower Sorbian-German and Lower Sorbian-Upper Sorbian Machine Translation @ WMT22

Edoardo Signoroni and **Pavel Rychlý**
Faculty of Informatics
Masaryk University
e.signoroni@mail.muni.cz, pary@fi.muni.cz

Abstract

We describe our neural machine translation systems for the WMT22 shared task on unsupervised MT and very low resource supervised MT. We submit supervised NMT systems for Lower Sorbian-German and Lower Sorbian-Upper Sorbian translation in both directions. By using a novel tokenization algorithm, data augmentation techniques, such as Data Diversification (DD), and parameter optimization we improve on our baselines by 10.5-10.77 BLEU for Lower Sorbian-German and by 1.52-1.88 BLEU for Lower Sorbian-Upper Sorbian.

Introduction

This paper describes our Machine Translation (MT) systems for the WMT22 shared task on "Unsupervised MT and Very Low Resource Supervised MT"[1], which features translation between Lower Sorbian, Upper Sorbian, and German. Lower (*dsb* and Upper Sorbian (*hsb*) are Slavic minority languages spoken in the Eastern part of Germany with 7.000 and 30.000 native speakers respectively. Text data for these languages collected and made available by the Sorbian Institute and the Witaj Language Centre (Libovický and Fraser, 2021).

We submit systems for Lower Sorbian-German and Lower Sorbian-Upper Sorbian in both translation directions. We focused on the supervised approach, using only the parallel data made available by the task organizers for all the above languages.

We were able to improve on our baselines by: i. employing a new tokenization algorithm, High Frequency Tokenizer (HFT) (Signoroni and Rychlý, 2022); ii. augmenting the original parallel data with the Data Diversification (DD) technique by (Nguyen et al., 2020); iii. tuning the architecture and the parameters of the models, such as encoder/decoder depth, number of attention heads, dropout, batch size, etc.

We employed HFT since it aims to obtain more meaningful subword dictionaries, while DD was chosen because it does not involve additional data apart from the original parallel corpus. Both this techniques are relevant when working with a limited amount of data.

This paper is structured as follows: Section 1 summarizes the data used in training; Section 2 outlines our methodology, introducing our novel tokenizer and the models we used; Section 3 sums up our final systems, while Section 4 relates and discusses the results of our experiments; Section 5 contains some final remarks.

1 Data

We experiment with Lower Sorbian-German and Lower Sorbian-Upper Sorbian translation, using only the parallel data provided for each pair.

The parallel data for the dsb-de and the dsb-hsb pairs consist of ∼40k and ∼62k sentences respectively. We use only these data, as the approach we decided to follow does not need additional data. After applying this method, our final corpus size for training is ∼360k sentences for dsb-de, and ∼560k for dsb-hsb.

2 Methodology

In this section, we first present briefly our novel tokenizer, High Frequency Tokenizer, or HFT. Then, we describe the architecture of our models and how we trained them.

2.1 High Frequency Tokenization

Sennrich and Zhang (2019) showed that a meaningful subword tokens vocabulary is crucial for achieving good performance in low-resource NMT. While they experiment with BPE, we employ our novel tokenization algorithm, High Frequency Tokenizer, or HFT. This word segmentation methods aims to provide more meaningful subword dictionaries by obtaining more frequent, and thus better

Figure 1: Special characters in the pretokenization and tokenization.

represented subwords. Given the importance of tokenization for low-resource NMT, we argue that is an important point to consider.

HFT uses the advantage of pretokenization, where sentences are split into tokens on the borders of alphanumeric and non-alphanumeric characters. The current prototype uses the regular expression `\b` of the Unix `sed`[2] command . Both the beginning and the end of each token is explicitly annotated, differently from previous systems such as `subword-nmt` BPE and `sentencepiece`.

HFT subwords are learnt from these tokens, they never cross the token boundaries, each token from the pretokenization is handled independently from other tokens. It speeds up both vocabulary learning and actual subword tokenization.

We also use case normalization for characters with both uppercase and lowercase. A single uppercase letter is changed to a special <uppercase-next> character and lowercase version of the given letter. A sequence of uppercase letters is changed to lowercase with a special <all-uppercase> and <end-of-uppercase> characters attached to the beginning and the end of the sequence. Figure 1 gives the special characters `hft` uses in pretokenization and tokenization.

The learning algorithm starts from a vocabulary containing all characters from the training text as possible subwords and the number of occurrences of the given subword (character). Then, it gradually increase the vocabulary in the following steps:

1. it processes all the words (tokens) from the pretokenized text to find the best subword segmentation using only subwords from the current vocabulary, counts the frequencies of each subword and of all possible subword candidates (pairs of succeeding subwords);

2. selects the top K candidates with the highest frequency and adds them as new subwords to the vocabulary (K is 5% of the target vocabulary size as default);

3. removes from the vocabulary all non-single-character subwords with frequency lower than the last added candidate;

4. repeat from 1. until the requested vocabulary size is reached

The best subword tokenization (in step 1) searches in all possible subword segmentation sequences the one with the lowest number of tokens and, for same number of tokens, the highest minimum frequency.

We evaluated HFT against Byte-Pair Encoding (BPE) (Sennrich et al., 2016) and Unigram (Kudo, 2018) on the metrics described by (Gowda and May, 2020) and on a weighted average of the frequencies of the tokens in the vocabulary. HFT performed well, providing better results for almost all test cases. Preliminary data on HFT's impact on downstream NMT also showed promising results. (Signoroni and Rychlý, 2022)

Moreover, during the experimentation for this task, we further confirmed that using HFT-tokenized data leads to better translation quality, calculated with sacreBLEU (Post, 2018), against a `subword-nmt` BPE baseline.

2.2 Data Diversification

For our final models we follow the Data Diversification (DD) approach of Nguyen et al. (2020). While most of the research in low-resource NMT avails itself of external data by employing techniques such as backtranslation and transfer learning, this simple, yet effective method does not need any external data, but only the original parallel corpus. The DD procedure is the following:

1. Train k different models on the authentic parallel corpus, in both the forwards and backwards directions;

2. Infer the translations with all the trained models, so to obtain k synthetic source and target data;

3. merge the translations to create a new parallel dataset, which comprises the original parallel data, plus an authentic source to synthetic target, and a synthetic source to authentic target section;

```

Figure 2: Sample of Lower Sorbian text tokenized with HFT.

4. Train new models on these augmented parallel data;
5. repeat for *n* rounds.

Since Nguyen et al. (2020) reports that additional rounds of DD do not boost the performance of the resulting systems significantly, our systems were trained after just one round of DD. We have a level of diversification *k*=4, since we included all the previous experiments models' output, plus the original parallel data.

2.3 Preprocessing

We use both training and development test data as provided, without cleaning of any kind. We tokenize the data with two subword tokenization algorithms, BPE and HFT. For the former, we use the `subword-nmt` implementation. For HFT, we use our own implementation. We experiment with different vocabulary sizes, and our results are in line with previous research, such as Sennrich and Zhang (2019). They showed that a smaller vocabulary sizes improves the performance of low-resource NMT. In line with these findings, our experiments with vocabulary size of 12k and 10k, even if well below the standard 32k, performed worse than our final choice of 4k tokens.

We train a tokenizer for each language on the train split of the datasets, and share the dictionaries during all the stages of training.

2.4 Models

Table 1 gives details about the architecture and training parameters of each model we trained.

We experiment with two different model architectures, both based on the Transformer (Vaswani et al., 2017). The first, which we dubbed t-[tok][3], is a standard Transformer (Vaswani et al., 2017); while the second, called and t-opt-[tok], is a Transformer with optimized parameters for the size of the dataset.

We use Fairseq (Ott et al., 2019) for training the models, generating translations, and evaluating them.

As our baseline, we train a Transformer (Vaswani et al., 2017) with default hyper parameters and BPE tokenization, which we refer to as t-bpe. [4] As a first experiment, we train t-hft, a standard Transformer trained on data tokenized with HFT. We use *adam* as optimizer and we maximize BLEU score on the validation set at each epoch. For the BPE models, we use detokenized BLEU, but for HFT this was not implemented during training. We train both t-[tok] models for 100 epochs with dropout of 0.1, and 10240 maximum tokens for each batch. We use a learning rate of 0.0005 and the inverted square root scheduler for all of our models.

Secondly, we train another Transformer with the optimized hyper parameters found by (Araabi and Monz, 2020) for a dataset of 40k sentence pairs: 5 encoder/decoder layers, 2 attention heads, and a feed-forward dimension of 2048. During our experiments, however, we observed that a feed-forward dimension of 1024 gives better results. We do this with data tokenized with both methods, obtaining t-opt-bpe and t-opt-hft. These models are trained for 100 epochs, with dropout of 0.3, label smoothing of 0.5, encoder and decoder word dropout of 0.1, activation dropout of 0.3, and a maximum batch size of 4096 tokens.

Lastly, we build the DD parallel corpus by collating the outputs of all previous systems in both directions, beginning with the authentic parallel data, and adding both combinations of original and synthetic source and target data. We then use the DD-data to train both t-bpe-dd and t-hft-dd, which share the same architecture the t-[tok] models. The training is also similar, just differing in the number of epochs, which for these last models is 50.

2.5 Evaluation

To find our best candidates for submission, we generate translation on a development test set of unseen sentence pairs, either provided by the task organizers, or set aside from the train portion of the data. We produce translations with the standard settings (beam search with a beam of 5) using the best

[3] We trained models on data tokenized both with BPE and HFT. Since they share the same architecture and training parameters, [tok] stands either for bpe or hft.

[4] We still use a vocabulary size of 4k, which is already an improvement on the standard size of 32k.

PARAMETER	MODEL		
	t-[tok]	t-opt-[tok]	t-[tok]-dd
Vocabulary size	4000	4000	4000
feed-forward dimension	2048	1024	2048
attention heads	8	2	8
dropout	0.1	0.3	0.3
enc/dec layers	6	5	6
label smoothing	0.1	0.5	0.1
enc/dec word dropout	0.0/0.0	0.1/0.1	0.0/0.0
activation dropout	0.0	0.3	0.0
max tokens	10240	4096	10240

Table 1: Architecture details and training parameters for each model.

	DSB-DE	DE-DSB	DSB-HSB	HSB-DSB
t-bpe	27.92	22.74	72.01	69.71
t-hft	34.20	30.86	72.21	70.71
t-opt-bpe	29.75	25.06	71.37	69.50
t-opt-hft	35.46	31.12	71.83	68.95
t-bpe-dd	33.02	28.54	73.47	71.98
t-hft-dd	38.42	33.53	73.53	71.59

Table 2: Trained models and BLEU score during inference on development test data

checkpoint of each model and evaluate the detokenized output with sacreBLEU (Post, 2018). For the BPE models, we detokenize with the provided argument, while for HFT we use our own plug-in script. We use the same settings to translate the test set for our submissions. Table 2 gives BLEU scores, computed on the development test sets, for each system we experimented with.

During inference on the development test set, models trained on HFT data outperformed the BPE baseline by 4.99 to 8.12 BLEU for the dsb-de pair, while for dsb-hsb the difference in score is minimal. t-opt-[tok] was better than the corresponding t-[tok] model in the dsb-de pair. For dsb-hsb, this does not hold true, with t-opt-[tok] always performing worse than the baseline. t-[tok]-dd improves on both the baseline and t-opt-[tok] for every language pair and direction.

2.6 Inconclusive and Negative Results

During DD, we collated data from all four experimental models for each pair, both t-[tok] and t-opt-[tok], regardless of their performance. This later resulted in our best systems. For the dsb-de pair, we also tried to ensemble data from the four best performing systems to create the DD train set, all from HFT data and ranging from 34.99 to 37.20 BLEU on the dsb-de side, and 31.12 to 30.42 on the reverse direction. This was done with the intuition that better train data should result in better performance. However, after training t-[tok]-dd on these data, the resulting system that performed worse by -0.58, giving 37.84 BLEU on the development test set. In contrast, the final t-[tok]-dd gave us 38.42 BLEU, and was trained on data generated with systems ranging from 27.92 to 35.46 BLEU on the dsb-de side, and from 22.74 to 31.12 for the reverse direction.

While this small difference in BLEU score may not be significative, further investigation should be conducted as this may indicate that a more diverse dataset is better than one with a higher quality for training with NMT systems with DD. Our initial hypothesis for why this happens is that being the systems' performance closer, the translations they generate are similar. This leads to worse generalization potential for the resulting final system.

3 Final Systems

Table 3 gives BLEU and chrF scores for our final submissions.

For all pairs and directions we worked on, our best systems was t-hft-dd, a Transformer trained on a single NVIDIA A40[5] for 50 epochs on DD

[5] Previous systems were always trained on a single GPU,

		t-hft-dd
DSB-DE	BLEU	49.5
	chrF	73.0
DE-DSB	BLEU	50.5
	chrF	74.1
DSB-HSB	BLEU	72.2
	chrF	87.5
HSB-DSB	BLEU	72.3
	chrF	87.5

Table 3: BLEU and chrF scores for our best systems on the final test set.

HFT-tokenized data, with a vocabulary size of 4k, feed-forward dimension of 2048, dropout 0.3, and 10240 for each batch.[6]

Our hypotheses on why HFT leads to improvements on these datasets are the following. On top of providing more frequent and better defined token for the model to learn, it also explicitly marks both beginning and end of the words during pretokenization. This could be relevant for morphologically complex languages, such as the ones in this task, since it provides more information to the model on possible prefixes and suffixes. Contrast this with the fact that `subword-nmt` BPE only explicitly mark continuation with the @@ marker. This kind of tokenization thus makes no distinction between full words and word endings. Moreover, it seems to struggle with capitalized words and punctuation, which can also be informative, if handled optimally. HFT's pretokenization seems to help with this issue. Investigating these topics will be further addressed by future work.

4 Conclusions

This paper described our submission for the WMT22 shared task on Unsupervised MT and Very Low Resource Supervised MT. We presented systems for Lower Sorbian-German and Lower Sorbian-Upper Sorbian translation in both direction under supervised training conditions. To train our best systems we employed a novel tokenization algorithm, HFT, to obtain more meaningful subword vocabularies, contrasted to a BPE baseline; and Data Diversification (Nguyen et al., 2020) to augment the training data using only the parallel dataset provided for each language pair.

During our experiments we confirmed that optimizing not only the Transformer's hyper parameters, but also the subword vocabulary quality and size, are crucial steps for low-resource NMT. Choosing the appropriate vocabulary size for the dataset, could lead to significant improvements in BLEU score even with a small amount of parallel data. These, however, are still open and complex problems, since previously proposed settings or, even more so default ones, did not always provide the best results.

Limitations and Future Work

While providing NMT systems for Lower Sorbian-German and Lower Sorbian-Upper Sorbian that perform reasonably well, some other methods, some of which were used by other submissions, could provide better results. These should be taken into account, if a system for these language pairs will be deployed for language conservation, revitalization, or everyday use. Such system may also be hampered by the limited scope of the training data, which is inherent in their size. As for other low-resource and, especially for endangered languages, documentation ventures such as those of the Sorbian Institute and the Witaj Language Centre are vital to create bigger, more comprehensive datasets, which are still needed for the current NLP methodologies to work at their best.

Ethics Statement

NMT systems are, as every other data-driven technology, sensible to biases and other shortcomings in their training data. De-biasing datasets and NLP systems' output is a scope of research that lies outside the scope of this shared task and thus, from the scope of this paper. If these systems were to be employed in a real-world scenario such as language conservation, revitalization or everyday translation, we advise caution as to the limitations mentioned above.

Following Lacoste et al. (2019), we report that the experiments and the research that led to the results presented in this paper were conducted on a private server infrastructure consisting of a NVIDIA Tesla T4, A40, and A100 for around 500 hours of training at an efficiency of 0.59 kg/kWh[7] for a total of 20.39 kg CO_2 eq.

variably on a A40, A100 or a Tesla T4. Training times did not exceed 12 hours for both t-[tok]-dd systems.

[6] Every other unmentioned parameter was left at the default setting.

Abstract

This paper presents our submissions to WMT 22 shared task in the Unsupervised and Very Low Resource Supervised Machine Translation tasks. The task revolves around translating between German ↔ Upper Sorbian (de ↔ hsb), German ↔ Lower Sorbian (de ↔ dsb) and Upper Sorbian ↔ Lower Sorbian (hsb ↔ dsb) in a both unsupervised and supervised manner. For the unsupervised system, we trained an unsupervised phrase-based statistical machine translation (UPBSMT) system on each pair independently. We pretrained a German-Slavic mBART model on the following languages Polish (pl), Czech (cs), German (de), Upper Sorbian (hsb), and Lower Sorbian (dsb). We then fine-tuned our mBART on the synthetic parallel data generated by the (UPBSMT) model along with authentic parallel data (de ↔ pl, de ↔ cs). We further fine-tuned our unsupervised system on authentic parallel data (hsb ↔ dsb, de ↔ dsb, de ↔ hsb) to submit our supervised low-resource system.

1 Introduction

Like most machine learning approaches, data can be considered the most important component of the recipe for modeling a solution for a given problem. Neural machine translation relies heavily on a large amount of training data to correctly model two languages and learn the mapping between them to produce semantically and syntactically right translations. However, machine translation is not available for the majority of the 7000 languages spoken on the earth. This is due to the fact that parallel corpora are scarce or non-existent. There have been several proposals to alleviate the issue of small amounts of parallel data such as pivot translation, multilingual training, and semi-supervised training which resulted in an acceptable performance.

Unsupervised machine translation became the go-to solution when lacking parallel data. The WMT 2022 Unsupervised MT Task focuses on two very low-resource languages: Upper Sorbian (HSB) and Lower Sorbian (DSB). Upper and Lower Sorbian are minority languages spoken in the federal states of Saxony and Brandenburg in Eastern Germany. With just 30,000 and 7,000 native speakers, working on these languages is an extreme low-resource task, with little prospect of ever approaching the number of resources available for languages with millions of speakers. However, because they are western Slavic languages, the Sorbian languages can benefit from Czech and Polish data (Libovický and Fraser, 2021).

In this paper, we describe our systems for translating between German ↔ Upper Sorbian (de ↔ hsb), German ↔ Lower Sorbian (de ↔ dsb), and Upper Sorbian ↔ Lower Sorbian (hsb ↔ dsb) in a both unsupervised and supervised manner.

We approach the task by combining two novel approaches for unsupervised machine translation. Influenced by (Artetxe et al., 2019), we start by developing unsupervised phrase-based statistical machine translation systems (UPBSMT) for all language pairs independently. In contrast to (Artetxe et al., 2019), (Lample and Conneau, 2019) relies on pre-training an XLM model on the source and target language to capture the translation signal instead of using (UPBSMT). Instead, we benefit from both the pre-training and UPBSMT. So, we pre-train an mBART model (Liu et al., 2020) on Polish, Czech, Upper Sorbian, Lower Sorbian, and German from scratch as we mentioned earlier that pl and cs are similar to dsb and hsb. We then fine-tune mBART on synthetic parallel data (de),(de ↔ hsb) and (hsb ↔ dsb) along with authentic parallel data (de ↔ pl, de ↔ cs).

We group pl, cs, dsb, hsb under one token $slavic$ while feeding it to the encoder. For our low-resource submission, we fine-tune the unsupervised model on the authentic parallel data provided by the task between (de ↔ hsb),(de ↔ dsb), and (hsb ↔ dsb).

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1117 - 1121
December 7-8, 2022 ©2022 Association for Computational Linguistics

Our unsupervised approach scored the highest BLEU in all directions except (de ↔ dsb) direction.

2 Related Work

The earliest approach on Unsupervised Machine Translation was introduced by (Ravi and Knight, 2011) where they frame the MT task as a decipherment task, treating the target language as cipher text of English. Their method is essentially the same approach taken by cryptanalysts and epigraphers when they use the source texts. They started by estimating the word translation probabilities using a devised Iterative EM algorithm, due to the huge consumption of memory since they operate on large-scale vocabularies. Followed by that, they propose a novel approach based on Bayesian Decipherment that outperformed the previous EM approach in all aspects. After that they build an n-gram translation table that was used to estimate an IBM Model 3 translation model, the highest BLEU (Papineni et al., 2002) score achieved was 19.3 on the Spanish-English OPUS subtitles data.

(Artetxe et al., 2019) provide a two-step solution to unsupervised machine translation. For step one, they start by building an UPBSMT system between source and target languages. Resulting in two translation models: source-to-target and target-to-source models. Using these models, they back-translate target monolingual data using the target-to-source model to generate $(\hat{src}, trg)$ pairs that will be used to train the source-to-target neural model. Similarly, they back-translate the source monolingual using the source-to-target model to generate $(src, \hat{trg})$ pairs that will be used to train the target-to-source neural model.

The second step is training two neural models, source-to-target and target-to-source, using the synthetic data generated from step 1 using iterative back-translation. The first iteration relies solely on data generated by UPBSMT, the following iterations substitute a percentage of synthetic data generated by UPBSMT by back-translated data from the neural model in the reverse direction. Until the whole training data is back-translated from the reverse model. In contrast, (Lample and Conneau, 2019) starts by pre-training an XLM encoder on Masked Language Modeling (MLM) task on the source and target languages.

After pre-training, they initialize an encoder-decoder model using the pre-trained XLM encoder. Their training step is composed of three tasks :

1. Denoising Auto encoding.
2. Cross Domain (Back-translation).
3. Adversarial Loss.

In our work, we combine the two methods. But instead of using neural iterative back-translation, we add authentic parallel data from related languages.

3 Approach

Inspired by (Artetxe et al., 2019) and (Lample and Conneau, 2019), we adapted a mixed approach to mitigate the weaknesses and combine the advantages of both methods. (Artetxe et al., 2019) use UPBSMT as an explicit initial translation signal to train two translation models from scratch on a translation task. But, UPBSMT's output is noisy and the translation model is trained from scratch without any denoising pre-training objective. In contrast, (Lample and Conneau, 2019) pre-trains an XLM encoder on MLM task and then use it to initialize a seq2seq model which will be trained to translate in an unsupervised manner as we discussed in Section 2. Although (Lample and Conneau, 2019) didn't train the translation model from scratch, they relied solely on the three training tasks discussed earlier to capture the cross-lingual translation signal in contrast to (Artetxe et al., 2019) who used an explicit cross-lingual translation signal.

We combine the best of both worlds by using UPBSMT as our initial translation signal to fine-tune a pre-trained mBART model on a multilingual translation task.

3.1 Unsupervised Phrase-based Statistical Machine Translation

We followed (Artetxe et al., 2018) approach to build an unsupervised phrase-based statistical machine translation system between the following pairs : $(de \rightarrow dsb)$, $(de \rightarrow hsb)$, $(dsb \rightarrow de)$, $(hsb \rightarrow de)$, $(hsb \rightarrow dsb)$ and $(dsb \rightarrow hsb)$.

Using the above models, we back-translated monolingual data of $lang_1$ to $\hat{lang_2}$ which will be used to train the reverse direction model as following :

1. de translated by $(de \rightarrow dsb)$ model, producing $(\hat{dsb}, de)$ pairs to train the $(dsb \rightarrow de)$ neural direction.
2. de translated by $(de \rightarrow hsb)$ model, producing $(\hat{hsb}, de)$ pairs to train the $(hsb \rightarrow de)$ neural direction.

3. dsb translated by $(dsb \rightarrow de)$ model, producing $(\hat{de}, dsb)$ pairs to train the $(de \rightarrow dsb)$ neural direction.

4. hsb translated by $(hsb \rightarrow de)$ model, producing $(\hat{de}, hsb)$ pairs to train the $(de \rightarrow hsb)$ neural direction.

5. dsb translated by $(dsb \rightarrow hsb)$ model, producing $(\hat{hsb}, dsb)$ pairs to train the $(hsb \rightarrow dsb)$ neural direction.

6. hsb translated by $(hsb \rightarrow dsb)$ model, producing $(\hat{dsb}, hsb)$ pairs to train the $(dsb \rightarrow hsb)$ neural direction.

3.2 German-Slavic mBART pre-training

Since Lower and Upper Sorbian are West-Slavic languages, their direct cousins in the West-Slavic family tree are Polish (pl) and Czech (cs). Polish and Czech are high-resource languages with a large-scale availability of both monolingual and parallel data. We pre-trained mBART model (Liu et al., 2020) from scratch on denoising auto-encoding objective on Polish (pl), Czech (cs), Upper Sorbian (hsb), Lower Sorbian (dsb), German (de).

3.3 mBART fine-tuning

Using the generated synthetic parallel data produced from UPBSMT step discussed in Section 3.1 along with authentic $(pl \rightarrow de)$ and $(cs \rightarrow de)$ from OPUS (Tiedemann, 2012). We fine-tuned our German-Slavic mBART on translation on $(pl \rightarrow de)$, $(cs \rightarrow de)$, $(de \leftrightarrow dsb)$, $(de \leftrightarrow hsb)$, $(hsb \leftrightarrow dsb)$. Taking advantage of the similarity between (pl, cs, dsb, hsb), we grouped those languages under one language token $(slavic)$ which is fed to the encoder of our mBART. This approach constructs our unsupervised submission.
For the low-resource submission, we further fine-tuned the resulted model on authentic parallel data provided by the task.

4 Experiments

In this section, we describe our experimental setup and results. Readers can refer to our GitHub Repository [1] for training scripts, checkpoints, hyper-paramters etc.

4.1 Data Pre-processing

We follow (Artetxe et al., 2019) cleaning approach as following :

1. `normalize-punctuation.perl` script from Moses library to normalize punctuations.

2. `remove-non-printing-char.perl` script from Moses library to remove non-printing characters.

3. Tokenizing using Moses Tokenizer.

4. Deduplication.

5. Cleaning by length, with minimum and maximum of 3 and 80 words respectively.

Table 1: Monolingual Data sets used in our experiments

4.2 Unsupervised Statistical Machine Translation Data

We use monolingual data of German, Upper Sorbian and Lower Sorbian stated in Table 1. We used a 20MILL random sample from the German monolingual data. The output of the UPBSMT is synthetic parallel data that will be used to fine-tune the pre-trained mBART on the unsupervised translation task. The number of synthetic parallel data is shown in Table 2.

[1] https://github.com/ahmadshapiro/WMT22

Language	Sentences
dsb → de	19,486,715
de → dsb	155,683
hsb → de	19,486,715
de → hsb	873,794
hsb → dsb	873,794
dsb → hsb	155,683

Table 2: Synthetic Parallel Data Generated by UPBSMT

4.3 mBART Pre-training

We pretrained mBART on 32 V100 GPUs from scratch for less than 2 epochs (24hrs) on all monolingual data from Table 1. We learned 32k BPE codes using SentencePiece Library (Kudo and Richardson, 2018) on the concatenation of all monolingual data. This SentencePiece model will be used for the rest of neural experiments involving mBART. The average valid perplexity for all languages reached 4.16. We decided to stop training due to the time limit. All of our neural models were developed using FairSeq Framework (Ott et al., 2019).

4.4 mBART Fine-tuning (Unsupervised Submission)

We fine-tuned our pre-trained mBART on translation task using authentic parallel data of (pl-de, cs-de) shown in Table 3 along with all synthetic parallel data shown in Table 2. We grouped (hsb, dsb, pl, cs) under one token (slavic) which is passed to mBART encoder as we discussed earlier in Section 3.3. The training was done on 27 V100 GPUs for less than 1 epoch (24hrs).

4.5 mBART Fine-tuning (Low Resource Submission)

We further fine-tuned mBART on authentic parallel task data of (hsb-de, dsb-de, hsb-dsb) shown in Table 3 for 3 epochs to submit our supervised model.

5 Results

In this section, we present our results on the blind test set of WMT 22 workshop.

5.1 Unsupervised Submission

Our approach scored the highest BLEU in all pairs except the (de ↔ dsb) directions. This can be attributed to the fact of having multiple errors in the UPBSMT experiment on this specific pair. Due to the time limit, we had to use the un-tuned/corrupted models for this pair. In contrast, (de ↔ hsb) directions models scored almost 18.0 BLEU score. Surprisingly, this can reflect the importance of the UPBSMT component in our experiments, since hsb and dsb are hugely similar. But, due to an error in the UPBSMT training, the former hugely outperformed the latter. Results are reported in Table 4.

Language	Datasets	Sentences
pl-de	DGT JRC-Acquis MultiParaCrawl EUbookshop Europarl QED	12,375,574
cs-de	DGT JRC-Acquis MultiParaCrawl EUbookshop Europarl QED	12,427,403

	Task Data (2021)	87,521
	Task Data (2022)	301,536
	Total	448,787
dsb-de	Task Data (2022)	40,193
hsb-dsb	Task Data (2022)	62,564

Table 3: Authentic Parallel Data sets from OPUS (Tiedemann, 2012) used in our experiments

Direction	BLEU
dsb → de	4.0
de → dsb	1.2
hsb → de	**18.0**
de → hsb	**17.9**
hsb → dsb	**35.9**
dsb → hsb	**44.2**

Table 4: Unsupervised results on Blind Test data of WMT22

5.2 Low Resource Submission

As shown in Table 5, further fine-tuning on authentic parallel data improved BLEU score in all directions even the corrupted (de ↔ dsb) directions. Our model was constantly improving through updates, but we had to stop the training due to time constraints. We didn't use any low-resource techniques such as back-translation, BPE dropout, etc.

Direction	**BLEU**
dsb → de	39.4
de → dsb	48.2
hsb → de	47.5
de → hsb	51
hsb → dsb	66.6
dsb → hsb	65.8

6 Conclusion and Future Work

In this paper, we describe our submission to the WMT 2022 shared task of Unsupervised and Very Low Resource Supervised Machine Translation. We combined the advantages and mitigated the weaknesses of two novel unsupervised approaches along with pre-training a German-Slavic mBART model. Ablation studies for different components of our approach are left for future work.

NICT at MixMT 2022: Synthetic Code-Mixed Pre-training and Multi-way Fine-tuning for Hinglish–English Translation

Raj Dabre
National Institute of Information and Communications Technology (NICT)
Kyoto, Japan
raj.dabre@nict.go.jp

Abstract

In this paper, we describe our submission to the Code-mixed Machine Translation (MixMT) shared task. In MixMT, the objective is to translate Hinglish to English and vice versa. For our submissions, we focused on code-mixed pre-training and multi-way fine-tuning. Our submissions achieved rank 4 in terms of automatic evaluation score. For Hinglish to English translation, our submission achieved rank 4 as well.

1 Introduction

Code-mixed translation is the task of translation involving code-mixed languages. A code-mixed language is one which combines words as well as grammar of two or more languages. Code-mixed translation is difficult because of the lack of training data for the same despite its ubiquitous usage. One widely used code-mixed language is Hinglish which combines Hindi and English. Hinglish sentences are typically constructed either by replacing some Hindi words or phrases with English ones in a Hindi sentence or vice versa. Sometimes, a sentence starts off in one language but ends in another. There are also complex cases where the grammatical structures of both languages are melded into one. Hinglish is typically written in Roman letters, although there are cases when it is written in Devanagari.

In this paper we describe our submissions to the MixMT task which involves Hinglish to English and English/Hindi to Hinglish translation. The main challenge of this task is that the parallel corpus available for training models is rather scarce. The total amount of clean, non-synthetic data available for MixMT is around 18,000 examples for both directions. Therefore, we have no choice but to rely on external sources of data, and use them to pre-train models. In our case, we leverage a large amount of Hindi–English parallel data and synthesize pseudo Hinglish data. To do this, perform word alignment on the Hindi–English data and then replace random English phrases with aligned Hindi phrases. We then use the synthetic Hinglish–English parallel data for pre-training. The pre-trained model is then fine-tuned to train a joint bidirectional Hinglish–English translation model. According to the automatic evaluation metrics, we obtain 4th rank and on human evaluation of Hinglish to English translation, we also obtain 4th rank. Unfortunately, for translation into Hinglish our system ends up copying the English inputs as outputs. Although automatic evaluation scores for this are reasonably high, their human evaluation scores are lowest since the sentences are not Hinglish at all.

2 Related Work

Work on code-mixed machine translation is relatively new, especially for Hinglish. Two important works in this regard are HinGE (Srivastava and Singh, 2021) which proposes a dataset for English/Hindi to Hinglish translation and PHINC (Srivastava and Singh, 2020) which proposes a dataset for Hinglish to English translation. The HinGE dataset contains natural as well as human rated synthetic examples in both Hindi and English as source languages. Having two sources is expected to help in Hinglish generation, as the model will have the advantage of contexts from both sources. In our case, we did not leverage both sources and focused only on English. On the other hand, PHINC is designed for Hinglish to English translation and is much larger than HinGE. Neither of these datasets are perfect and contain some noisy examples, but the lack of other datasets leaves us with no choice.

Due to lack of code-mixed data, it is natural to consider synthetic code-mixed data creation where Gupta et al. (2020) show that leveraging an XLM model (CONNEAU and Lample, 2019) and linguistic features can help generate high quality code-mixed sentences. However, we opted for a quicker way using word alignment and phrase substitution

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1122 - 1125
December 7-8, 2022 ©2022 Association for Computational Linguistics

approach. Using pre-trained models, can be very helpful in code-mixed translation as they are able to represent them effectively (Santy et al., 2021). Agarwal et al. (2021) have shown that pre-trained models (Liu et al., 2020) are highly effective, but we focused more on using our own models trained on our synthetic data.

Apart from machine translation, code-mix Hinglish has been reasonably explored for natural language understanding tasks, particularly for sentiment analysis. We refer interested readers to the following works: Baroi et al. (2020); Singh and Lefever (2020); Mathur et al. (2018); Bhange and Kasliwal (2020).

3 Methods

We describe the synthetic code mixed pre-training and multi-way fine-tuning approaches we used for our submissions.

3.1 Synthesizing Code-Mixed Data

We assume the existence of a large amount of Hindi–English parallel corpus, which we use to synthesize Hinglish. Since Hinglish is written in the Roman alphabet, we first Romanize it. We then use an aligner to obtain word alignments between Hindi and English. For each English sentence, we take a random span of tokens, find the corresponding aligned span of tokens in Hindi and replace it with the English tokens span. We note that this assumes that the language structure of Hindi is preserved in this process. To determine the span in the target language, we find the indices of the aligned target words and then choose the smallest as the starting index and the largest as the ending index as the span to be replaced. This is known as the min-max approach, which was used by Zenkel et al. (2021). As a result of this process we obtain a Hinglish–English parallel corpus where Hinglish is synthetic.

3.2 Code-mixed Pre-training

We train a multilingual model (Dabre et al., 2020; Firat et al., 2016; Johnson et al., 2017) model for synthetic Hinglish to English and English to synthetic Hinglish. We append a token indicating the source language at the end of the source sentence and a token indicating the target language at the beginning of the target sentence. This bidirectional model is trained till convergence on the development set provided by the organizers after the dev set evaluation phase. We expect that code-mixed pre-training, even if the Hinglish is synthetic, should help overcome the scarcity of code-mixed parallel corpus.

3.3 Multi-way Fine-tuning

We fine-tune the pre-trained model on Hinglish to English and English to Hinglish jointly. We use a small subset of the English side[1] of our synthetic data and the entire clean parallel corpus (PHINC+HinGE) together. We do this to prevent the model from overfitting on the small training data. The English subset is used as the source as well as the target and hence, in order to prevent the model from learning to copy the English data, we randomly mask spans of English tokens on the source. This is the same as denoising, which is used in BART (Lewis et al., 2020). This concept of using the pre-training data along with the fine-tuning data is also known as mixed fine-tuning (Dabre et al., 2019; Chu et al., 2017). As during pre-training, the development set data is used.

4 Experiments

We describe our experiments in our submissions.

4.1 Datasets and Pre-processing

We use the PHINC and HinGE datasets for our experiments. We do not use the synthetic parts of HinGE. During our preliminary experiments we used the development data provided with HinGE but found it to be unreliable and therefore used the development data provided after the first evaluation phase. We combined the data from both sources and overall we had 18,095 training instances for each direction for a total of 36,190 training instances. Note that HinGE has sources in English as well as Hindi, and this is also available for the development and test sets for translation into Hinglish. However, we do not explore multi-source translation in this paper. For pre-training, we used the Hindi–English part of the Samanantar dataset[2] (Ramesh et al., 2022) which contains 8.56M parallel sentences. We used the Romanization script from the Indic NLP Library[3] to convert

[1] We do not use the Hinglish side since it's synthetic and do not want it to interfere in the learning of actual Hinglish.

Direction	Rouge-L	WER	Human Rating
Hinglish → English	0.52878 (4)	0.71517 (4)	2.85
English → Hinglish	0.46276 (4)	0.79271 (5)	1.00

Table 1: Official results of evaluation of Hinglish to English and English to Hinglish.

Devanagari to the Roman alphabet for Hindi. No other pre-processing was done.

4.2 Model Training and Decoding

We train transformer models (Vaswani et al., 2017) using the transformer-big settings. We used the YANMTT toolkit[4] (Dabre and Sumita, 2021) for training our models. We trained a joint Hinglish and English tokenizer of 16,000 subwords using all the synthetic and real training data we had. Pre-training was done on 8 NVIDIA V100 GPUs till convergence on the development data. (Mixed) Fine-tuning was done on a single GPU due to the relatively smaller size of the data. Once training has converged, we choose the checkpoints giving the highest development scores for decoding the test sets. We experimented with both BLEU and Rouge-L as metrics to determine convergence, but used BLEU as it is much stricter. We decode using beam search with a beam size of 32 and a length penalty of 1.6 both of which are empirically determined on the development set.

4.3 Results

Table 1 shows the official results obtained using the official evaluation servers. The organizers use Rouge-L and Word Error Rate (WER) as well as Human Ratings by evaluating 50 translations from our submissions. Overall, our automatic evaluation scores achieved a rank of 4 out of 8 participants. Compared to some of the baselines trained using only HinGE and PHINC, our main results using pre-training and fine-tuning are vastly better.

4.4 Analysis

We got a human rating score of 1 for translation into Hinglish and upon investigation we noted that our model simply copies the English sentence to the target. We are not sure why this happens. Regardless, on the development set, copying seems to give high BLEU and Rouge-L scores. However, the output is not Hinglish and is heavily penalized. We also did not conduct back-translation (Sennrich et al., 2016) of English into Hinglish due to this issue. We will probe our models deeper to understand why this happens. Due to lack of access to the official evaluation interface after the submission deadline, we were unable to conduct additional experiments.

5 Conclusion

In this paper, we have described our submission to the MixMT shared task at WMT 2022. We have used a combination of synthetic Hinglish–English parallel data creation, pre-training and fine-tuning to obtain our submissions which ranked 4th. Our analyses reveal that our English to Hinglish translation model actually ended up copying the English sentence as target. We will investigate and fix this in the future.

Abstract

Code-mixed machine translation has become an important task in multilingual communities and extending the task of machine translation to code mixed data has become a common task for these languages. In the shared tasks of WMT 2022, we try to tackle the same for both English + Hindi to Hinglish and Hinglish to English. The first task dealt with both Roman and Devanagari script as we had monolingual data in both English and Hindi whereas the second task only had data in Roman script. To our knowledge, we achieved one of the top ROUGE-L and WER scores for the first task of Monolingual to Code-Mixed machine translation. In this paper, we discuss the use of mBART with some special pre-processing and post-processing (transliteration from Devanagari to Roman) for the first task in detail and the experiments that we performed for the second task of translating code-mixed Hinglish to monolingual English.

1 Introduction

Code Mixing occurs when a multi-lingual individual uses two or more languages while communicating with others. It is the most natural form of conversation for multilinguals. It is often confused with code-switching but there is a slight difference between the two. Both these phenomena include communicating in multiple languages but code switching usually takes place within multiple sentences while code mixing usually refers to words of different languages used in the same sentence. In code mixing, phrases, words and morphemes of one language may be embedded within an utterance of another language. Code mixing is extensively observed on social media sites like Facebook and twitter. With the rapid growth of social media and consequently, increase in the use of code-mixed data, it becomes important to develop systems to process such text.

Machine Translation, also known as automated translation, is the process where a software translates text from one language to another without any human involvement. There are multiple forms of machine translation, however, over the past few years, neural machine translation has become extremely popular. The WMT shared task had two subtasks. The first subtask consisted of the translation of Hindi-English parallel sentence pairs to Hindi-English code mixed sentences through machine translation. The second subtask consisted of the translation of Hindi-English code mixed sentences to English.

2 Background

While there is a growing interest in code-mixed text analysis as a research problem, there is one bottleneck that has hindered the growth of such works, and that is the lack of data. Due to this, there aren't many robust models for code-mixed text. To build standardized datasets of code-mixed text, we need to come up with ways of text generation of these code-mixed texts. These texts would be very helpful in training language models for various code-mixed pairs as language models only need unsupervised data.

Code Mixed text generation is a relatively new problem, and so is its initial stage. One of the recent works in this field (Rizvi et al., 2021) tried to use linguistic theories to synthetically build code-mixed text using parallel monolingual corpora of two languages. The Equivalence Constraint Theory (Poplack, 1980) says that code-mixing can only occur at parts of the text where the surface structures of two languages map onto each other. So in these parts, the grammatical rules of both languages are followed. The Matrix Language Theory (McClure, 1995) tries to solve this problem by separating the two languages into a base language and a second language. The grammatical rules of the base lan-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1126 - 1130
December 7-8, 2022 ©2022 Association for Computational Linguistics

guage are followed, and parts of the base language are replaced by the corresponding parts of the second language whenever it is grammatically feasible to do so.

Deep Learning and Neural Networks have also been used to build systems for code mixed generation. In these systems, the problem of text generation has been posed as one of machine translation, where monolingual text is translated to code-mixed text. Some of the early work involved using the then state of the art encoder-decoder models like pointer generator networks(Winata et al., 2019) and GANs(Chang et al., 2019) to translate two sets of monolingual corpora into code mixed text. With the rise of multilingual models like mT5 (Xue et al., 2020), mBART, indicBART (Dabre et al., 2021), etc. the task of translation has become much easier as these models understand both languages and this has been shown to outperform previous models in many workshops.

mBART(Liu et al., 2020) is a denoising autoencoder which has been trained on a very large dataset which contains text from 25 languages. It has the same transformer based architecture and training objective as BART, a denoising autoencoder which was shown to be one of the best performing sequence to sequence models at the time. It has been trained to reconstruct original text which has been corrupted as a way to add noise. It can perform various downstream sequence to sequence tasks like machine translation, text summarization, etc. mBART consists of 12 encoder layers and 12 decoder layers. There are 16 heads and a model dimension of 1024.

Another solution to circumvent the data problem is to create translation systems that can translate code-mixed text to monolingual text. This allows us to use robust NLP systems for various downstream tasks.

While we have the above said top performing models at the moment, they are very heavy computational wise due to their large parameter sizes. With resource constraints, it is tough to replicate their performance. Helsinki's OPUS-MT (Tiedemann and Thottingal, 2020) model was of comparabaly smaller size and focused on the initiative of supporting low-resource languages. It does accordingly have lower performance. We have attempted at utilizing this model in our case with further training on provided data to understand whether under the resource constraints, we can observe competitive performance.

Data	Length
Synthetic (Train)	3263
Synthetic (Validate)	396
Human Generated (Train)	1800
Human Generated (Validate)	376

Table 1: Distribution of Sentences in the data

The model architecture is based on a standard transformer setup with 6 self-attentive layers in the encoder and decoder network. It has 8 attention heads in each layer. This is hence comparatively low compute seeking as compared to the mainstream models.

3 System Overview

3.1 Task 1

In this section we propose our system for Task 1 which is English and Hindi to code-mixed text translation

3.1.1 Dataset and Data Preparation

The dataset that we used for Task 1 was the HinGE dataset (Srivastava and Singh, 2021). It is divide into two parts, the synthetic dataset or the machine generated dataset and the human generated dataset. (Table 1) There were 3659 and 2176 sentences respectively.

3.1.2 Model

In this task we finetune the mBART model on the data given to us. Since mBART is a very large model we needed to decrease its size. We do this by reducing the vocabulary of the model as the vocabulary adds to the model size by a lot and we don't need the vocabulary from the rest of the 25 languages. To reduce the vocabulary we create our own vocabulary using the tokens present in the task dataset, IIT-B English-Hindi parallel corpus (Kunchukuttan et al., 2018) and the Dakshina Dataset (Roark et al., 2020) as we feel the two datasets were large enough to create a vocabulary extensive enough to solve the given task. We process the input data from the given task data as explained above to create our input. Using the corresponding code-mixed sentences as the gold output we finetune the mBART model.

3.1.3 Post Processing

The output of our model was in a mixed script (Roman + Devanagari). So the post processing

Post Processing	ROUGE-L	WER
Normal Output	0.39091	0.81884
With Automated Transliteration	0.48376	0.72561
With Automated Transliteration + Dictionary Based Transliteration	**0.61667**	**0.63342**

Table 2: ROUGE-L and WER scores after different post processing tasks

becomes one of the important step in this task as we wanted our output Hinglish sentences to be only in Roman script. We used transliteration function from indicate library as our first step to see how good the results will be. There were many instances where the transliteration done by indicate was not accurate. So the next step that we did was to create a dictionary of most common words and numbers with their corresponding transliterated Roman text. This dictionary over the automatic transliteration by indicate was used to get the best output of our model in the Roman script.

3.2 Task 2

In this section we propose our system for Task 2 which is Hinglish (code-mixed) to English text translation.

3.2.1 Observations

The data for task 2 are tweets based data. Due to the tweets nature, we observed that:

- The URLs included tended to be at the end of the sentences.
- The mentions (of the form '@<some_user_tag>' for instance @LokSabha) at the beginning and the end of tweets are generally such that the sentences can be translated without them with no-low loss of information.
- Hashtags which are added at the end of the tweets are generally for increasing outreach and exposure.

Based on the above observations, we found that the information provided by these tokens to the translation was not significant as compared to the loss of information due to incorrect translation of these units. Hence, we applied heuristics to appropriately preprocess the input data to exclusively and exhaustively split the tweets into sentences (which will be translated), URLs, mentions and hashtags, which are then concatenated after the translation in postprocessing.

3.2.2 Dataset and Data Preparation

The dataset that we used for Task 2 was the PHINC dataset (Srivastava and Singh, 2020). It contains 13,738 parallel sentences in Hinglish (code-mixed) and English of which we used a train-val-test split of 80-10-10. We transliterated the Hinglish sentences from the Roman script to the Devanagiri script using the Google Transliterate API, to utilise pre-trained Hindi to English translation models. This transliterator was used among others due to it having one of the best performance, it's similarity in the vocabulary space with the input dataset as compared to the other transliterators available and also that PHINC was jointly created using Google Translate.

3.2.3 Model

Due to compute constraints, we decided to utilize pretrained models, that would be efficient for our dataset. To access better models, we went ahead with models trained with a task or a subtask of Hindi to English machine translation. We appropriately processed the data for the same. We hence decided to finetune Salesken.AI's pretrained model provided on Huggingface Transformers. They have finetuned Helsinki's OPUS-MT model on AI4Bharat's Samanantar dataset (Ramesh et al., 2021), a large indic dataset.

4 Experimental Setup

In task 1, we use the fairseq implementation of mBART as our base model which has been trained on 4 Nvidia GeForce RTX 2080 Ti GPUs. The model has been trained using label smoothed cross entropy as the loss criterion. The model uses an Adam optimizer with polynomial decay learning rate scheduling, dropout = 0.3, learning rate = $3 * 10^{-5}$, $\epsilon = 10^{-6}$, $\beta_1 = 0.9$ and $\beta_2 = 0.98$.

The model was trained on 10000 steps with 2500 warm up steps and a batch size of 512 tokens.

We validate the model on each epoch on a validation set and at the end we select the model with the lowest loss.

In task2, for fine-tuning we use the Salesken.AI's pretrained model provided on Huggingface Transformers. The model was trained on Nvidia GeForce RTX 2080 Ti GPUs.The model has been trained using label smoothed cross entropy as the loss criterion. The model uses an Adam optimizer with learning rate = $3 * 10^{-4}$, $\epsilon = 10^{-9}$, β_1 = 0.9 and β_2 = 0.98.

5 Results and Evaluation

The test dataset consisted of 500 sentences. These sentences also had both English sentence and its corresponding Hindi sentence. ROUGE-L score and WER score was considered for evaluation. ROUGE-L score considers longest common subsequence for its scoring. It counts the longest subsequence which is shared between both reference and the output. Its different from precision as it only counts the ratio between longest subsequence matched and the number of words matched. It does not take all the words in the reference.

The WER score represents the word error rate. Total errors between the reference and output is considered for this score. It adds up all the substitution, addition and deletion required to convert the output to the reference sentence and treat it as total error of the output. It can be treated same as calculating Levenshtein distance.

So our aim was to maximise ROUGE-L score and minimize WER score. Our score improved as we translitered the output from Devanagari to Roman using indicate library. The score increase significantly after we created a dictionary of words for transliterating most common Hindi words and numbers. We achieved a ROUGE-L score of 0.61667 and WER score of 0.63342 after both the post processing steps.

The test set provided for Task 2 contained 1500 lines, which were processed as mentioned in 5 The results for the evaluation metrics we obtained for the test set provided for Task 2 is available in 3. Using the Google Transliterate API significantly improved the quality of the input data, and also the similarity of vocabulary with the dataset as mentioned earlier. The application of heuristics also bolstered the approach's performance.

Based on qualitative evaluation, it was observed that it struggled to get long sentence translations which can be attributed to the source of the dataset being of of tweets which have a noisy and inconsistent structure. This is alongside the lower parameter size and attention heads.

Metric	Score
ROUGE-L	0.41493
WER	0.80804

Table 3: Results for Task 2

The model was trained till significant learning on a wide array of parameters, till resource permits, in an attempt to provide more opportunities to appropriately fine-tune the model, but even though there was a sign of the model learning, the performance was observed to be not competitive to the current top performers.

6 Conclusion

In this paper, we approached code mixed machine translation problem from both the direction. We used mBART for our first task of translating English and corresponding Hindi sentences to Hinglish sentence. The results were significantly improved through transliterating the output from Devanagari script to Roman script. Two different methods were used for the same. Our model surpassed baseline in ROUGE-L and WER scores by a huge margin.

For the second task of translating Hinglish sentences to English sentence by fine-tuning Salesken.AI's pre trained model. We cleared the baseline but their is still work to be done in that field as we think that it can be further improved. For the future work in this area we would like to work further on the second task in hand of translating codemixed language to a monolingual language. We need to retrieve information about both the languages from the code mixed sentence and try to give a output in a mono lingual langauge without disturbing the word order.

Abstract

Code-mixing is the phenomena of mixing various linguistic units such as paragraphs, sentences, phrases, words, etc., of two or more languages in any text. It is predominantly used to post the comments by social media users who know more than one language. Processing code-mixed text is challenging because of its complex characteristics and lack of tools that support such data. Developing efficient Machine Translation (MT) systems for code-mixed text is challenging due to lack of code-mixed data. Further, existing MT systems developed to translate monolingual data are not portable to translate code-mixed text mainly due to the informal nature of code-mixed data. To address the MT challenges of code-mixed text, this paper describes the proposed MT models submitted by our team MUCS, to the Code-mixed Machine Translation (MixMT) shared task in the Workshop on Machine Translation (WMT) organized in connection with Empirical models in Natural Language Processing (EMNLP) 2022. This shared task has two subtasks: i) subtask 1 - to translate English sentences and their corresponding Hindi translations written in Devanagari script into Hinglish (English-Hindi code-mixed text written in Latin script) text and ii) subtask 2 - to translate Hinglish text into English text. The proposed models that translate English text to Hinglish text and vice versa, comprise of i) transliterating Hinglish text from Latin to Devanagari script and vice versa, ii) pseudo translation generation using existing models, and iii) efficient target generation by combining the pseudo translations along with the training data provided by the shared task organizers. The proposed models obtained 5th and 3rd rank with Recall-Oriented Under-study for Gisting Evaluation (ROUGE) scores of 0.35806 and 0.55453 for subtask 1 and subtask 2 respectively.

1 Introduction

In linguistic terms, code-mixing is the practice of switching between two or more languages within or across sentences/words in any text (Joshi, 1982). Due to the widespread use of social media platforms like Twitter, Facebook, Reddit, etc., users are generating more and more code-mixed content. In Indian scenario, social media users usually blend English with their mother tongue or local language, for instance, English and Hindi, mainly for the technological limitations of computer keyboard or smartphone keypads to enter text in local languages. Further, as most of the text processing tasks are developed for handling monolingual and formal text, informal and/or code-mixed text such as Hinglish is less explored. As the code-mixed text like Hinglish is increasing day by day, many applications such as MT, sentiment analysis, emotion analysis, etc., are also increasing. This has created a great demand for the tools and resources to process code-mixed data. Sample Hinglish text along with their Hindi and English translations are given in Table 1.

In recent years, pre-trained transformer-based language models have become state-of-the-art models for most of the downstream tasks including MT, text classification, text generation, and natural language understanding. To train such models, underlying data is drawn from a sizable monolingual corpus that is available in Wikipedia, book corpora, etc. Several models like Multilingual Bidirectional and Auto-Regressive Transformer (mBART) (Liu et al., 2020) and Multilingual Text to Text Transformer (mT5) (Xue et al., 2021) are readily available for many languages. However, due to the scarcity of code-mixed corpus, developing the pretrained language models for code-mixed text is very challenging.

MT being one of the important applications of code-mixed texts mainly focuses on translating monolingual text leaving aside the code-mixed data. Further, for under-resourced languages with rich morphological features like Hindi (Sangwan and Bhatia, 2021), developing MT models become more challenging in the code-mixed sce-

nario. To address these challenges, in this paper, we - team MUCS, describe the models submitted to MixMT-2022[1] shared task organized by WMT-2022 at EMNLP 2022. The shared task consists of two subtasks: i) subtask 1 - to translate English sentences and their corresponding Hindi translations into Hinglish text and ii) subtask 2 - to translate Hinglish text into English text. The proposed methodology consists of i) transliteration of Hinglish text from Latin script to Devanagari script and vice versa, ii) generating pseudo translations for monolingual data using pretrained MT models, and iii) target generation by fine-tuning the pretrained models with a combination of the pseudo parallel data obtained as the output of pseudo translations and the dataset provided by the organizers of the shared task.

The following is a breakdown of the paper's structure: Section 2 contains the related work and the proposed methodology is explained in Section 3. Section 4 gives the details about experiments and results and the paper concludes in Section 5 with future work.

2 Related work

Due to the increasing amount of code-mixed text, MT of code-mixed text is gaining attention of the researchers and the description of few of the models developed to translate Hinglish text into English text and vice versa are given below:

Srivastava and Singh (2020) manually developed a parallel corpus of 13,738 Hinglish sentences and their translations in English with the help of 54 annotators. They proposed a simple tagging approach for tagging each token in a sentence with the language it belongs to and evaluated Bing Translate (BT) and Google Translate (GT) models - the two popular MT services using their parallel corpus. Among the two models, GT model outperformed with a better Bilingual Evaluation Understudy (BLEU) score of 0.153 when compared to that of BT. Dhar et al. (2018) manually developed a Hinglish-English parallel corpus of 6,096 parallel sentences with the help of 4 human translators. Using a language identification technique, they tagged every word in a sentence with the name of the language to which it belongs. They proposed an MT model comprising three steps: i) identifying the matrix language, ii) translation of source text into matrix language, and iii) translation of matrix language into the target language by training BT. Considering steps i) and ii) as preprocessing, they obtained considerable translation with BLEU score of 25.0.

Jawahar et al. (2021) created a parallel corpus of 17.8 million English-Hinglish sentence pairs by leveraging bilingual word embeddings to translate English text into Hinglish text and vice versa. Further, they fine-tuned mBART and mT5 - the pretrained text generators using their newly constructed parallel corpus. The mT5 model obtained a better BLEU score of 13.95 compared to that of mBART. Gautam et al. (2021) proposed an effective fine-tuning of mBART using English-Hinglish dataset[2] to translate English text to Hinglish text and vice versa. They transliterated the Hinglish text in Latin script to Devanagari script to fine-tune the mBART model and obtained BLEU scores of 11.86 and 12.22 for Hinglish to English and English to Hinglish translations respectively.

From the literature, it is clear that very few attempts are made to explore English-Hinglish code-mixed parallel corpus for MT. Hence, there is enough space to explore new techniques in this direction.

Script conversion from Latin to Devanagari (Hindi)
Collecting monolingual Hindi text from available resources
Generation of pseudo translation
Combining pseudo parallel text with the shared task dataset
Generating target text by fine-tuning the indicTrans model

Figure 1: Workflow of the proposed method

3 Proposed methodology

Inspired by Gautam et al. (2021), a pipeline of transliteration and fine-tuning indicTrans[3] (used for translation) pretrained models is proposed to address subtask 1 and subtask 2. EN-Indic and Indic-EN models are used for generating Hinglish text and pseudo translations respectively. The purpose of transliteration is to utilize pretrained models which are trained using the text in their native script. Further, the proposed methodology also consists of the generation of pseudo translations where pseudo translation mimics the translation process.

The framework of the proposed model is given in Figure 1 and the system descriptions of each subtasks are given below:

Subtask 1 - In addition to the dataset provided by the organizers[4] for this shared task, monolingual Hindi text is collected from the available resources[5] and the further steps used to accomplish the subtask 1 are given below:

1. Transliteration is carried out using indic-trans[6] to transliterate Hinglish text in Latin script to Devanagari script
2. EN-Indic and Indic-EN models trained on Samanantar[7] corpus are used for translations (Ramesh et al., 2022)
3. Pseudo translations are generated using the Indic-EN model considering monolingual Hindi text
4. The shared task dataset is combined with the pseudo parallel data and EN-Indic model is then fine-tuned on this data
5. Finally, the target Hinglish text is generated by transliterating Devanagari script to Latin script using indic-trans

Subtask 2 - For subtask 2, the procedure similar to that of subtask 1 is followed considering Hinglish text as the source and English text as the target to generate the required output.

Subtask	Train set	Development set	Test set
subtask 1	2,766	500	1,500
subtask 2	13,738	500	1,500

Table 2: Statistics of the shared task dataset for both the subtasks in terms of the number of sentences

4 Experiments and Results

The statistics of the dataset provided by the organizers for both the subtasks which are used to build the proposed models are given in Table 2. The data provided for subtask 1 is the synthetic data (Srivastava and Singh, 2021) which consists of English sentences and their corresponding Hindi translations as the source and Hinglish as the target. For subtask 2, the dataset consists of Hinglish-English sentence pairs (Srivastava and Singh, 2020) to generate English text.

EN-Indic and Indic-EN models which are trained on Samanantar corpus are fine-tuned with the combination of the shared task dataset and pseudo parallel text. Exhaustive experiments are carried out to get the best results by tuning the hyperparameters, which control the learning process of EN-Indic and Indic-En models. Table 3 gives the hyperparameters and their values used to fine-tune the EN-Indic and Indic-EN models that gave the best results on development set.

The user predictions for the given Test set submitted to the organizers of the shared task are evaluated based on ROUGE score and Word Error Rate (WER). ROUGE score is calculated based

Hyperparameters	Values
max-token	1,568
learning rate	0.00003
label smoothing	0.1
optimizer	adam
dropout	0.2

Table 3: Hyperparameters and their values used to fine-tune the EN-Indic and Indic-EN models

Subtask		ROUGE	WER
subtask 1	Development set	0.38935	0.72310
	Test set	0.35806	0.76096
subtask 2	Development set	0.54556	0.65938
	Test set	0.55453	0.64737

Table 4: Performance measures of the proposed method for both Development set and Test set

on the overlapping of n-grams between the candidate string and reference string whereas WER score is calculated by dividing the number of errors by the total number of words. Performance measures of the proposed models for both Development set and Test set is given in Table 4. From Table 4, it is clear that the ROUGE score of subtask 2 is better than subtask 1 as the dataset used for subtask 1 is very small compared to that of subtask 2. Further, the performance of Indic-EN model is better than EN-Indic model (Ramesh et al., 2022) and the same is reflected in Table 4. The comparison of the ROUGE score of the proposed models with the models submitted by all the participants of the shared task for subtask 1 and subtask 2 are shown in Figure 2 and 3 respectively. From Figure 2 and 3, it is clear that the proposed method obtained considerable ROUGE scores for both the subtasks.

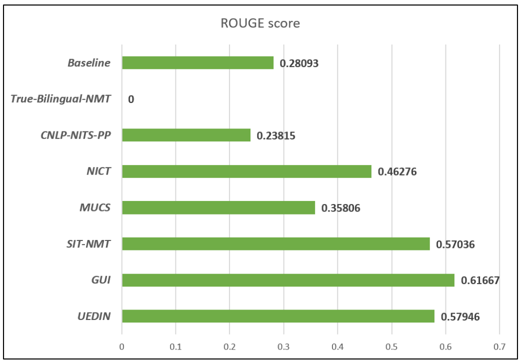

Figure 2: Comparison of ROUGE score of participated teams with the proposed model for subtask 1

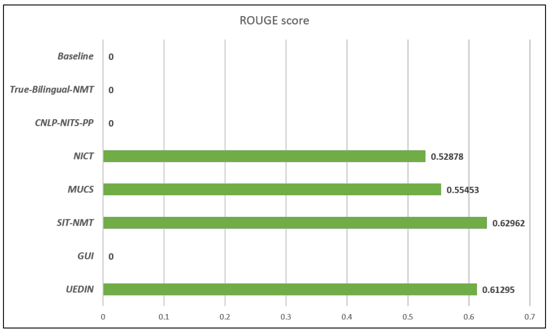

Figure 3: Comparison of ROUGE score of participated teams with the proposed model for subtask 2

5 Conclusion and Future work

This paper describes the models submitted by our team - MUCS to MixMT 2022 shared task to perform MT from English text and their corresponding Hindi translations into Hinglish text and from Hinglish text to English. The proposed models consist of transliteration and pseudo translation generation followed by fine-tuning the pretrained MT models using the combination of pseudo parallel data and the shared task dataset for target generation. These models obtained ROUGE scores of 0.35806 and 0.55453 securing 5th and 3rd rank for subtask 1 and subtask 2 respectively. The efficient transliteration techniques with effective fine-tuning of the pretrained models for code-mixed Hinglish translation will be explored further.

Abstract

This paper describes the Stevens Institute of Technology's submission for the WMT 2022 Shared Task: Code-mixed Machine Translation (MixMT). The task consisted of two subtasks, subtask 1 Hindi/English to Hinglish and subtask 2 Hinglish to English translation. Our findings lie in the improvements made through the use of large pre-trained multilingual NMT models and in-domain datasets, as well as back-translation and ensemble techniques. The translation output is automatically evaluated against the reference translations using ROUGE-L and WER. Our system achieves the 1^{st} position on subtask 2 according to ROUGE-L, WER, and human evaluation, 1^{st} position on subtask 1 according to WER and human evaluation, and 3^{rd} position on subtask 1 with respect to ROUGE-L metric.

1 Introduction

Code-mixing (or code-switching) is the phenomenon when another language like Hindi is interleaved with English words in the same sentence. This code-mixed language is mostly used in social media text and is colloquially referred to as Hinglish. Despite Hindi being the fourth most widely spoken language in the world (Lewis, 2009), research in Hinglish translation has been a relatively unexplored task.

A major challenge in creating a translation system for code-mixed text is the limited amount of parallel data (Ranathunga et al., 2021). Typical methods use standard back-translation techniques (Sennrich et al., 2015a) for generating synthetic parallel data for training. Massive multilingual neural machine translation (NMT) models have recently been shown to improve the translation performances for low-resource and even zero-shot settings. We propose using such large multilingual NMT models for our code-mixed translation tasks.

Previous work has only used smaller multilingual architectures (Gautam et al., 2021). We use pre-trained multilingual models trained in up to 200 language directions. We finetune these models for the Hindi to Hinglish and Hinglish to English tasks. One major challenge when using these massive models is the GPU memory constraint. Another issue is the ratio of English and Hinglish words interleaved for each translation output. We use multiple state-of-the-art GPUs with model parallelization to overcome the memory issue. For the amount of English in the outputs, we tune the model parameters including learning rate, dropout, and the number of epochs to get the optimal translations.

Along with these pre-trained multilingual NMT models, we also use additional in-domain data, back-translation to generate additional parallel data, and using multi-run ensemble to improve the final performance. All these methods gave us an improvement of +24.4 BLEU for Hindi to Hinglish translation (subtask 1) and +28.1 BLEU points for Hinglish to English translation (subtask 2) compared to using only the organizer provided data and the baseline experiment.

In this paper, we discuss our submission for the WMT 2022 MixMT shared task. We participate in both the subtasks and our submission system includes the following:

- Tune very large pre-trained multilingual NMT models and finetune on in-domain datasets;
- Back-translation to create synthetic data for in-domain monolingual data;
- Multi-run ensemble to combine models trained on various datasets;

- Tune model parameters to enhance model performance.

2 Related Work

Multilingual Neural Machine Translation (MNMT) Word and subword-level tokenizations are widely used in natural language processing, including NMT/MNMT. Morishita et al. (2018) propose to incorporate hierarchical subword features to improve neural machine translation. Massively multilingual NMT models are proposed by Aharoni et al. (2019) and Arivazhagan et al. (2019). They are trained on a large number of language pairs and show a strong and positive impact on low-resource languages. However, these models tend to have representation bottlenecks (Dabre et al., 2020), due to the large vocabulary size and the large diversity of training languages. Two MNMT systems (Tan et al., 2019; Xiong et al., 2021) are proposed to solve this problem by modifying the model architectures, adding special constraints on training, or designing more complicated preprocessing methods. Xiong et al. (2021) adopt the contrastive learning scheme in many-to-many MNMT. Tan et al. (2019) propose a distillation-based approach to boost the accuracy of MNMT systems. However, these word/subword-based models still need complex preprocessing steps such as data augmentation or special model architecture design.

Code-mixed NMT The majority of research for code-mixed translation focuses on generating additional data using back-translation methods. Winata et al. (2019) used the sequence to sequence models to generate such data and Garg et al. (2018) used a recurrent neural network along with a sequence generative adversarial network. Pratapa et al. (2018) generated linguistically-motivated sequences. Additionally, there have been several code-mixed workshops (Bhat et al., 2017; Aguilar et al., 2018) to advance the field of code-mixed data.

Hindi or Hinglish NMT Researchers have worked on machine translation from Hindi to English (Laskar et al., 2019; Goyal and Sharma, 2019), however, there has been far less work for Hinglish. A major issue is the lack of parallel Hinglish-English data. Additional parallel data generated by back-translation is used to improve the performance (Gautam et al., 2021; Jawahar et al., 2021). The CALCS'21 competition (Solorio et al., 2021) had a shared task for English to Hinglish for movie review data.

3 Background

3.1 Task Description

The WMT 2022 CodeMix MT task consists of two subtasks. Subtask 1 is to use Hindi or English as input and automatically translate it into Hinglish. Subtask 2 is to input a Hinglish text and translate it into English. Participation in both subtasks was compulsory for the competition. We use Hindi only as the source for subtask 1.

3.2 Neural Machine Translation

The Neural Machine Translation (NMT) task uses a neural network-based model to translate a sequence of tokens from one human language to another. More formally, given a sequence of tokens in source language $x = \{x_1, x_2, \cdots, x_n\}$, the model outputs another sequence of tokens in target language $y = \{y_1, y_2, \cdots, y_m\}$. The input sequence x is encoded into the latent representation by a neural network-based encoder module, and these representations are decoded by the neural network-based decoder module. We train transformer-based encoder-decoder models (Vaswani et al., 2017) to translate the data. These models use a self-attention mechanism in their architectures to boost performance.

3.3 Multilingual NMT (MNMT)

Initial NMT systems were only capable of handling two languages. However, lately, there has been a focus on NMT models which can handle input from more than two languages (Dong et al., 2015; Firat et al., 2016; Johnson et al., 2017). Such models, commonly called Multilingual NMT (MNMT) models, have shown improvement in low-resource or zero-shot Neural Machine Translation settings. Instead of translating a sequence of tokens in source language x to another sequence in target language y, the MNMT system uses multiple sources and target languages.

There are two main approaches: (1) use a separate encoder and decoder for each of the source and target languages (Gu et al., 2018), and (2) use a single encoder/decoder which shares the parameters across the different languages (Johnson et al., 2017).

The issue with the first approach is that it requires a much larger memory due to multiple encoders and decoders (Vázquez et al., 2018). The second approach is much more memory efficient due to parameter sharing (Arivazhagan et al., 2019).

Training a model using the second approach can be done by adding a language tag to the source and target sequence. Specifically, when the decoding starts, an initial target language tag is given as input, which forces the model to output in that specific language.

4 Methods

For the initial set of experiments, we use the baseline transformer model (Vaswani et al., 2017). For all the other experiments, we use pre-trained multilingual NMT models and fine-tuned them for the specific datasets. We can divide these into three groups based on the number of parameters. (1) smaller models including mBART-50 (Tang et al., 2020) and Facebook M2M-100 medium model (Fan et al., 2021) (M2M-100), (2) the medium models include the Facebook NLLB-200 (Costa-jussà et al., 2022) (NLLB-200) and Google mT5 XL (Xue et al., 2021) (mT5-XL), and (3) for large model we use the Google mT5 XXL model (Xue et al., 2021) (mT5-XXL). The parameter count for each of the models and the training time per epoch for baseline datasets are mentioned in Table 1.

For both subtasks, we use Hindi as the source language tag and English as the target language tag.

4.1 Pre-trained Models

To train the transformer, mBART-50, and M2M-100 models, we use the Fairseq toolkit (Ott et al., 2019), and the larger NLLB-200, mT5-XL, and mT5-XXL models use the Huggingface toolkit (Wolf et al., 2019). Table 1 lists the parameter count for each pre-trained multilingual model.

Model	Params
mBART-50	611M
M2M-100	1.2B
NLLB-200	3.3B
mT5-XL	3.7B
mT5-XXL	13B

Table 1: Parameter count for each pre-trained multilingual model.

4.2 Data Augmentation

We use three different ways to add additional in-domain data for training our models.

Additional in-domain data We use additional in-domain parallel data and add it to the training data for accuracy improvement. Since our focus is on Hindi for subtask 1 and Hinglish for subtask 2, we tried to look for data from additional domains with Hindi or Hinglish as the source. We use Kaggle Hi-En (Chokhra, 2020) and MUSE Hi-En dictionary (Lample et al., 2017) for subtask 1. For subtask 2, we use Kaggle Hg-En data (Tom, 2022), CMU movie reviews data (Zhou et al., 2018), and CALCS'21 Hg-En dataset (Solorio et al., 2021). We also use selected WMT'14 News Hi-En sentences (Bojar et al., 2014) and the MTNT Fr-En and Ja-En data (Michel and Neubig, 2018). Table 2 all lists these datasets.

Back-translation A common technique used to increase the data size for low-resource languages is to use in-domain monolingual data and generate synthetic translations using a reverse translation system (Sennrich et al., 2015a). We use google translate for back-translation. We translate samples from the English side of Tatoeba Spanish to the English dataset (Tatoeba, 2022) and Sentiment140 dataset (Go et al., 2009) into Hinglish and use the synthetic translations as additional bilingual data.

4.3 Ensemble

We use a multi-run ensemble (Koehn, 2020) to combine multiple model's best checkpoints to boost the final performance. We average the probability distribution over the vocabulary for all the models to generate a final probability distribution and use that to predict the target sequence.

Dataset	Sentences	V_R	V
HinGE Hi-Hg	2.3K	103K	19K
PHINC Hg-En	13K	302K	55K
HinGE Hg-En	11K	109K	22K
Kaggle Hi-En	11K	220K	31K
Kaggle En-Hg	1.8K	98K	17K
MUSE Hi-En	30K	29K	24K
CMU Reviews Hg-En	8K	180K	24K
CALCS'21 Hg-En	8K	182K	23K
Back-translation Hg-En	8.5K	48K	7K
WMT'14 Hi-En	15K	181K	21K
MTNT Fr-En	10K	16K	14K
MTNT Ja-En	3.5K	120k	8K

Table 2: Datasets provided by the organizers and additional in-domain and out-of-domain datasets used for subtask 1 and 2. V_R is the number of running words and V is the vocabulary size.

5 Datasets

The competition provided one dataset for each of the subtasks, HinGE Hi-Hg (Srivastava and Singh, 2021) for subtask 1 and PHINC Hg-En (Srivastava and Singh, 2020) for subtask 2. The competition also provided the validation data. In addition to these, we also use additional in-domain and out-of-domain datasets.

Due to a large overlap of English and Hinglish vocabulary, we use Hindi-English (Hi-En) and Hindi-Hinglish (Hi-Hg) datasets for subtask 1. For subtask 2, we use various Hinglish-English datasets. All the competition provided datasets, the additional in-domain datasets, and the additional out-of-domain datasets used for both the subtasks are listed in Table 2. As HinGE En-Hg has multiple Hinglish translations for a single English sentence. We duplicated the English to increase the size of the data. For the WMT'14 Hi-En dataset, we selected the closest 15K sentences, selected using cosine similarity with source-side validation data.

To preprocess the data, we tokenize using the Moses tokenizer (Koehn et al., 2007) or the model-specific tokenizer provided by Huggingface. Additionally, we apply either Byte pair encoding (BPE) (Sennrich et al., 2015b) for the baseline transformer model and sentence piece (Kudo and Richardson, 2018) for all other models including mBART-50, M2M-100, NLLB-200, mT5-XL and mT5-XXL to split words into subwords tokens.

6 Experiments

This section describes the experimental details, including the toolkits, the parameter settings for the model training and decoding, and the results.

6.1 Tools & Hardware

For the Models mentioned in Section 4.2, we train the smaller models on 32GB NVIDIA Tesla V100 GPUs, and the medium and larger models require multiple 80GB NVIDIA A100 GPUs. We use a total of 4 V100 GPUs and 16 A100 GPUs. Due to GPU memory usage (see Section 1), we parallelized the training of the medium and larger models using the DeepSpeed package (Rasley et al., 2020).

6.2 Training Details

As an NMT baseline, we use the baseline transformer model (Vaswani et al., 2017) provided by the Fairseq toolkit. The model has half number of attention heads and the feed-forward network dimension compared to the Transformer (base) model in Vaswani et al. (2017). The rest of the network architecture is the same. We train this model from scratch by adding additional datasets and finally tuning it on the validation data.

We use the Fairseq toolkit for training the baseline transformer from scratch and for finetuning the mBART-50 and M2M-100 models. For finetuning NLLB-200, mT5-XL, and mT5-XXL models, we use the Huggingface toolkit. For the pre-trained multilingual models, we use the Hindi language encoder and English language decoder for finetuning and decoding.

As shown in Table 4, we finetune the models with the listed datasets for each subtask. We initially fine-tune these models on ID 4 dataset mentioned in Table 4. Finally, we further finetune the models on the validation datasets provided by the organizers.

Hyper-parameter settings We train the Transformer model from scratch and finetune all the multilingual pre-trained models. We train Transformer, mBART-50, and M2M-100 models for 10 epochs on the ID 4 datasets and 5 epochs on the validation dataset. We finetune the larger models listed in Table 3, for a maximum of 3 epochs before tuning on the validation for 7 epochs for subtask 1 and 4

Model	Train time/epoch	
	Subtask 1	Subtask 2
mBART-50	2 mins	14 mins
M2M-100	8 mins	33 mins
NLLB-200	16 mins	1.5 hrs
mT5-XL	20 mins	15 hrs
mT5-XXL	5.5 hour	24 hrs

Table 3: Per epoch training time for each of the models. The training time is for ID 4 datasets in Table 4.

epochs for subtask 2, respectively. We set the Adam betas to 0.9 and 0.98 for all the models and tuned the learning rates between $1e^{-5}$ and $9e^{-5}$. We opt for higher learning rates for the initial epochs and use lower learning rates for the remaining epochs. Finetuning with a high learning rate for fewer epochs is particularly helpful as larger models take much more time per epoch, even with the larger GPU memory. We also experiment with tuning the dropout between 0.1 and 0.15, and we get the best performance with the dropout rate set to 0.1. The batch size is limited to smaller values due to memory constraints. We set the batch size to 10 or 20 for larger models and 40 or 50 for medium-sized or smaller models.

Decoding parameters For the decoding step for both tasks, we set English as the target language tag for all the models. We tune the beam size, and the optimal beam size is 17 for both subtasks on the validation set. We limit the maximum sentence length to 128 only for the medium and larger models like NLLB-200, mT5-XL, and mT5-XXL. Finally, we detokenize the translation output as a post-processing step (Koehn et al., 2007).

6.3 Additional Experiments

We also perform additional experiments that are helpful but not included in the final submission due to limited time. These are the MTNT datasets and the ensemble methods. Firstly, we use the MTNT dataset as an additional bilingual in-domain data set containing different source languages. We also apply the multi-run ensemble method to combine models trained on multiple datasets together (Koehn and Knowles, 2017). For both tasks, we train M2M-100 models on the MTNT Fr-En data and the MTNT Ja-En data before tuning them on the baseline datasets, respectively. Additionally, we first fine-tune the WMT'14 News Hi-En data and then fine-tune the baseline data. Then we ensemble these two models with the original base model.

7 Results

We evaluate the models with respect to the BLEU score using `sacrebleu`. Table 5 shows the results of the experiments for both tasks and all the models. In general, we get improvement with larger multilingual models and with validation finetuning.

Table 4 shows the results of training from scratch using the transformer model with additional in-domain datasets. We get a maximum improvement of 9.3 for subtask 1 and 4.0 for subtask 2 using the additional datasets. Finally, tuning on validation gave an additional boost of +1.1 and +0.2 BLEU for subtasks 1 and 2 respectively. Table 5 shows the results for using pre-trained multilingual models on the ID 4 datasets. We get a maximum improvement of 25.6 and 32.6 for subtasks 1 and 2. This is +14.0 and +23.9 BLEU points higher than the best transformer model's results in Table 4.

Table 6 shows the ensemble results of a multi-run ensemble of the three models: (1) The baseline M2M-100 model in Table 5, (2) The M2M-100 model first trained on MTNT data and then on the baseline data, and (3) Training the M2M-model on MTNT data, then on WMT data, and finally on the baseline data. We get a slight decrease of −0.3 BLEU for subtask 1 compared to the baseline. However, for subtask 2, the performance improves by +0.8 BLEU points.

8 Analysis

We analyze the translation outputs of NLLB, mT5-XL, and mT5-XXL models. For subtask 1, the issues we faced were that the sentences were translated entirely to English and did not contain any Hinglish words. Some words were translated partially to Hinglish, and a portion of the words remained in the Hindi language. For subtask 2, the issues we faced were that the names of animal species were not translated correctly. And idioms lose their meaning in translation. Examples of these issues are shown in Table 7 & 8.

ID	Datasets	Hi-Hg
1	HinGE	1.2
2	[1]+Kaggle	6.4

9 Conclusion

This paper describes our submitted translation system for the WMT 2022 shared task MixMT competition. We train five different multilingual NMT models including mBART-50, M2M-100, NLLB-200, mT5-XL, and mT5-XXL, for both subtasks. We finetune on in-domain datasets including the validation data and significantly enhance our translation quality from 1.2 to 25.6 and 4.5 to 32.6 for subtasks 1 and 2 respectively. Additionally, we also apply data-augmentation techniques including back-translation, tuning on in-domain data, and checkpoint ensemble. Our system got the 1^{st} position in subtask 2 for both ROUGE-L and WER metrics, the 1^{st} position in subtask 1 for WER, and 3^{rd} position in subtask 1 for ROUGE-L.

Abstract

The University of Edinburgh participated in the WMT22 shared task on code-mixed translation. This consists of two subtasks: i) generating code-mixed Hindi/English (Hinglish) text generation from parallel Hindi and English sentences and ii) machine translation from Hinglish to English. As both subtasks are considered low-resource, we focused our efforts on careful data generation and curation, especially the use of backtranslation from monolingual resources. For subtask 1 we explored the effects of constrained decoding on English and transliterated subwords in order to produce Hinglish. For subtask 2, we investigated different pretraining techniques, namely comparing simple initialisation from existing machine translation models and aligned augmentation. For both subtasks, we found that our baseline systems worked best. Our systems for both subtasks were one of the overall top-performing submissions.

1 Introduction

Code-mixing is the shift from one language to another within a single conversation or utterance (Sitaram et al., 2019). It is an extremely common and diverse communicative phenomenon worldwide (Doğruöz et al., 2021; Sitaram et al., 2019), though one which is currently under-served by many NLP technologies (Solorio et al., 2021).

One of the most well-known examples of code-mixing is between Hindi and English, commonly referred to as Hinglish[1]. It is extremely common amongst Hindi-English bilingual speakers in both speech and text, used across a range of genres and media (Parshad et al., 2016), and has its own distinctive features and linguistic forms (Kumar, 1986; Sailaja, 2011). The process of generating Hinglish from the written text is non-trivial, as code-mixing may happen at the phrase or word level, but Hindi and English differ substantially syntactically.

As a novel addition to the current code-mixing NLP research, we investigated lexically constraining the Hinglish output in subtask 1 to only contain words from English and Hindi sources. Through analysis, we demonstrated that transliteration mismatches could affect performance.

Another novel approach we explore for this task, particularly for subtask 2, is a denoising-based pretraining technique called Aligned Augmentation (AA) (Pan et al., 2021). AA, which trains MT models to denoise artificially generated code-mixed text, was shown by Pan et al. (2021) to boost translation performance across a variety of languages - thanks to the enhanced transfer learning brought about by code-mixed pretraining. In this work, we explored if this general-purpose approach could be useful for translating authentic, human-generated code-mixed text, focusing on Hinglish.

Despite these efforts, we found that for both subtasks our original baselines worked better and constituted our final submissions for this task, which ranked as one of the top-performing systems for both subtasks, by both automatic and human evaluation. We hope our methods, particularly Hinglish data generation, that allowed us to build these systems would be useful to the community; as would the findings from our additional research explorations.

2 Related Work

2.1 Code-mixing

Due to an increasing prevalence of code-mixed data on the Internet, there is a growing body of research into code-mixing, particularly for Hinglish, in the NLP community. Doğruöz et al. (2021) provide a comprehensive literature review of code-mixing in the context of language technologies. Whilst they highlight several challenges inherent

[1] In the scope of this paper, we designate "hg" as the language code for Hinglish.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1145 - 1157
December 7-8, 2022 ©2022 Association for Computational Linguistics

in NLP with code-mixed text (such as understanding cultural and linguistic context, evaluation, and a lack of user-facing applications), the most notable obstacle for this shared task is the lack of data. They note that there are very few code-mixed datasets, making it challenging to build deep learning models such as those for NMT. In this work, we use backtranslation as our main data augmentation method (Edunov et al., 2020; Barrault et al., 2020; Akhbardeh et al., 2021, *inter alia*). This allows us to leverage the larger amount of monolingual data for better final model performance. The XLM toolkit (Lample and Conneau, 2019) seemed an ideal choice to backtranslate our Hinglish. This is because it has shown promising results in unsupervised and semi-supervised settings where parallel data is sparse, but monolingual data is ample. Also given that Hinglish is closely related to both languages, we believed Hinglish should be an ideal language to use in a semi-supervised setting.

2.2 Constrained decoding

Constrained decoding involves applying restrictions to the generation of output tokens during inference. Most implementations have the goal of ensuring that desired vocabulary items appear in the target side sequence (Hokamp and Liu, 2017; Hasler et al., 2018; Post and Vilar, 2018). Alternatively, Kajiwara (2019) paraphrase an input sentence by forcing the output to not include source words, and Chen et al. (2020) constrain NMT decoding to follow a corpus built in a trie data structure to find parallel sentences.

To the best of our knowledge, previous linguistics research investigated and applied the grammatical constraints in code-mixing (Sciullo et al., 1986; Belazi et al., 1994; Li and Fung, 2013), rather than the novel method in our work of introducing lexical constraints.

2.3 Aligned augmentation

Several recent works (Yang et al., 2020a,b; Lin et al., 2020; Pan et al., 2021) have explored enhancing cross-lingual transfer learning by pretraining models on the task of 'denoising' artificially code-mixed text. Methods to create the necessary code-mixed data vary, and include bilingual or multilingual datasets and word aligners (Yang et al., 2020a, 2021), lexicons (Yang et al., 2020b; Lin et al., 2020; Pan et al., 2021), or combining code-mixed noising with traditional masked noising approaches (Li et al., 2022).

The most successful among these methods is Aligned Augmentation (AA) (Pan et al., 2021), which randomly substituting words in the source sentence with their word-level translations, as obtained from a MUSE (Lample et al., 2018) dictionary. Pan et al. (2021) showed that their technique can effectively align multilingual semantic word representations and boost performance across various languages. However, these methods focus on training general-purpose MT models. In this work, we investigate their utility for translating real human-generated code-mixed text.

2.4 Automatic evaluation metrics

Automatic translation evaluation is usually done using BLEU (Papineni et al., 2002), yet there is no comprehensive study on its suitability for code-switched translation. Specifically in this task, the organisers announced that the participating systems will be evaluated using ROUGE-L (Lin, 2004) and word error rate (WER). Nonetheless, the packages implementing these metrics were not specified. Since ROUGE comes with different language, stemming and tokenisation settings, we instead used BLEU, ChrF++ (Popović, 2017), translation error rate (TER), and WER[2] for our internal validation. The first three are as implemented with sacreBLEU (Post, 2018). We stick to the default configurations, except that the ChrF word n-gram order is explicitly set to 2 to make it ChrF++. In addition, the organisers performed a small-scale human evaluation on 20 test instances for all submissions.

In this work, we advocate for a character-based metric when evaluating the Hinglish output in subtask 1. This is because for the code-switched language, there is no formal spelling or defined grammar, and words may have a diverse range of acceptable transliterations and lexical forms.

3 Subtask 1: Translating into Hinglish

Good quality Hinglish data is hard to come by, and parallel Hinglish data with Hindi or English even more frugal. Therefore, for both subtasks we concentrated our efforts on generating good Hinglish backtranslation. We planned to use the model which produced the highest quality Hinglish for subtask 1 as our backtranslator for subtask 2, hence we focused our efforts on each subtask sequentially.

[2] https://github.com/jitsi/jiwer

3.1 Data cleaning and preprocessing

After deduplicating the data, we removed non-printing characters and normalised the punctuation. We then ran rule-based filters, removing any sentences with fewer than two or more than 150 words, where fewer than 40% of the words are written in the relevant script, or where over 50% of characters are not letters in the relevant script. For English and Hindi, we ran `fasttext` language ID and removed any sentence which was not classified as the relevant language.[3] For Hinglish, we also removed any sentence with a predicted probability of English greater than 0.99 in order to remove sentences that were solely in English. We tokenised English and Hinglish using Moses scripts (Koehn et al., 2007) and tokenised Hindi using the `indicnlp` library (Kunchukuttan, 2020).

We decided to add explicit preprocessing and postprocessing capabilities for handling social media text, given that this was the domain for subtask 2. On both source and target sides, we replaced URLs, Twitter handles, hashtags and emoticons each with their own placeholder tokens[4], to be replaced back from the source after inference. These placeholders made up 1.7% of the validation set tokens for subtask 2, far higher than would appear in general domain data.

3.1.1 The HinGe dataset

The primary dataset for subtask 1 was the HinGe dataset (Srivastava and Singh, 2021), which consisted of hi-en-hg parallel sentences, with some examples synthetic and some human-generated. This was provided to us pre-split into training and development sets for both data types. However, we noticed that these sets were not mutually exclusive, and after deduplication and filtering on the synthetic data human annotations[5], we had 6,727 hi-en-hg examples in total.

3.1.2 Base hi↔en translation models

Firstly, we trained four Transformer-base (Vaswani et al., 2017) models with different seeds using Marian (Junczys-Dowmunt et al., 2018) for both hi→en and en→hi directions, using the data from the hi-en parallel Samanantar corpus[6] (Ramesh et al., 2021). Given the findings of Ding et al. (2019) with regard to vocabulary choice for low-resource scenarios, and that our task inherently contains transliteration, we opted for a low BPE (Sennrich et al., 2016) merge size of 4k, resulting in a small joint vocabulary of 7.9k. We used the hi-en FLORES development set (Goyal et al., 2022) for validation and early stopping, and noticed our model produced surprisingly good quality translations in both directions[7]. We used these models (along with vocabulary) to both initialise subsequent models and generate backtranslation for more training data.

3.1.3 Hinglish data

L3Cube-HingCorpus (Nayak and Joshi, 2022) and CC-100 Hindi Romanized (Conneau et al., 2020a) are two Hinglish corpora that we wished to backtranslate into both English and Hindi. Given that we only had a small amount of parallel Hinglish data, compared to our 'monolingual' datasets, we used the XLM toolkit (Lample and Conneau, 2019) to train a semi-supervised model (see Appendix A for details). We then backtranslated the monolingual Hinglish data into both English and Hindi. However, given the noisy quality of the data and translations themselves, we decided to evaluate them using our hi→en and en→hi Marian models. Specifically, for an en-hi backtranslated (XLM) sentence pair, we translated the en/hi into hi/en respectively, then evaluated the double translated output using ChrF, with the XLM backtranslations as the references. We then took a mean of the English and Hindi ChrF score to get our final confidence value. We used the resulting hg-en-hi sentence trios with values at least 0.4, to compromise between the quality and quantity of data available to use as training. Most of the sentences scored quite poorly, and filtering on 0.4 yielded 2.1M sentences, only about 12% of the original Hinglish monolingual dataset.

3.1.4 Transliteration

In order to best leverage the Samanantar hi-en parallel corpus, we transliterated the Hindi side into Roman script[8], on the word level. Although this

[3] Our cleaning scripts are adapted from those provided by the Bergamot project. https://github.com/browsermt/students/tree/master/train-student Specifically, we add support for Hindi and Hinglish text.

[4] `<URL>, <TH>, <HT>` and `<EMO>` respectively

[5] We only kept sentences with an average rating greater than 4, and annotator disagreement less than 5

[6] Each sentence was annotated with the LaBSE (Feng et al., 2022) Alignment Score (between 0 and 1), so we filtered out values less than 0.65, resulting in around 10.1M sentences

[7] sacreBLEU: 33.8 for hi→en and 32.7 for hi→en on FLORES development set

[8] In the scope of this paper, we use "ht" to denote pure romanised Hindi transliteration

Beam Size	BLEU (↑)	ChrF++ (↑)	TER (↓)	WER (↓)

Table 1: Experimental results on the validation set with unconstrained and constrained decoding for subtask 1.

forward transliteration was not likely to contain much code-mixed text, it would still be useful training data for our model, given that both the Hindi and English sources are assumed to be either the original sources or human translationese.

We used the AI4Bharat Indic transliterator (Madhani et al., 2022), to convert (on the word level) all romanised tokens contained in our monolingual Hinglish datasets into Devanagari script. This tool is a neural-based model with beam search capabilities, therefore we generated the top 4 results in Hindi for each Hinglish token. We used the top 4 instead of the most likely candidate as, upon inspection, we found that the correct corresponding Hindi token was not always predicted first. We also used a human-generated list of Hinglish-English pairs form the Xlit-Crowd corpus (Khapra et al., 2014) which we treated as the gold standard.

To summarise, our training data for our hi→ht transliterator[9] consists of 5.3M Hinglish-Hindi word pairs (1.3M unique Hinglish words), and 15k from XlitCrowd, of which we use 1k as a validation set for early stopping. We train a small transformer model with Marian on the **character-level** for both input and output. When forward transliterating the Hindi side of the Samanantar corpus, we copied over non-standard strings (such as numbers, punctuation etc.), or else we looked up the token (if it existed) in our gold standard list. Otherwise, we used our transliteration model as a final back-off. In hindsight, one disadvantage of our approach was that we did not generate multiple candidates for each Hindi word, to reflect the diversity of possible romanised candidate tokens.

We also used this transliteration model as part of our constrained decoding experiments later (see Section 3.3).

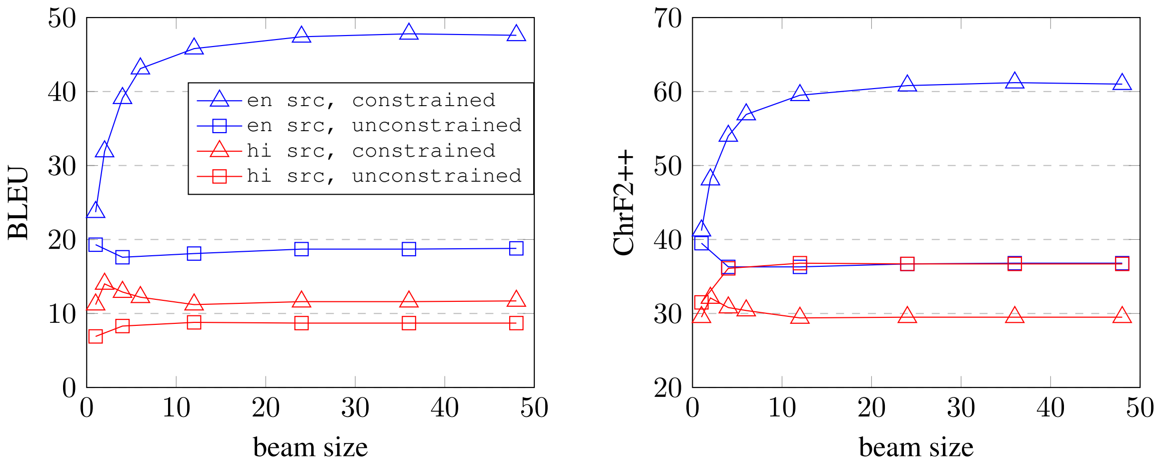
3.2 Baseline (unconstrained decoding)

We decided to use a dual encoder setting given that we have two inputs in this task, and initialise our model from our previously trained Marian MT systems. We used hi→en to initialise the Hindi-decoder and the English-encoder cross attention parameters, whereas en→hi was used to initialise the English-encoder and all other decoder parameters. Our vocabulary was the same as the pretrained models.

Early stopping with patience 10 on the HinGe dataset was used for convergence - for all of the experiments mentioned in this paper. Our training regime consisted of two stages:

- General domain - The training datasets used were the backtranslated Hinglish and forward transliterated Samanantar corpora. We used all of the HinGe dataset as a validation set.
- Finetuning - We continue training on a sub-

[9] We decided to build our own transliterator as we found existing tools in this direction to be of poor quality



(a) BLEU

(b) ChrF++

Figure 1: Validation BLEU and ChrF++ of the constrained and unconstrained outputs scored against English and transliterated Hindi *sources* separately.

set of HinGe dataset, using a distinct smaller subset (1k) of it as a validation set.

3.3 Constrained decoding

After analysing the training data, we hypothesized that nearly all the output words should either be from the English source, or as a transliteration of a word from the Hindi source, with likely little change in sentence structure. This inspired us to use the technique of constrained decoding when generating Hinglish.

Unlike standard constrained decoding where a model is forced to incorporate certain words in the output, our proposal is to exclude vocabulary words that do not exist in English or transliterated Hindi source sentences. Following Chen et al. (2020)'s notion, we applied pre-expansion pruning: disallowed word paths are assigned an extremely small score before hypotheses are ranked and expanded. Specifically, to obtain Hindi transliteration, we used our transliteration model described in Section 3.1.4.

We performed beam searches with constrained decoding and reported automatic scores on the validation set in Table 1. Unfortunately, constrained decoding does not beat unconstrained decoding. As a general trend, WER and TER do not change much as beam size increases, while BLEU and ChrF++ significantly improve.

To better understand the impact of constrained decoding, we score the validation outputs against English and transliterated Hindi sources separately, then plot BLEU and ChrF++ numbers in Figure 1a and Figure 1b. We observe that with increasing beam sizes, constrained decoding prefers to generate English tokens instead of transliterated Hindi. Unconstrained decoding achieves a much better balance.

One hypothesis is that the quality of Hindi transliteration is not perfect, resulting in the model preferring English tokens from the vocabulary. Hence, we compute the percentage of words in the gold reference as well as in the unconstrained (baseline) output that come from neither the English nor the transliterated Hindi source. Surprisingly, on average 45.1% of the total words in the unconstrained output do not appear in the sources; as for the gold reference, it is 39.8% which is slightly lower. It is worth noting that the numbers might be inflated as we computed the word overlap after outputs are detokenised. Yet it implies that many of the reference words do not exactly appear in the lexical constraints determined from the source senteneces.

Finally, we visualise the first five validation sentences in Table 2. We highlight in *red* the target words that do not exist in the source sentences; we also label the possible corresponding tokens from the sources in *blue*. It can be confirmed that most mismatches are due to differences in Hindi transliteration and letter cases. This indicates that the lexical constraint idea is suitable in theory, but it is hindered by the error propagation in transliteration. This may have been alleviated by running multiple transliteration schemes on the Hindi source to make the constraints more diversified.

hi source	1995 से 2004 के दौरान औसत धरातलीय तापमान 1940 से 1980 तक के औसत तापमान से भिन्न्न है

Table 2: The first five validation instances: English and Hindi sources, as well as constrained, unconstrained and reference outputs. *red* denotes the target side words that do not appear in either of the source sentences from a constrained aspect; *blue* denotes possible source-target matches in a different surface form.

4 Subtask 2: Hinglish-to-English

4.1 Data cleaning and preprocessing

The primary dataset provided for this task PHINC (Srivastava and Singh, 2020) is relatively small at 13.7k English-Hinglish pairs. Therefore, we aimed to generate domain-specific parallel data using our baseline model from Subtask 1 on English monolingual data.

We analysed the source side of the validation dataset to determine the most frequent content words (see Table 3) and then selected these words (and any morphological/spelling variants) from the English WikiMatrix corpus (Schwenk et al., 2021). This yielded a total 477k English sentences and we henceforth refer to this selection of sentences as ToxicWiki. We also used Sentiment140 (Sahni et al., 2017), a dataset of 1.6M tweets in English, as the domain of our validation set is also Twitter.

Word	Validation	WikiMatrix
rape	249	23,198
hate	117	16,824
terrorism	24	11,160
khoon (blood)	21	59,526
murder	21	75,066
india	16	291,054
Total	-	476,828

Table 3: Frequency of top content words present in our validation set, and the number of sentences within WikiMatrix that contained the word (or morphological variants). The resulting sentences formed ToxicWiki

To obtain the Hinglish side of both Sentiment140 and ToxicWiki datasets, we backtranslated into Hindi using our en→hi Marian model, and then used the en-hi pair and our baseline system for subtask 1 to obtain the corresponding Hinglish. However, many of the placeholders (such as <HT>) did not occur frequently enough during the training of subtask 1 for the model to learn to consistently copy them across; therefore the model was not able to predict them with a large degree of accuracy. Therefore, we ran a postprocessing script that corrected for placeholders on the backtranslated Hinglish, given the English source, so that our downstream model would be able to learn to simply copy these placeholders across. Specifically, we made sure that the number of each placeholder type in the backtranslated Hinglish was the same (and in roughly the same position) as that in the source sentence.

For the AA experiments described in Section 4.3, we used monolingual Hindi, English and Hinglish data. For Hindi and English, we randomly sampled 20M sentences from the News Crawl corpora (Akhbardeh et al., 2021). For Hinglish, the monolingual corpora described above was used. In order to code-mix these corpora as described in the AA algorithm, we used MUSE dictionaries for the Hindi-English pair. For Hinglish-Hindi pairs, we used the data generated with AA for the transliteration model.

4.2 Baseline systems

We used a hi→en MT to initialise the baseline hg→en model.

Our training regime consisted of three stages:

1. General - Training on the backtranslated en-hg internet corpora (with confidence value at least 0.4), and ht-en side of the Samanantar corpus, where we treat the transliteration as Hinglish. We used the PHINC dataset as our validation set for early stopping.

2. We continued training on Sentiment140 and ToxicWiki corpus, using the same validation set as before, until convergence.

3. We continued training on the PHINC dataset, using a small subset (1k) of it as validation data for early stopping.

As we had multiple hi→en MT systems, we also trained an ensemble model of four, where we followed the same training regime above with parameters initialised from each of our hi→en models. Our results are shown in Table 4, with our ensemble model outperforming the single on all metrics.

4.3 Aligned Augmentation for subtask 2

Our Aligned Augmentation (AA) experiments where implemented with Fairseq (Ott et al., 2019), and we used the Transformer architecture, with 12 encoder and 12 decoder layers. Our first step consisted of pretraining these models on Hindi, English, and Hinglish corpora, with the target being the "denoised" sentence - thus training the model to reconstruct the original sentence, following the AA algorithm. For validation, we randomly sampled 1k sentences from the training corpus.

We then finetuned this model on the Hinglish-English parallel corpora mentioned above. The major AA baselines we trained and their performances are listed in Table 5 - along with a randomly initialised baseline that was trained solely on the parallel corpora. The data sources we used in our experiments were quite diverse: we started with high-quality monolingual data for pretraining followed by parallel datasets of varying domains and qualities, (the Hinglish backtranslated corpora, Sentiment140, PHINC and ToxicWiki). We attempted to explore how best these resources could be utilised. We started with our default training paradigm: we finetuned on backtranslated Hinglish, followed by the ToxicWiki and then a shuffled concatenation of the social media datasets - the Sentiment140 and PHINC datasets respectively. This was based on the intuition that the final model should be most recently trained on datasets from similar domains as the test set.

Following this paradigm, we conducted two sets of experiments: a "validation experiment" that tries to estimate the best choice of validation sets, and "training experiments" to verify the importance of some training sources empirically. The former is a crucial decision in our experiments given our use of early stopping. We find that validating on the official MixMT validation sets released for Subtask 2 ends up performing significantly worse than validating on a subset of the respective training datasets. This is surprising given the performances reported in Table 5 are evaluated on the same validation sets. This suggests that training and validating the model on corpora from different domains can help boost the final performance - even if it does not improve loss on the final validation set. In the latter body of experiments, we attempted to determine the value of the XLM backtranslated corpora on performance - which seems very noisy on manual inspection, with the target side (English) being

	BLEU (↑)	ChrF++ (↑)	TER (↓)	WER (↓)
Baseline Experiments				
Single model	24.5	47.0	65.1	72.0
Ensemble (of 4)	**25.5**	**48.7**	**62.9**	**70.5**

Table 4: Baseline results for subtask 2 on the MixMT validation set.

generated through backtranslation. Surprisingly, its inclusion significantly enhances performance, by +5 BLEU points. This could be due to various reasons: its sheer size (15M sentences), the presence of word-level translations between English to Hinglish in parallel sentences (despite grammatical errors), the similarity between the source and the target encouraging “copying" which can sometimes be beneficial for this task, etc. We also find that the inclusion of hi-en along with hg-en further boosts performance, consistent with the findings of previous works on multilingual MT. We empirically found that including ‘all’ available hi-en sentences and ‘all’ available hg-en sentences was more beneficial than splitting our parallel dataset into the two respective directions – despite the target sentence being duplicated in the former.

Compared to the Random baselines, our final AA baselines show consistent improvement for all given metrics - though the improvement is not very significant with respect to BLEU o TER. A closer glance at the validation set and the generated predictions reveals the potential reason behind this - there is a significant amount of noise present in the validation sets due to the social media domain, with errors in both syntax and semantics. Given that it is not always easy to comprehend and translate such sentences well, the gold reference sentences are sometimes of relatively poor quality - containing various potential errors such as inaccurate word form predictions, grammatical errors, misspellings etc. While word-based metrics may fail to handle these cases; ChrF++, being a character-based metric, can likely alleviate noise that may have propagated to reference sentences and might be a more suitable metric for Subtask 2 as well. It is encouraging to note AA’s improvement over the Random baseline in this light.

AA appears to bring about some improvement qualitatively, especially regarding noisy input - for instance, it was able to more accurately translate misspellings and handle grammatical inconsistencies. However, the frequency of sentences where AA performs better than its randomly initialized counterparts seems relatively low. One explanation could be that fine-tuning the model on 18M parallel sentences could lead it to ‘forget’ the representations learned during pretraining. This is in line with the findings of (Pan et al., 2021) that observe relatively lower improvements for high-resource languages. While adding large corpora (15M sentences) such as the XLM backtranslated corpora does lead to net improvements, it is possible optimization in the size of finetuning data used could lead to even greater gains. Secondly, given that our dictionaries appear to help in noise resolution, it might be useful to incorporate various types of misspellings rigorously in the code-mixing lexicons created - thus enabling the final model to be more robust. Finally, including training corpora from other Indo-Aryan languages like Urdu or Marathi could be beneficial. Although Subtask 2 focuses on the translation of Hinglish-English, the validation and test sets (as well as training sets) contain many examples of code-mixing between related Indo-Aryan languages and English - most prominently in Urdu, which is historically and linguistically similar to Hindi.

In the end, we observe that the AA models we train are unable to beat our original single-model baseline, despite having more parameters. Curiously, this is also the case for the randomly initialized baseline in Table 5. Due to time constraints, we are unable to investigate the reasons behind these. Possible explanations could include: training paradigm differences (initializing with hi→en vs mixing hi→en with hg→en), ensembling, experimental setting disparities, inherent differences between training libraries (Fairseq vs Marian). It is possible that addressing these disparities, as well as exploring the directions suggested in the previous paragraph, could enable AA baselines to yield superior results for code-mixed translation.

	BLEU (↑)	ChrF++ (↑)	TER (↓)	WER (↓)
Validation Experiments				
AA (dev = MixMT valid)	20.5	41.2	72.7	78.6
AA (dev = train subset)	23.3	45.7	68.3	74.6
Training Experiments (dev=train subset)				
AA (train = all Hg->En minus XLM BT data)	18.3	38.4	78.3	83.4
AA (train = all Hg->En)	23.3	45.7	68.3	**74.6**
AA (train = all Hg->En + all Hi->En)	**24.4**	**46.2**	**68.2**	74.9
Random	24.3	45.2	68.4	74.6

Table 5: Aligned Augmentation experiments for subtask 2, as evaluated on the official MixMT Subtask 2 validation set. “Validation experiments" refers to experiments performed to select the best choice of the validation set for early stopping. ‘MixMT valid’ refers to the same validation set mentioned earlier (that is also used for evaluation), while ‘train subset’ refers to a subset (last 1000 sentences) of the respective training corpus. “Training experiments” seek to explore various dataset choices during training time, using a subset from the training corpus for validation.

	BLEU	ChrF++	TER	WER	ROUGE-L	Human Eval. Score
Subtask 1	26.9	52.7	55.2	56.2	57.9	3.85
Subtask 2	28.7	51.2	59.1	61.3	62.5	3.75

Table 6: Final Test Results for the University of Edinburgh’s submissions of MixMT 2022. BLEU, ChrF++ and TER were evaluated by us while WER and ROUGE-L results are from the official Codalab leaderboard. Human evaluation (on a scale of 1-5) was provided by the organisers on 20 random sentences and we report the average.

5 Test Results

The final test results for our submissions are listed in Table 6. For Subtask 1, we used unconstrained decoding with beam-size 12, and for Subtask 2 we used our baseline ensemble (4) with beam-size 36. We evaluated BLEU, ChrF++ and TER ourselves, while the other metrics are provided by the organizers. We ranked second in both subtasks on the MixMT leaderboard[10] although in both the automatic and human evaluation[11], there does not appear to be a statistically significant difference. Furthermore, we note that some participants have an exceedingly high number of test submissions and would encourage future shared tasks to put in place measures to avoid this.

6 Conclusion

In this work, we described our various findings and experiences while building NMT systems that translated between Hinglish and monolingual English/Hindi - as part of the WMT22 Code-Mixing Shared Task. We proposed various corpora that could be useful for these tasks - many of which we create as part of this work - and utilizing these, build high-performing MT systems that, for both subtasks, constituted one of the leading unconstrained models. In addition, we also explored and analysed some alternative approaches for training our models like constrained decoding and Aligned Augmentation (AA) which, despite not beating our original baselines, yielded findings that are useful for future research. Perhaps the most notable of these suggests that efforts to create Hinglish datasets, including using transliterated Hindi as an approximation, can be fruitful and pivotal to high performance. While efforts to handle noise in social media text (such as AA-based pretraining) can also help, further research is required to establish the most optimal ways to do the same.

A XLM details

In order to backtranslate the Hinglish data, we hoped to train a good quality semi-supervised system using the XLM toolkit (Conneau et al., 2020b). We use Masked Language Modelling

(MLM) to pretrain a transformer encoder model on English, Hindi and Hinglish monolingual data. The model consisted of 6 layers, 1024 embedding dimensions, batch size 128, and a 0.1 dropout rate. We use 16.5M sentences of English WikiMatrix (Schwenk et al., 2021), 20M of HindiMono (Bojar et al., 2014) and 18.8M of Hinglish from L3Cube-HingCorpus (Nayak and Joshi, 2022) and CC-100 Hindi Romanized (Conneau et al., 2020a). Vocabulary and data preprocessing is the same as for the Marian models (4k BPE merges).

We then initialised a full transformer model with the pretrained encoder, and further trained with denoised autoencoding, MLM, machine translation[13], and backtranslation[14]objectives. We use the Samanantar corpus (10.1M) for the hi↔en translation objective, the 6.7k HinGe sentences as validation for hg↔en and hg↔hi directions, and the hi-en FLORES development set for hi↔en.

[13] hi↔en directions only

Abstract

The mixing of two or more languages in speech or text is known as code-mixing. In this form of communication, users mix words and phrases from multiple languages. Code-mixing is very common in the context of Indian languages due to the presence of multilingual societies. The probability of the existence of code-mixed sentences in almost all Indian languages since in India English is the dominant language for social media textual communication platforms. We have participated in the WMT22 shared task of code-mixed machine translation with the team name: CNLP-NITS-PP. In this task, we have prepared a synthetic Hinglish–English parallel corpus using transliteration of original Hindi sentences to tackle the limitation of the parallel corpus, where, we mainly considered sentences that have named-entity (proper noun) from the available English-Hindi parallel corpus. With the addition of synthetic bi-text data to the original parallel corpus (train set), our transformer-based neural machine translation models have attained recall-oriented understudy for gisting evaluation (ROUGE-L) scores of 0.23815, 0.33729, and word error rate (WER) scores of 0.95458, 0.88451 at Sub-Task-1 (English-to-Hinglish) and Sub-Task-2 (Hinglish-to-English) for test set results respectively.

1 Introduction

The mixing of alternating words from two different language vocabulary without misinterpreting the context of the sentence is known as code-switching or code-mixing (Poulisse, 1998). This style of communication is one of the most frequent in multilingual communities, such as India. English is extensively mixed with local languages, such as Hindi, and Bengali, which causes code-mixed English-Hindi: Hinglish and English-Bengali: Binglish languages (Sailaja, 2011). Code-mixing is not observed in formal literature such as books but is commonly used on social media platforms such as Facebook and Twitter. The WMT22 organizes shared task code-mixed machine translation for English-to-Hinglish and Hinglish-to-English, where the main challenge is low-resource availability of parallel corpus. We have participated in the same task and to mitigate the issue of data scarcity, a synthetic Hinglish-English parallel corpus is prepared (as discussed in Section 3.1). In this work, the transformer-based neural machine translation (NMT) technique (Vaswani et al., 2017; Laskar et al., 2022) is utilized to build NMT models for both directions (English-to-Hinglish, Hinglish-to-English) of code-mixed MT.

2 Related Work

In recent times, many significant NLP studies have included the study of code-mixed languages. The EMNLP 2022 seventh conference on machine translation (WMT22) has put forward several tasks directed to meet new challenges in the field of NLP for code-mixed Indian languages. The competition has attracted many researchers to follow up with these tasks, which have eventually led to new directions and problems in this domain. The task of machine translation for code-mixed languages has not been an active area of research due to the scarcity of manually annotated datasets. Recently, researchers have been developing datasets for code-mixed MT that includes Hinglish-English parallel corpus, namely, HinGe (Srivastava and Singh, 2021) and PHINC (Srivastava and Singh, 2020) to overcome the datasets scarcity issue to build code-mix MT that is associated with the code-mixed text from various social media platforms. In this work, we addressed the issue of data scarcity by using synthetic Hinglish–English parallel corpus to increase the training data for code-mixed MT shared tasks at WMT22.

3 System Description

The experiments are carried out in four phases, namely, synthetic data preparation and augmentation to the train set, data preprocessing, model training, and testing. The OpenNMT-py (Klein et al., 2017) tool is utilized to build the NMT models independently for English-to-Hinglish (subtask-1) and Hinglish-to-English (subtask-2).

3.1 Dataset Description

We have used the dataset provided by the WMT22 organizer[1] and the statistics are presented in Table 1. Moreover, the synthetic English-Hinglish parallel dataset is prepared and directly augmented with the train set to expand the training amount of data. For synthetic data preparation, the English-Hindi parallel sentences are collected from Samanantar dataset (Ramesh et al., 2022) and selected $100k$ sentences (maximum length of 15 words). To select parallel sentences, the following steps are considered:

- Step-1: Extract proper nouns (named-entity) from the English side using NLTK[2] toolkit.
- Step-2: Extract English sentences that have extracted proper nouns in Step-1.
- Step-3: Select corresponding Hindi sentences of English that are extracted in Step-2.

Then, Hindi side sentences are transliterated into English script using Indic-trans[3] (Bhat et al., 2014) and prepared synthetic Hinglish sentences. Thus, we have prepared $100k$ Hinglish–English synthetic parallel corpus. The sample sentences of synthetic Hinglish-English are presented in Figure 1. The data statistics of the train set, before and after augmentation of synthetic Hinglish–English corpus is presented in Table 2.

Figure 1: Sample sentences of synthetic Hinglish-English.

3.2 Experimental Setup

We have performed byte pair encoding jointly (subword level) (Sennrich et al., 2016) on the Hinglish-English with $32k$ merge operations. The subword level source-target vocabulary is shared during the training process of the NMT model. The OpenNMT-py toolkit has been used for text data tokenization, preprocessing, and conducting the NMT model training. We have followed the default settings of the 6 layer transformer model (Vaswani et al., 2017) in the training process. We have used a batch size of 32, 0.1 drop-outs, and an Adam optimizer with a 0.001 learning rate during the training process. The NMT model is trained on a single GPU with early stopping criteria, i.e., the model training is halted if it does not converge on the validation set for more than 10 epochs. The obtained trained model is used to translate the test data provided by the WMT22 organizers.

4 Results

The WMT22 shared task organizer published the evaluation result[4] of the code-mixed machine translation (MixMT) task for English–Hinglish language pair. We participated with the team name CNLP-NITS-PP in the monolingual to code-mixed machine translation: English-to-Hinglish (Sub-Task-1) and code-mixed to a monolingual machine translation: Hinglish-to-English (Sub-Task-2) submission tracks of the same task where ten teams participated. The automatic evaluation metrics, namely, ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (Lin, 2004), WER (Word Error Rate) (Morris et al., 2004) and human evaluation (HE) are used for the evaluation of results. Table 3, 4 reported the official results of our systems in terms of automatic and HE evaluation metrics. We

have attained better automatic evaluation scores and positions in Sub-Task-2 as compared to Sub-Task-1 for the validation and test set, whereas, in the case of human evaluation, we have achieved a higher score and position in Sub-Task-1 than Sub-Task-2. It is observed that due to the presence of a high amount of transliteration errors in synthetic code-mixed sentences, i.e., Hinglish, the predicted sentences suffer lower translation accuracy. A few examples of transliteration errors are presented in Figure 2.

5 Conclusion and Future Work

In this work, we have investigated a transformer-based model for Hinglish–English language pair in the WMT22 code-mixed MT task. We have addressed the data scarcity issue by the augmentation of synthetic Hinglish–English parallel sentences to the train set for both English-to-Hinglish and Hinglish-to-English translation tasks (Sub-Task-1 and Sub-Task-2). Furthermore, synthetic parallel data will be corrected in the future to improve translational performance.

Domain Curricula for Code-Switched MT at MixMT 2022

Abstract

In multilingual colloquial settings, it is a habitual occurrence to compose expressions of text or speech containing tokens or phrases of different languages, a phenomenon popularly known as code-switching or code-mixing (CMX). We present our approach and results for the Code-mixed Machine Translation (MixMT) shared task at WMT 2022: the task consists of two subtasks, monolingual to code-mixed machine translation (Subtask-1) and code-mixed to monolingual machine translation (Subtask-2). Most non-synthetic code-mixed data are from social media but gathering a significant amount of this kind of data would be laborious and this form of data has more writing variation than other domains, so for both subtasks, we experimented with data schedules for out-of-domain data. We jointly learn multiple domains of text by pretraining and fine-tuning, combined with a sentence alignment objective. We found that switching between domains caused improved performance in the domains seen earliest during training, but depleted the performance on the remaining domains. A continuous training run with strategically dispensed data of different domains showed a significantly improved performance over fine-tuning.

1 Introduction

Code-mixing (CMX) denotes the alternation of two languages within a single utterance (Poplack, 1980; Sitaram et al., 2019). Code-mixing occurs mostly in unofficial groups in multilingual environments. More than 77% of Asians are multilingual (Ramakrishnan and Ahmad, 2014), and other statistics estimate that 64.5% of Europeans speak more than two languages, with more than 80% of adults in the region being bilingual (Eurostat, 2019). Code-mixing happens far more often in conversations than in writing, and mostly in unofficial settings, hence it rarely occurs in documented settings. This makes substantial data gathering for computational approaches to translations of code-mixed language difficult. Parallel corpora for code-switched data is very scarce (Menacer et al., 2019), this is because code-mixing mostly occurs in unofficial conversations like social media interactions.

Contemporary Neural Machine Translation (NMT) mostly makes use of parametric sequence-to-sequence models (Bahdanau et al., 2014; Vaswani et al., 2017), where an encoder receives a source sentence and outputs a set of hidden states, the decoder then scrutinizes these hidden states at each step, and outputs a sequence of softmax distribution over the target vocabulary space. Considering that we would need vast quantities of data to train an adequate NMT for this task, we leverage large-scale synthetic and available small data and notably rank data on domain relevance, by fine-tuning with it, initiating training with the relevant domain and strategically placing it at the premier batches of the training data.

Essentially, the characteristics of the data an NMT model is trained on are paramount to its translation quality, in particular in terms of size and domain. It is quintessential to train NMT models based on the domain relevance of corpora. Since most code-mixing occurs in unofficial communication, it is costly to find a lot of labeled data for every domain we are interested in. Hence we attempt to find less expensive exigencies to supplement training data, pretrain on largely available data of different domains, strategically construct synthetic data, and apportion data to make up for missing domains.

In these WMT Subtasks – monolingual to code-mixed machine translation (Subtask-1) and code-mixed to monolingual machine translation (Subtask-2), we also fine-tune on different domains, align representations of data and find the best combination of approaches to solving the subtasks. The main intuition behind our proposed solution is that NMT models exhibit a significant translation correlation when trained on data from the same or similar domains. With different data domain re-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1162 - 1169
December 7-8, 2022 ©2022 Association for Computational Linguistics

quirements, it performs better when trained with data of the most relevant domain as preliminary batches compared to finetuning. As most natural code-mixed data source is social media and it is difficult to gather a good amount to train a model, it is incumbent to find a strategy that makes the model prioritize this form of data above others. Accordingly, we attempt to find less expensive techniques to supplement training data, pretrain on largely available data of different domains, strategically construct synthetic data, and apportion data to make up for missing domains. Our result showed improved performance on innate code-mixed data (and non-synthetic WMT test set samples) when this was prioritized and performed strongly in a test with a mix of several other data sources. We observed a better performance with domain-specific evaluation upon finetuning but this intensely plummeted performance on other 'pretraining domains', and more balanced performance on passing the interesting domain in the preliminary batches in a single 'all domain' training.

2 Related Work

It is laborious to obtain 'one-fits-all' training data for NMT. Most publicly available parallel corpora like Tanzil, OPUS, UNPC are sourced from documented communication, and these are often domain-specific. In NMT, data selection e.g. Axelrod et al. (2011) has remained as an underlying and important research concern. Choosing training examples that are relevant to the target domain, or by choosing high-quality examples for data cleaning (also known as denoising), has been essential in domain adaptation. Building a large-scale multi-domain NMT model that excels on several domains simultaneously becomes both technically difficult and practically back-breaking. Addressing research problems such as catastrophic forgetting (Goodfellow et al., 2013), data balancing (Wang et al., 2020), Adapters (Houlsby et al., 2019) have shown improvement. Unfortunately, several domains are difficult to handle with the single-domain data selection techniques currently in use. For instance, improving translation quality of one domain will often hurt that of another (Britz et al., 2017; van der Wees et al., 2017).

Song et al. (2019) replaced phrases with pre-specified translation to perform "soft" constraint decoding. Xu and Yvon (2021) generated code-mixed data from regular parallel texts and showed this training strategy yields MT systems that surpass multilingual systems for code-mixed texts.

Considering that code-mixed text belongs in less documented domains than most, there may be a need for domain adaptation used on sufficiently available data domains. Our work is inspired by the following approaches: Wang et al. (2019) executed simultaneous data selection across several domains by gradually focusing on multi-domain relevant and noise-reduced data batches while carefully introducing instance-level domain-relevance features and automatically constructing a training curriculum. Park et al. (2022) demonstrated that instance-level features are better able to distinguish between different domains compared to corpus-level attributes. Dou et al. (2019) proposed modeling the difference between domains instead of smoothing over domains for machine translation.

Anwar et al. (2022) showed that an encoder alignment objective is beneficial for code-mixed translation, in addition to Arivazhagan et al. (2019) that proposed auxiliary losses on the NMT encoder that imposed representational invariance across languages for multilingual machine translation.

Table 1: Examples from the WMT Shared Task Dataset.

3 Data

In table 1 we show some samples from the WMT shared task, sourced from the non-synthetic validation data. The data provided for Subtask-1 (Srivastava and Singh, 2021) contains synthetic and human-generated data and Subtask-2 Parallel Hinglish Social Media Code-Mixed Corpus (Srivastava and Singh, 2020) for both tasks are mostly unofficial, mostly short conversational sentences, with some letters asterisked for privacy/derogatory reasons.

Since we need to augment provided data for a reasonable quantity to train a NMT model, we generated synthetic code-mixed data from the IITB

Table 2: Examples from IITB Corpus.

corpus (Kunchukuttan et al., 2017) which is from 17 sources of different domain mostly HindEnCorp (Bojar et al., 2014), Gyaan-Nidhi Corpus (Garg et al., 2018), Indian Government corpora - CFILT, Mahashabdkosh, Tanzil, and GNOME (Kunchukuttan et al., 2017) (details in section 3.1). Synthetic code-switched sentences generated from the IITB corpus belong to a different domain than the WMT evaluation data, as we illustrate with the English translation samples in table 2.

For the pretraining-finetuning setup, we pretrain with synthetic code-switched data generated from IITB corpus and fine-tune on the WMT data provided for each task. For both pretraining and finetuning, we coordinate the data similar to (Anwar et al., 2022) – For Subtask-1, Monolingual to code-mixed machine translation subtask, we use the Hindi sentence (Devanagari script) as source sequence and the corresponding code-switched sentence (Roman script) as target, then alternated the English sequence (Roman script) as source sentence and the same corresponding code-switched sentence as the target sequence. The above two source-target parallel data are set after each other. For Subtask-2, Code-mixed to monolingual machine translation subtask, we have a similar arrangement as in Subtask-1, but with the source sequences of Hindi and code-mixing (Hinglish) in Roman script and as the target the corresponding English sequence. We removed sequences shorter than 2 tokens, and those longer than 250 tokens, and a target-to-source token ratio of more than 1.5. After cleaning the pretraining data, for Subtask-1, we have about 2.5M parallel sentences and 2.3M parallel sentences for Subtask-2.

For the finetuning process, we made use of the WMT training data provided for each subtask and organized like the pretraining data as described above. After cleaning, for Subtask-1 (Synthetic + Human-generated), we have a total of over 11K parallel sentences. For subtask-2, over 12K parallel sentences remain after cleaning.

Since the IITB corpus encompasses multiple sources and domains where code-mixing infrequently occurs, we decided to configure our model in a way it first learns from natural code-mixed data provided by WMT. We experiment with a hand-designed curriculum of the Synthetic Code-switched data generated from the IITB corpus and the WMT provided data. We supply the model the non-synthetic WMT data only in the first few batches in the hope that this would faintly familiarize the model with domain-specific features before it learns from the synthetic code-switched data we generated from other domains. We compare the results of this approach to the above described pretraining-finetuning setup. All data is tokenized and normalized using sentencepiece[1].

3.1 Code Switched Data Generation

Given that most publicly available corpora are monolingual, it is requisite to generate sufficient synthetic code-mixed data for training. Moreover, there have been works on generating synthetic code-mixed data linguistically, there are a few rules theories that are essential.

The **Equivalence Constraint Theory** states that intra-sentential code-mixing can only happen where the surface structures of two languages map onto each other, implicitly following both languages' grammatical norms (Poplack, 1980). Fundamentally, we can only attempt code-mixing at points where both languages coincide on the parse tree to equivalent phrase structure.

The **Matrix Language Theory** explains code-mixing by introducing the concept of a "Matrix Language," or base language, into which clusters of the "Embedded Language," or second language, are introduced in such a way that the former sets the grammatical structure of the sentence and the latter "switches-in” at grammatically correct points of the sentence (Myers-Scotton, 2001). The Matrix language has more tokens in the sequence and its rules are designated above the embedded language's.

Considering the linguistic theories above, we

[1] https://github.com/google/sentencepiece

generate code-mixed data by locating where both languages coincide based on a word-level alignment extracted and only replace tokens based on the "matrix language theory". Roughly following the recipes by (Song et al., 2019; Rizvi et al., 2021; Xu and Yvon, 2021; Anwar et al., 2022), we generate synthetic code-switched data from the IITB parallel data: We create code-mixed data by first transliterating Hindi (Devanagari script) to Roman script using Ritwik's tool[2], then extract word alignments using the giza++ toolkit (Och and Ney, 2003), and extract minimal alignment units following the approach of (Crego, 2005). We choose Hindi as the "matrix language" by determining this from the provided WMT training data, we extract word alignments and find how many tokens in each sequence belongs to which language using the language detector of Googletrans python library[3] and assign the language with more tokens as the matrix language. Figure 1 shows the Hindi/English matrix language ratio for both subtasks.

Similar to MLM pre-training used by BERT (Devlin et al., 2018), we randomly replace 15% of the tokens in each Hindi sentence with their aligned segments in the embedded language (English). For short sequences with less than 7 tokens we make only one replacement, chosen uniformly at random.

4 Training Objective

Considering the effectiveness of clean finetuning (Wu et al., 2019), and pre-training (Mathis et al., 2019), we attempt a combined pipeline of pretraining+finetuning experiment and also a single training but with tactical positioning of the most important domain. In the finetuning process and training with specially ordered data, as recommended by (Anwar et al., 2022), we add an alignment loss to the encoder to encourage source and target representations to be close in representation space minimizing the max-pooled cosine distance of the encoder representation as shown in equation 1:

$$\Omega = \mathbb{E}_{D_{(en,hi)}}[1 - sim(Enc(x_{src}), Enc(x_{tgt}))] \quad (1)$$

Where Ω is the encoder loss, $D_{(en,hi)}$ is the data consisting of the parallel pairs of code-mixed to monolingual or monolingual to code mixed depending on which subtask the data belongs to, x_{src} is the source sequence and x_{tgt} is the target sequence, Enc(x) is the max-pooled encoder representation of sentence x similar to (Gouws et al., 2014) and (Coulmance et al., 2015), and sim is the cosine similarity. Unlike (Arivazhagan et al., 2019) where the whole model's parameters are updated as shown in figure 2.

5 Experiments and Results

In all of our experiments, we used Transformer-Base (Vaswani et al., 2017) configuration with the Fairseq (Ott et al., 2019) framework. All models were trained on four Tesla T400 GPUs using IITB and WMT-'22 MixMT data for training as described in Section 3, with a shared vocabulary of 77K BPE (Sennrich et al., 2015) sub-words to create a joint vocabulary for both tasks and all models. The model's hyperparameters can be found in Appendix A.

5.1 Results

Based on the human evaluation by the organizers of the subtasks, the translation result of our initial models - v0.2 submitted – which was trained with mixing the IITB with the WMT without prioritizing the target domain – had an overall rating of 1.75 from 10 random translations for each subtask, this ranked inferior to many other submissions.

With the help of native Hindi speakers to investigate our data, we found some of the causes it performed decumbent, which were as a result of some of the different data preprocessing tools we used: For Transliteration, We tried a few devanagari to roman tools but had some shortcomings like:

- Lipika-ime[4]: inappropriate handling of diacritic characters.
- Indic-trans[5]: Removal of vowels (e.g. default -> difolt, highlight -> hilite, method -> methd, etc..), Splitting of words that lead to suboptimal outputs (e.g. "un he" instead of "unhe").
- Sheental[6]: repetition of vowels e.g. jane -> jaane, yaar -> yaara, incorrect replacement of characters e.g. om -> on and occurence of

Mixed-data training (target domain first)	0.76	0.79	**0.62**	**0.64**	0.70	0.73

Table 3: Translation accuracy of subtask-1 and subtask-2 of Hindi-English in ROUGE-L (F1-Score) on different **test** data of different domains, based on models trained on different domain training data, data arrangement or training pipeline.

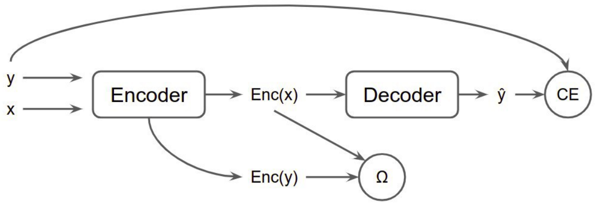

Figure 2: The loss function visualization, CE is the Cross Entropy, Ω is the encoder loss.

needless suffixes e.g. palat -> palata, some diacritic appeared independently.

- Ritwik's: inappropriately breaking very long sentences into multiple lines, replacing individually occurring tokens like um -> oon and abruptly stopping when ran over large amount of data so we divided the data into chunks each containing not more than 200K sequences, optimized by parallel computing using dask, and replaced the individually occurring tokens changed afterwards.

We also investigated our initial model and discovered a few other issues like:

- Cases of translation of proper nouns in Subtask-2 (e.g. Sapna -> dream) which we deduce as a pointer to insufficient training data.
- Imprecise tokenization and detokenization, we also switched to use of Google sentencepiece instead of Moses SMT
- Also, the organizers noticed the team's output had an incorrect order. A problem where the post-processing had sorted the hypothesis and fragmented longer sentences also influenced the rating.

Upon inspecting our model outputs we found a few inaccuracies with the tools we used for transliteration and tokenization for the submitted model hypotheses. We fixed these, and present the results in the following section.

5.2 Post-Submission Results

Table 3 shows the experimental results based on different test data of samples each from IITB corpus, WMT, and a Mixed test sample evenly selected from Samanatar (includes IITB corpus, CCMatrix, Hindi-News, Jagran, Livehindustan, Patrika and WMT). We made use of other reputable tools to fix the aforementioned errors, added the domain curriculum technique, and ran the experiment again and present it in table 3.

Table 3 shows that fine-tuning on the WMT domain improves translation accuracy on this domain slightly, but the model suffers 'catastrophic forgetting' on domains it was initially trained on. Pretraining did not lead to a good generalization for the WMT test samples provided, hence a need for domain adaptation. Placing the relevant domain in the preliminary batches for mixed-data training also improves training on such a domain but hurts other domains slightly.

6 Conclusion

We present a data domain sorting method that improves translation performance based on a target domain for the WMT 2022 code-switching shared tasks. We compared our result to a pretraining and fine-tuning pipeline, and demonstrated that the finetuning method improves on specified domain but upsets on previously learned data domain. An aspect we intend to delve further into is efficient domain adaptation strategies that may help low-resource domains such as code-mixing, and have little or no effect on high-resource domains, we are currently looking into domain adaptation learning curve (Park et al., 2022), extraction of domain-specific parameters (Dou et al., 2019) for better data augmentation strategies, better acquisition of code-mixed data, and the use of Adapters (Houlsby et al., 2019).

Lingua Custodia, France
{melissa.ailem,jingshu.liu,j-g.barthelemy,raheel.qader}@linguacustodia.com

Abstract

This paper presents Lingua Custodia's submission to the WMT22 shared task on Word Level Auto-completion (WLAC). We consider two directions, namely German-English and English-German. The WLAC task in Neural Machine Translation (NMT) consists in predicting a target word given few human typed characters, the source sentence to translate, as well as some translation context. Inspired by recent work in terminology control, we propose to treat the human typed sequence as a constraint to predict the right word starting by the latter. To do so, the source side of the training data is augmented with both the constraints and the translation context. In addition, following new advances in WLAC, we use a joint optimization strategy taking into account several types of translation context. The automatic as well as human accuracy obtained with the submitted systems show the effectiveness of the proposed method.

1 Introduction

Modern advances in Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Vaswani et al., 2017) gave rise to a new era, where the translation quality significantly surpasses previous statistical machine translation (SMT) models (Och and Ney, 2002; Koehn et al., 2003; Koehn, 2010).

Although these approaches generate high quality translations, there is still a long way to go towards meeting human quality. In fact, NMT models can still generate several types of grammatical and/or semantic mistakes, which is not tolerated in scenarios requiring accurate and prompt translations. These scenarios include for instance the translations of legal and financial documents, where mistakes are not permitted and can be costly. To overcome this issue, several Computer-aided translation (CAT) systems have been proposed (Knowles and Koehn, 2016; Santy et al., 2019) to refine NMT models. CAT tools include for instance Automatic Post-edition (Junczys-Dowmunt and Grundkiewicz, 2017; Correia and Martins, 2019; Lopes et al., 2019), terminology control (Hokamp and Liu, 2017; Post and Vilar, 2018; Dinu et al., 2019; Ailem et al., 2021) and sentence vs word-level autocompletion (Knowles and Koehn, 2016; Zhao et al., 2020; Li et al., 2021).

Figure 1: Given the source sentence to translate, the translation contexts, and the human typed characters, the WLAC task aims to predict a target word starting by the human typed sequence. As illustrated, the word to predict is not necessarily consecutive to the left and right contexts.

The current shared task is on Word-Level Auto-Completion (WLAC) methods, whose objective, as illustrated in Figure 1, is to predict a target word given a source sentence, a translation context, and at least one human typed character. WLAC is a central Computer-aided task as it helps human translators generate diverse translations quickly and effectively. Unfortunately, due to the lack of benchmark datasets, very little work has considered this task. Existing methods include the work of Huang et al. (2015), where the authors leverage the source sen-

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1170 - 1175
December 7-8, 2022 ©2022 Association for Computational Linguistics

tence as well as human typed characters to predict the target word. More recently, Li et al. (2021) proposed to use context information in addition to human-typed characters and source sentence. Furthermore, the authors presented a generic procedure to simulate WLAC data from any parallel translation datasets, and proposed the first public benchmark for this task. The benchmark dataset contains several types of contexts and therefore a joint optimization strategy is used to take into account all context types during training.

We participate in two directions, namely English-German (EN-DE), German-English (DE-EN), and we submitted four systems, two for each language direction. Following previous work (Li et al., 2021), our method leverages source sentence, translation context as well as human-typed characters, and it uses a joint objective function to learn model parameters on different types of contexts simultaneously. Furthermore, inspired by recent progress in Terminology Control (TC) for NMT (Dinu et al., 2019; Ailem et al., 2021), we propose a new WLAC method that treats the human typed sequence as a constraint to generate the right word. To do so, we augment our training data with translation context as well as human typed characters (constraints). We use tags where needed to distinguish these terms from source tokens.

The rest of the paper is organized as follows. Section 2 describes the details of our system, section 3 presents the data, while section 4 shows the different experimental settings and results.

2 Method

Herein we present our WLAC approach which is inspired by recent advances in this task (Li et al., 2021) as well as recent work on terminology control (Ailem et al., 2021).

2.1 Data Annotation

Inspired by previous work on Terminology Control (Ailem et al., 2021), the idea here is to consider human typed characters as a constraint. In particular, the objective is to constrain the NMT model to predict a word that, obligatorily, starts with human typed characters. To do so, we augment the source side of our training data with the translation context as well as the human typed sequence of characters. Furthermore, we use tags to specify the constraints (human typed characters) in the context translation where relevant, and use the special token MASK in order to provide a more general pattern for the model to learn how to predict the right word starting with human sequence. The WLAC data provided by the WMT task and used in (Li et al., 2021) contains 4 types of context, namely left and right contexts (bi-context), left context only (prefix), right context only (suffix), and no context at all (zero context). The different annotations according to each context types are depicted in table 1.

2.2 Joint Cross-Entropy Loss

Let $\mathbf{x} = (x_1, x_2, ..., x_m)$ denotes the input sentence to translate, $\mathbf{s} = (s_1, s_2, \ldots, s_k)$ a sequence of human typed characters, and $\mathbf{c} = (c_l, c_r)$ the translation context, where $c_l = (c_{l,1}, c_{l,2}, \ldots, c_{l,i})$ denotes the left context, while $c_r = (c_{r,1}, c_{r,2}, \ldots, c_{r,j})$ denotes the right context. The objective of the WLAC task is to predict a word w given a source sequence $\mathbf{x}$, human typed sequence $\mathbf{s}$ and a translation context $\mathbf{c}$ in order to establish a partial translation. The training data $\mathcal{D}$ of a WLAC task can be described as a set of tuples $(\mathbf{x}, \mathbf{s}, \mathbf{c}, w)$. From a probabilistic perspective, a WLAC task can be cast as estimating the conditional distribution $p(w|\mathbf{x}, \mathbf{c}, \mathbf{s})$. Since there is different types of context (as described in section 2.1), we follow the work of Li et al. (2021) and adopt a joint training strategy. In particular, the four types of context are considered during training giving rise to the following loss function:

$$\begin{aligned}\mathcal{L} &= -\log p(w|\mathbf{x}, \mathbf{c}, \mathbf{s}) \\ &= -\sum_{(\mathbf{x},\mathbf{c},\mathbf{s},w)\in\mathcal{D}_{bi}} \log p(w|\mathbf{x}, c_l, c_r, \mathbf{s}) \\ &\quad - \sum_{(\mathbf{x},c_r,\mathbf{s},w)\in\mathcal{D}_{suf}} \log p(w|\mathbf{x}, c_r, \mathbf{s}) \\ &\quad - \sum_{(\mathbf{x},c_l,\mathbf{s},w)\in\mathcal{D}_{pre}} \log p(w|\mathbf{x}, c_l, \mathbf{s}) \\ &\quad - \sum_{(\mathbf{x},\mathbf{s},w)\in\mathcal{D}_{zero}} \log p(w|\mathbf{x}, \mathbf{s})\end{aligned} \tag{1}$$

where $\mathcal{D}_{bi}$, $\mathcal{D}_{suf}$, $\mathcal{D}_{pre}$, $\mathcal{D}_{zero}$ correspond respectively to bi-context, suffix context, prefix context and zero context.

3 Data

We participate in two directions, namely English-German and German-English. We use the parallel

	Prefix Context	Seebarsch gebacken auf seinem Rücken , fein zerschnippelter Porree und Zitronenmelissekraut . <SEP> Bar baked on the back with finely <S> MASK <C> chop </C>		chopped
	Suffix Context	Seebarsch gebacken auf seinem Rücken , fein zerschnippelter Porree und Zitronenmelissekraut . <SEP> <S> MASK <C> B </C> lemon melissa herbs .		Bar
	Zero Context	Seebarsch gebacken auf seinem Rücken , fein zerschnippelter Porree und Zitronenmelissekraut . <SEP> <S> MASK <C> bak </C>		baked

Table 1: Illustration of our German-English training data. The WLAC training data can be build from traditional parallel translation data. During sampling, for each parallel sentences four samples are generated corresponding to four types of translation context, namely left and right contexts (bi-context), left context (prefix), right context (suffix) and no context at all (zero). The source side of the training data is a concatenation of the German source side and the English translation context separated by the tag **<SEP>**. Translation context is also augmented with human typed characters, which are considered as a constraint to orient the model to predict the right word. The tags <S>, <C> and </C> are added to differentiate between the constraints and other tokens in the input.

English-German data provided by the WLAC task consisting of almost 4.5M parallel sentences. Following task instructions, we use the script proposed in (Li et al., 2021) to simulate the WLAC training data from the provided classical translation data.

3.1 Parallel Data Cleaning

Before creating the WLAC samples, we apply several cleaning steps on the data to eliminate bad alignments. First, the data is re-segmented using the Python package pySBD (Sadvilkar and Neumann, 2020) in order to detect sentence boundaries. This step increases the number of parallel sentences to almost 6.5 M. Second, each parallel entry is scored between 0 and 1 using several tools. These tools include bicleaner (Ramírez-Sánchez et al., 2020), similarity scoring using LaBSE (Feng et al., 2020), and bicleaner-ai, which is inspired by the BERT-based model proposed in (Açarçiçek et al., 2020) for sentence classification. Table 2 presents the different scoring thresholds used to clean the parallel corpus. In particular, we rely on a combination of bi-cleaner and similarity scoring as well as bicleaner-ai. In our experiments, we consider both initial uncleaned data (Noisy) and the cleaned data. In addition to these scoring, we also rely on fast-text (Bojanowski et al., 2017) to eliminate sentence pairs identified as written in the wrong language (e.g., A french sentence in an English-German parallel corpus). After the cleaning we obtain a corpus of around 2.7 M parallel segments.

	Clean	Noisy
Bicleaner + Similarity	>1.4	>0
Bicleaner-ai	>0.25	>0.1
Total sentences	2 717 737	4 404 427

Table 2: The different thresholds applied on the corpus. Noisy corresponds to the original parallel data provided by the WLAC task. The threshold 1.4 is a combination of Bi-cleaner and Similarity scoring thresholds.

3.2 WLAC Data Construction

The parallel data commonly used for NMT and provided by the WLAC task cannot be used directly to train a WLAC model. Thus, following the task instructions, we use the script proposed in (Li et al., 2021) to simulate several samples for the WLAC training. For each sentence pair, 4 samples are created according to the four context types as presented in table 1. Since the provided initial data contains almost 4.5M parallel sentences, we obtain a WLAC corpus of almost 18M entries (4.5×4). As presented in the previous section, we have also used a cleaned version of the provided corpus, containing around 2.7M entries. For the

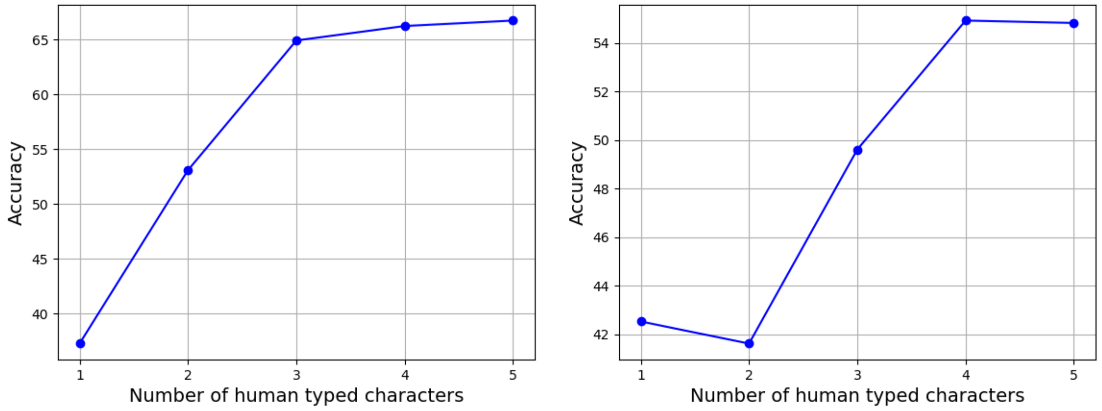

Figure 2: Accuracy obtained with different number of human typed characters. Left : German-English system with initial corpus. Right : English-German system with initial corpus.

latter, we obtain around 10.8M WLAC training samples. Hence, synthetic WLAC training data are build for the two corpus versions (clean and initial) in the two considered directions: English-German and German-English. The dev sets are build from 3000 EN-DE and DE-EN parallel sentences from the initial corpus. To do so, the same sampling script is used resulting in 20K entries for both directions. The test sets released by the WLAC task contain 29596 and 25895 samples for DE-EN and EN-DE respectively.

4 Experiments

4.1 Settings

We use a Transformer architecture (Vaswani et al., 2017) with 6 stacked encoders/decoders and 8 attention heads as a building block for our systems. For both EN-DE and DE-EN, the source and target embeddings are tied with the softmax layer. We use 512-dimensional embeddings, 2048-dimensional inner layers for the fully connected feed-forward network and a dropout rate of 0.3. The models are trained for a minimum of 50 epochs and the validation set is used to compute the stopping criterion[1]. We use a batch size of 4000 tokens per iteration and an initial learning rate of 5×10^{-4}. For each language pair, the validation set is used to compute the stopping criterion. We use a beam size of 5 during inference for all models.

Before annotating our corpus as presented in table 1, we first tokenize the data using Moses tokenizer (Koehn et al., 2007). After augmenting the data with translation context and human typed sequence, we perform a BPE encoding (Sennrich et al., 2015) with 40k merge operations to segment words into subword-units, which results in a joint vocabulary size of around 44K tokens for both German-English and English-German.

Accuracy (%)		
	German-English	English-German
Cleaned Corpus	54.84	48.43
Initial Corpus	57.36	48.97
Human Evaluation (%)		
Cleaned Corpus	74.50	61.00
Initial Corpus	76.75	61.75

Table 3: Accuracy and Human Evaluation results.

4.2 Results

For both considered directions, the systems are evaluated using the Accuracy measure, corresponding to the percentage of correctly predicted words. This automatic accuracy is obtained using one single ground truth word for each sample. However, one sentence may have multiple translations, thus several Ground Truth are possible, making the automatic accuracy inadequate. To overcome this limitation, a human evaluation is applied on 400 randomly sampled entries from the test set. In particular, given the human typed sequence, the translation context and the source sentence to trans-

[1] The stopping criterion corresponds to 5 successive epochs without decreasing the validation loss function.

late, human annotators judge whether a predicted word can be correct according to the given context. The results obtained with our systems are presented in table 3.

Surprisingly, we observe that cleaning the different corpora is mirrored by a deterioration in results. Indeed, the best results are reached with the systems using initial training corpus. This might be due to the excessive cleaning, removing some scenarios that could be present in the test set.

Furthermore, we notice that the chances of predicting the right word are positively related with the number of human typed characters. We present in figure 2 the accuracy obtained with different numbers of human typed characters. In both directions, we observe that the accuracy improves with the typed sequence length. This is natural, as with few typed characters, several choices are possible, especially when the translation context is restricted or even non-existent (zero context situation).

5 Conclusion

This paper describes our submission to the WLAC shared task. We participate in two language directions, EN-DE and DE-EN, and submitted two systems for each direction. For each direction, the first system is trained using initial data provided by the task, while the second system is trained on cleaned data. The evaluation in terms of accuracy shows the effectiveness of the proposed method. Furthermore, a significant improvement of accuracy is observed when the number of human typed characters is greater than 1, suggesting that entering at least two characters restrain the search space and improve the chances to predict the right word.

Abstract

Research on Machine Translation (MT) has achieved important breakthroughs in several areas. While there is much more to be done in order to build on this success, we believe that the language industry needs better ways to take full advantage of current achievements. Due to a combination of factors, including time, resources, and skills, businesses tend to apply pragmatism into their AI workflows. Hence, they concentrate more on outcomes, e.g. delivery, shipping, releases, and features, and adopt high-level working production solutions, where possible. Among the features thought to be helpful for translators are sentence-level and word-level translation auto-suggestion and auto-completion. Suggesting alternatives can inspire translators and limit their need to refer to external resources, which hopefully boosts their productivity. This work describes our submissions to WMT's shared task on word-level auto-completion, for the Chinese-to-English, English-to-Chinese, German-to-English, and English-to-German language directions. We investigate the possibility of using pre-trained models and out-of-the-box features from available libraries. We employ random sampling to generate diverse alternatives, which reveals good results. Furthermore, we introduce our open-source API, based on CTranslate2, to serve translations, auto-suggestions, and auto-completions.

1 Introduction

Translation auto-suggestion and auto-completion are among the important features that can help translators better utilize Machine Translation (MT) systems. In a Computer-Aided Translation (CAT) environment, a translator can make use of the MT word auto-suggestion feature as follows:

- typing a few words, or clicking a word in a proposed MT translation, a list of suggestions is displayed, as illustrated by Figure 1.
- selecting one of the word suggestions from the list, the rest of the translation is modified accordingly.

The WMT's Word-Level AutoCompletion (WLAC) shared task addresses a more specific scenario, where the user types a few characters, and the system predicts and auto-completes the correct word, given the current context. The WLAC task even suggests that the context might be partial, and it can consist of preceding and/or following words. Given a source sequence x, typed character sequence s and a context c, WLAC aims to predict a target word w which is to be placed in the middle between the left context $\mathrm{c_l}$ and right context $\mathrm{c_r}$ to constitute a partial translation. Note that the last word of $\mathrm{c_l}$, the auto-completed word w, and the first word of $\mathrm{c_r}$ are not necessary consecutive.

Previous work proposed diverse approaches, mostly to translation sentence-level auto-suggestion and auto-completion. In their work, Li et al. (2021) proposed an approach to tackle the word-level auto-completion task. Given a tuple (x, c, s), the system decomposes the word autocompletion process into two parts: 1) model the distribution of the target word w based on the source sequence x and the translation context c; and 2) find the most possible word w based on the distribution and human typed sequence s. Hence, they first use a single placeholder [MASK] to represent the unknown target word w, and use the representation of [MASK] learned from the word prediction model, based on BERT (Devlin et al., 2019), to predict it. Then, the predicted distribution of the masked token is used over the vocabulary to filter out invalid words, namely those that do not start with the human typed sequence s.

Figure 1: Auto-Suggest: Word Suggestions List[1]

Finally, they return the token with the highest probability over the new distribution.

Researchers in other natural language processing areas such as language modelling offered approaches to improve predictions of decoder-only autoregressive models, trained to predict the next word given the previous context. Among these approaches are top-K sampling and top-p (nucleus) sampling (Fan et al., 2018; Holtzman et al., 2018; Radford et al., 2019; Holtzman et al., 2020). Since neural machine translation inference depends on a decoder model, such approaches from language modelling can be employed. In particular, we investigate the use of top-K sampling during decoding to generate better word-level auto-completions.

2 User Survey

Previous work reported that a user can save over 60% of the keystrokes needed to produce a translation in a word completion scenario (Langlais et al., 2000). Other researchers noted that post-editing is faster than MT auto-completion (Koehn, 2009) while MT auto-completion can yield higher quality translation when the baseline MT quality is high (Green et al., 2014).

In a user survey we designed and distributed via social media networks, we asked participants whether they thought an MT word-level auto-suggestions feature could be helpful, and provided a simple definition and an illustrative image. If their answer was "yes", the respondent was asked to specify a reason. By the time of writing this paper, we received 41 responses to our survey. While we do not believe this survey is enough to justify introducing an auto-suggestions feature into every MT system, it can be an indicator as to why some users think such a feature could be helpful. To answer the question, "Which of the following best describes you?" 46.3% (19) of the respondents chose "Translator/Linguist", 31.7% (13) selected "NLP Engineer/Researcher", and the rest 22% (9) were other "MT Users", not included in the two aforementioned categories.

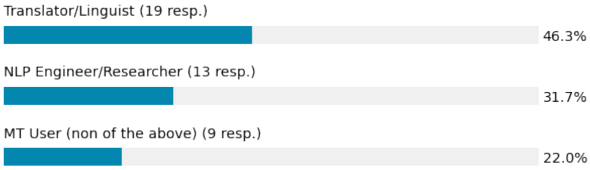

Figure 2: MT user categories

Among the respondents to the survey, 90.2% (37) answered "Yes" to the question "In general, do you believe that a word-level auto-suggestions feature is helpful?" Figure 3 shows the breakdown of answers to the question, "Why do you believe that a word-level auto-suggestions feature can be helpful?" taking into consideration those who answered "No" to the previous question.

Out of the 37 persons who believed a word-level auto-suggestions feature can be helpful, 40.5% (15) of the respondents specified that it can give them some inspiration. This answer is specifically interesting as it is not constrained by time-saving benefits; hence, it focusses more on effectiveness rather than efficiency. The respondent that answered with "Other" mentioned that it allows them to look for alternative senses or phrasings, especially when they suspect the initial translation is bad, and referred to this as "human in the loop".

Respondents were allowed to give extra comments; among the notable comments were:

[1] The image is from our demo at: https://www.machinetranslation.io/

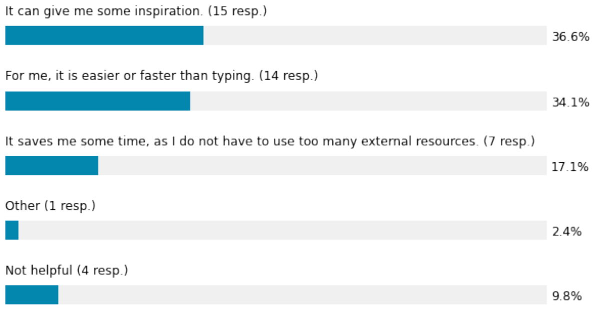

Figure 3: How translators and other MT users perceive word-level auto-suggestions

- *I think word-level suggestions can be a useful feature, particularly when the target language can have several translations of a single source word.*
- *Word-level suggestions can be helpful, but sometimes you end up spending a lot of time figuring out if the MT suggestion is a valid translation in that context. So, I'm not really sure yet how I feel about it.*
- *It's useful, as long as it's seen as a suggestion, and not inserted in the target where the translator is typing.*

Among the respondents who chose "For me, it is easier or faster than typing", comments included:

- *Though most of the time; the suggestions are lousy.*
- *I don't think it gives me inspiration as I mostly need it for structures, not single words.*
- *Auto-suggestion does not have to come from machine translation. History is much more useful.*

The last comment above might be referring to the fact that in some CAT tools, auto-suggestions can also include glossary terms, and translation memory sub-segments, which encourages further research efforts to investigate methods to enhance leveraging and interaction between various translation resources in human-in-the-loop environments.

We hope this survey will inspire future user studies to look deeper into how diverse users of MT and CAT tools prefer to utilize certain features, such as auto-suggestions, and the value they seek. More aspects should be taken into consideration such as language pairs, translation workflows, and user interfaces. This can help improve these features to better support linguists and other MT users and boost their productivity as well as translation quality.

3 Experimental Setup

Models We use OPUS pre-trained models[2] based on the Transformer architecture (Vaswani et al., 2017) for the Chinese-to-English, English-to-Chinese, German-to-English, and English-to-German language directions.

Tokenizers OPUS models depend on SentencePiece[3] (Kudo and Richardson, 2018) for tokenization. Hence, we use their provided subword models during our pre-processing and post-processing processes. As OPUS's English-to-Chinese model requires defining the target dialect using a pre-specified token, we prepend [">>cmn_Hans<<"] to the list of tokens generated by SentencePiece. For word-level tokenization, we use NLTK for English and German, and Jieba[4] for Chinese. This list of words can be used later to find the word that starts with the typed sequence.

Inference Engine We employ CTranslate2 (Klein et al., 2020) for sentence-level MT, as well as for translation auto-suggestions. To this end, we first convert OPUS models into the CTranslate2 format. After that, we utilize a number of CTranslate2 decoding features, including "alternatives at a position" and "auto-completion".[5] The translation options $return\_alternatives$ and $num\_hypotheses$ are essential for all our experiments; the former should be set to $True$ while the latter determines the number of returned alternatives. These decoding options can be used with regular beam search, prefix-constrained decoding, and/or random sampling. If the decoding option $return\_alternatives$ is used along with $target\_prefix$, the provided target left context is fed into the decoder in the teacher forcing mode,[6] then the engine expands the next N most likely words, and continues (auto-completes) the decoding for these N hypotheses independently. The shared task investigates four context cases:

[2] https://github.com/Helsinki-NLP/Tatoeba-Challenge

[3] https://github.com/google/sentencepiece

[4] https://github.com/fxsjy/jieba

[5] https://github.com/OpenNMT/CTranslate2/blob/master/docs/decoding.md

[6] In *teacher forcing* (Williams and Zipser, 1989), ground truth previous tokens are fed into the decoder, instead of the predicted tokens y_{i-1} as suggested by Bahdanau et al. (2015)

(a) empty context, (b) right context only, (c) left context only, and (d) both the right and left contexts are provided. Hence, for all cases we returned multiple alternative translations, while for (c) and (d) we also returned another set of alternative autocompletions using the left context as a target prefix. In this sense, it is worth noting that we make use only of the left context, when available, and we do not use the right context at all, which we might investigate further in the future. To enhance diversity of translations, especially for (a) and (b), we applied random sampling with the CTranslate2's decoding option $sampling\_topk$, with various sampling temperatures. Our experiments are further elaborated in Section 4 and Section 5.

Pinyin The official Romanization system for Standard Mandarin Chinese is called Pinyin. Since the task organizers used the pypinyin library[7] to prepare the test files, we did too. OPUS English-to-Chinese models accept Chinese input, so we had to use the library to convert between the two writing systems. Since the conversion from Chinese characters to Pinyin is a lossy process and cannot be perfectly converted back, we keep a list of Chinese words resulted from tokenization with Jieba to be able to map Pinyin tokens to Chinese tokens later.

4 Method

We experimented with both beam search alternatives and random sampling, and found that the latter achieves better results. This could be due to the fact that alternatives generated from each beam are usually very similar, and lower beam values tend to generate translations of lower quality. This section elaborates on the actual methods we used for our submissions, while more details about initial experiments that led us to these decisions are explained in Section 5.

Random sampling is a decoding mode that randomly samples tokens from the model output distribution. In our experiments, we restrict the sampling to the top-10 candidates at each time-step. To obtain diverse generations from the MT model, we rely on randomness in the decoding method, in particular through top-K sampling that samples the next word from the top-K most probable choices (Fan et al., 2018; Holtzman et al., 2018; Radford et al., 2019), instead of aiming to decode text that maximizes likelihood.

For each translation, we use the CTranslate2 option *return_alternatives* to return 10 sequences, with 10 top-K sampling. If the entry has a left context starting with a capital letter, we use the prefix to constrain the decoding. In CTranslate2, combining *target_prefix* with the *return_alternatives* flag returns alternative sequences just after the prefix. We compose a list of alternatives with and without the prefix, and try to find the word starting with the typed sequence.[8] If the word is not found, we repeat the same process for up to five runs. In each new run, random sampling can generate a new set of alternatives. Our experiments show that returning 20 sequences with 20 top-K sampling could lead to more correctly predicted words (cf. Table 2); however, we had to consider the trade-off between quality and efficiency.[9]

Furthermore, we investigate increasing the randomness of the generation by using a value for sampling temperature between 1.0 and 1.3. For each run, a random value is generated in this range. The default sampling temperature in CTranslate2 is 1, which achieved relatively better results, as demonstrated in Table 1.

Language	Settings	Accuracy	Human
de-en	ST=1.0	0.614441141	0.885
	ST=1.3	0.609237735	0.8875
en-de	ST=1.0	0.589418807	0.6725
	ST=1.3	0.584939177	0.655
zh-en	ST=1.0 + detok	0.504113456	0.8675
	ST=1.3 + detok	0.502598878	0.8675
	ST=1.0	0.493476989	0.86
	ST=1.3	0.490619944	0.87
en-zh	ST=1.0	0.319424091	0.5775
	ST=1.3	0.319350821	0.5725

Table 1: Evaluation results on the test datasets. Automatic evaluation uses the "Accuracy" metric. "Human" refers to human evaluation. Results obtained from sampling temperature (ST) 1.0 are slightly better than those with the value 1.3. When the source is Chinese, detokenization (detok) resulted in slightly better scores.

[7] https://github.com/mozillazg/python-pinyin

[8] In a prefix-free target sequence, if multiple words start with the typed sequence, we return the first word. In practice, users could be prompted to choose from potential options.

[9] Our scripts are available at: https://github.com/ymoslem/WLAC

5 Other Experiments

This section elaborates on some initial experiments we conducted to decide what approach to use. The final approach we actually used in our submissions is explained in Section 4.

We used 10,000 entries of a Chinese-to-English golden sample provided by the organizers to evaluate various experiments. For sentence translation, when there is no left context, we experimented with the following values:

- beam size 1, 5, and 10, without sampling
- beam size 1, with random sampling top-K 10, 20, and 50

Table 2 shows the results for these experiments, and demonstrates that random sampling achieves the best overall accuracy. Random sampling with beam size 1 reveals better results than mere beam size 1 and even beam sizes 5 and 10 without random sampling. Multiple runs of random sampling can result in more correctly predicted words.

Beam Size	Sampling Top-K	Hypotheses	Accuracy	Runs
1	N/A	10	0.6519	1
5	N/A	10	0.6588	1
10	N/A	10	0.6573	1
1	10	10	0.6918	1
1	20	10	0.6907	1
1	**20**	**20**	**0.7108**	**1**
1	50	10	0.6853	1
5	N/A	10	0.6588	5
1	10	10	0.7165	5
1	**20**	**20**	**0.7310**	**5**

Table 2: Results for the Chinese-to-English golden sample dataset (10,000 entries). Random sampling outperforms even higher beam sizes.

6 API

Our API project[10] offers an easy way to integrate translation, auto-suggestion, and auto-completion features into translation environments. We chose FastAPI[11] for its high performance that beats many other Python web frameworks[12] in addition to its easy integration with OpenAPI (Swagger) documentation.

6.1 API Endpoints

The API consists of a number of endpoints, receiving requests and sending the relevant responses in the JSON format. Each of the MT features has its endpoint.

6.1.1 Translation Endpoint

The API handles a POST request (e.g. received from a CAT environment), including:

- $sentences$: list of the source sentences to be translated.
- $source\_language$: in a format like “fr” for French, and the default is “auto” to run language auto-detection.
- $target\_language$: in a format like “en” for English.

The API response is a list of strings for the MT translations in a JSON format.

6.1.2 Auto-Suggestions Endpoint

When the user clicks on one word of the MT translation, the CAT environment sends a request to the API including:

- $sentence$: sentence to be translated.
- $prefix$: words to start the translation with.
- $source\_language$: in a format like “fr” for French, and the default is “auto” to run language auto-detection.
- $target\_language$: in a format like “en” for English.

The API response is a list of the MT word suggestions/alternatives for the current word, and the translation auto-completions if the user selects a specific suggestion.

6.2 JSON Response Examples

This is an example of a response to the translation request referred to in Section 6.1.1.

```
{ ‘id’: 10550004
  ‘source_lang’: "fr",
  ‘target_lang’: "en",
  ‘translations’: [
    ‘The COVID−19 crisis has deepened already
         existing inequalities.’
  ]
}
```

This is an example of a response to the auto-suggestions request referred to in Section 6.1.2.

Abstract

This paper describes our submission to the Word-Level AutoCompletion Shared Task of the WMT 2022. We participate in the pair of languages, English–German, in both ways. We propose a segment-based interactive machine translation approach whose central core is a machine translation (MT) model that predicts the complete translation from the context provided by the task and picks the word we were trying to autocomplete from there. We show with this approach that it is possible to use the MT models in the autocompletion task by performing minor changes at the decoding step and obtaining good accuracy.

1 Introduction

Machine translation (MT) has significantly improved in recent years with the emergence of neural machine translation (NMT), but it still cannot assure high-quality translations for all tasks (Toral, 2020). For those scenarios with rigorous translation quality requirements, it is critical for professional translators to manually validate the translations generated by the NMT system. The computer-aided translation (CAT) tools show up to improve the validation and editing process carried out by translators. Researchers approached CAT tools from many directions with the aim of reducing the human effort of correcting the automatic translations. Among CAT tools such as translation memory (Zetzche, 2007), augmented translation (Lommel, 2018) and terminology management (Verplaetse and Lambrechts, 2019); we can find autocompletion tools, which help professional translators by providing new partial translations according to the validated parts they have supplied to the system.

Word level autocompletion (WLAC) (Li et al., 2021) is a new shared task introduced in WMT22. Its aim is to complete a target word given a source sentence, a sequence of characters typed by the human translator and a translation context. Four types of context are possible:

Zero-contex: no context is given.

Suffix: a sequence of translated words located after the word to autocomplete.

Prefix: a sequence of translated words located prior to the word to autocomplete.

Bi-contex: A combination of the *suffix* and the *prefix* type. That is, there is a sequence of translated words located after the word to autocomplete, and a sequence of translated words located prior to the word to autocomplete.

Note that, in all cases, the word to autocomplete is not necessarily consecutive to these contexts.

We have experimented with a similar CAT tool from the interactive machine translation (IMT) framework. In this field of research, the translation is generated in a collaborative process between the human translator and the MT model. Among the different approaches, the segment-based IMT (Domingo et al., 2017; Peris et al., 2017) protocol presents certain similarities with WLAC: at each step, the user validates sequences of translated words—the context—and makes a correction—the word to autocomplete.

Therefore, in this work we have approached WLAC as a simplification of segment-based IMT, using the context as the validated segments and the typed characters as the word correction; and limiting the process to the first iteration. This has allowed us to tackle WLAC by training a conventional NMT model and adapting it at the decoding step.

2 Segment-based interactive machine translation

Segment-based IMT establishes a framework in which a human translator works together with

Figure 1: Examples of a segment-based IMT session to translate a sentence from Spanish to English; and a WLAC session for predicting a word for a source sentence, a translation context, and a human-typed character sequence.

the MT system to produce the final translation. This collaboration starts with the system proposing an initial translation hypothesis y_1^I of length I. Then, the user reviews this hypothesis and validates those sequence of words which they consider to be correct ($\tilde{\mathbf{f}}_1, \ldots, \tilde{\mathbf{f}}_N$; where N is the number of non-overlapping validated segments). After that, they are able to merge two consecutive segments $\tilde{\mathbf{f}}_i$, $\tilde{\mathbf{f}}_{i+1}$ into a new one. Finally, they correct a word—which introduces a new one-word validated segment, $\tilde{\mathbf{f}}_i$, which is inserted in $\tilde{\mathbf{f}}_1^N$. This correction can also consist in a partially typed word $\tilde{\mathbf{f}}'_i$, in which case the system would complete it as part of its prediction.

The system's reacts to this user feedback by generating a sequence of new translation segments $\widehat{\mathbf{g}}_1^N = \widehat{\mathbf{g}}_1, \ldots, \widehat{\mathbf{g}}_N$; where each $\widehat{\mathbf{g}}_n$ is a subsequence of words in the target language. This sequence complements the user's feedback to conform the new hypothesis:

$$\begin{cases} \hat{y}_1^I = \tilde{\mathbf{f}}_1, \widehat{\mathbf{g}}_1, \ldots, \tilde{\mathbf{f}}'_i \widehat{\mathbf{g}}_i, \ldots, \tilde{\mathbf{f}}_N, \widehat{\mathbf{g}}_N \text{ if } \tilde{\mathbf{f}}'_i \in \tilde{\mathbf{f}}_1^N \\ \hat{y}_1^I = \tilde{\mathbf{f}}_1, \widehat{\mathbf{g}}_1, \ldots, \tilde{\mathbf{f}}_N, \widehat{\mathbf{g}}_N \text{ otherwise} \end{cases} \tag{1}$$

The word probability expression for the words belonging to a validated segment $\tilde{\mathbf{f}}_n$ was formalized by Peris et al. (2017) as:

$$p(y_{i_n+i'} \mid y_1^{i_n+i'-1}, x_1^J, f_1^N; \Theta) = \mathbf{y}_{i_n+i'}^\top \mathbf{p}_{i_n+i'}, \quad 1 \le i' \le \hat{l}_n \tag{2}$$

where l_n is the size of the non-validated segment generated by the system, which is computed as follows:

$$\hat{l}_n = \underset{0 \le l_n \le L}{\arg\max} \frac{1}{l_N + 1} \sum_{i'=i_n+1}^{i_n+l_n+1} \log p(y_{i'} \mid y_1^{i'-1}, x_1^J; \Theta) \tag{3}$$

3 Approach

Given a source sentence x_1^J, a sequence of typed characters $s_1^K = s_1, \ldots, s_K$ and a context $\mathbf{c} = \{\mathbf{c}_\mathrm{l}, \mathbf{c}_\mathrm{r}\}$, where $\mathbf{c}_\mathrm{l} = c_{\mathrm{l}1}, \ldots, c_{\mathrm{l}S}$ and $\mathbf{c}_\mathrm{r} = c_{\mathrm{r}1}, \ldots, c_{\mathrm{r}R}$; WLAC aims to autocomplete s_1^K to conform the word $w_1^W = s_1, \ldots, s_K, w_{K+1}, \ldots, w_W$. If we consider the context as the sequence of segments validated by the user ($\tilde{\mathbf{f}}_1^N = \mathbf{c}_\mathrm{l}, \mathbf{c}_\mathrm{r}$) and the sequence s_1^K as the partially-typed word correction (which would be inserted in $\tilde{\mathbf{f}}_1^N$ as a new one-word validated segment; leading to $\tilde{\mathbf{f}}_1^N = \mathbf{c}_\mathrm{l}, s_1^K, \mathbf{c}_\mathrm{r}$), we can view WLAC as a simplification of segment-based IMT. With that in mind, we can rewrite Eq. (1) as:

$$\hat{y}_1^I = \mathbf{c}_\mathrm{l}, \widehat{\mathbf{g}}_1, s_1^K \widehat{\mathbf{g}}_2, \mathbf{c}_\mathrm{r}, \widehat{\mathbf{g}}_3 \tag{4}$$

which, knowing that the prediction of the partially-typed correction corresponds to the first word of $\widehat{\mathbf{g}}_2$, can be rewritten as:

$$\hat{y}_1^I = \mathbf{c}_\mathrm{l}, \widehat{\mathbf{g}}_1, s_1^K w_{K+1}^W, \widehat{\mathbf{g}}'_2, \mathbf{c}_\mathrm{r}, \widehat{\mathbf{g}}_3 \tag{5}$$

Therefore, we can obtain the autocompleted word ($w_1^W = s_1^K w_{K+1}^W$) by performing a single step of the segment-based IMT protocol, discarding the rest of the translation prediction.

Figure 1 illustrates an example of segment-based IMT compared to the WLAC task for the same case.

In the segment-based IMT (Fig. 1a) example, at iteration 0, the system generates an incorrect first hypothesis. The, at iteration 1, the user validates a sequence of segments and types the first character of the word 'translated' to help the system fulfill the sequence of words between the first two segments. After that, the system generates a new translation with all the validated segments and the human-typed character sequence. The system repeats this process at the second iteration, ending with a correct translation. The WLAC (Fig. 1b) example simplifies the case that happens at iteration 1. Although we have the same source sentence, validated segments (left and right context) and human-typed character sequence, in this case, the system only has to find one word between the two segments instead of generating the whole sentence.

4 Experimental setup

In this section, we present the details of our experimental session.

4.1 Evaluation

The WLAC 22 shared task selected accuracy as the automatic metric with which to report the evaluation of the different systems[1]. This metric is computed as the total number of correctly predicted words normalized by the total number of words to complete:

$$\text{Acc} = N_{\text{match}}/N_{\text{all}} \tag{6}$$

where N_{match} is the number of predicted words that are identical to the human desired word, and N_{all} is the total number of testing words.

4.2 Corpora

We conducted our experiments using the English–German corpus provided by the organizers, which is a version of the WMT14's dataset, preprocessed by Stanford NLP Group. We saved 2000 sentences to use as validation, which we processed with the provided script[2] in order to create the simulated data. Table 1 presents the data statistics.

Table 1: Statistics of the WLAC 2022 corpus. *Avg.* stands for average, *Run.* for running, K for thousands and M for millions.

Partition	**Characteristic**	**De**	**En**
Training	Sentences	$4M$	
	Avg. Length	25	26
	Run. Words	$110M$	$116M$
	Vocabulary	$1.6M$	$800K$
Validation	Sentences	2000	
	Avg. Length	27	27
	Run. Words	$53K$	$53K$

4.3 Systems

Our MT systems were trained using *OpenNMT-py* (Klein et al., 2017). We made use of two different network architectures: recurrent neural network (RNN) (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017).

The RNN model uses an encoder–decoder architecture with long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) cells. We set the size of the encoder, decoder and word embedding layers to 512. The encoder and decoder models use a single hidden layer of the same size. We used Adam (Kingma and Ba, 2014) as the learning algorithm, with a learning rate of 0.0002 with a batch size of 10.

The Transformer model uses a word embedding size of 512. The hidden and output layers were set to 2048 and 512, respectively. Each multi-head attention layer has eight heads, and we stacked six encoder and decoder layers. We used Adam as the learning algorithm, with a learning rate of 2.0, b_1 of 0.9 and b_2 of 0.998. We set the batch size to 4096 tokens.

Additionally, we made use of the byte pair encoding (BPE) (Sennrich et al., 2016) algorithm, which was jointly trained on both languages of the dataset, applying a maximum number of 10.000 merges.

Finally, we used our own implementation (based on *OpenNMT-py*) of segment-based IMT, which we adapted for WLAC. This implementation is openly available[3] for the benefit of the community.

5 Results

In this section we present our experimental results. We trained four different models, alternating between the RNN and Transformer architectures and the use of the BPE algorithm on the En-

[1] A human evaluation was also performed.

Table 2: Experimental results, measured in terms of accuracy. Test values are taken from the official evaluation. Best results from the validation set are denoted in **bold**.

Partition	Approach	De–En	En–De
Validation	RNN	0.568	**0.535**
	RNN + BPE	0.554	0.498
	Transformer	0.563	0.524
	Transformer + BPE	**0.586**	**0.534**
Test	Transformer + BPE	0.390	0.340

glish–German language pairs.

Prior to submitting our systems, we used the synthetic validation dataset created from the provided data (see Section 4.2). As reflected in Table 2, all approaches yielded similar results. They correctly completed the word the user was trying to type around 60% of the time. Since the *Transformer + BPE* combination yielded a two points improvement for De–En, and also achieved—together with the *RNN* approach—the best results for En–De, we selected this model for our submission.

Table 2 also contains the official accuracy scores published by the organizers. For the blind test, our system's performance dropped near a 20%. While we are waiting for the publication of the findings to have a better understanding of the cause of this drop, we suspect that it is related with the test set being from a different domain than the training data, which would have a considerable impact in our MT model.

All in all, these results show that the segment-based IMT methodology is a promising approach to adapting an MT model to the WLAC task. Moreover, due to the shared task constrains, we trained our systems using only the data provided by the organizers. However, one of the benefits of our approach is that any MT system can be easily adapted to be used for WLAC.

6 Conclusions

In this work, we have presented our submission to WLAC shared task from WMT22. Our approach consisted in adapting the segment-based IMT methodology to the WLAC task, which allows us to use a conventional NMT model to tackle this task by simply adapting it at the decoding step. We tested some of the most used NMT architectures, achieving very encouraging results.

As a future work, we would like to test our approach using a more robust NMT system, adapted to the domain of the task to perform—instead of training an ad hoc system, as we did in this work due to the task restrictions.

Abstract

This paper presents IIGroup's submission to the WMT22 Word-Level AutoCompletion(WLAC) Shared Task in four language directions. We propose to use a *Generate-then-Rerank* framework to solve this task. More specifically, the generator is used to generate candidate words and recall as many positive candidates as possible. To facilitate the training process of the generator, we propose a span-level mask prediction task. Once we get the candidate words, we take the top-K candidates and feed them into the reranker. The reranker is used to select the most confident candidate. The experimental results in four language directions demonstrate the effectiveness of our systems. Our systems achieve competitive performance ranking 1st in English to Chinese subtask and 2nd in Chinese to English subtask.

1 Introduction

Recent advances in neural machine translation (Bahdanau et al., 2015; Vaswani et al., 2017) allow us to generate high-quality translation results. However, as it's pointed out by Li et al. (2021) that in some scenarios(e.g., legal instruments), the results of machine translation can't directly replace human translations due to their imperfections(e.g., terminology translation error). Therefore, more and more researchers pay attention to *Computer-aided translation*(CAT)(Barrachina et al., 2009; Santy et al., 2019; Huang et al., 2021; Xiao et al., 2022), which focuses on leveraging the advantages of NMT systems to increase the effectiveness and efficiency of the human translation process.

To further promote the development of CAT, WMT22 proposes a novel task —— Word-Level AutoCompletion(WLAC). In the Word-Level AutoCompletion task, given a source sentence $\boldsymbol{x}$, target context and human-typed characters $\boldsymbol{t}$, an ideal system is expected to be able to predict the target word w that should be placed in the target context.

We participate in the WMT22 shared Word-Level AutoCompletion task in four language directions: Chinese ⇒ English, English ⇒ Chinese, German ⇒ English and English ⇒ German and submit a system for each language direction.

We develop a *Generate-then-Rerank* framework-based system for each language direction. Based on the vanilla Transformer architecture, we adopt a bidirectional decoder, which can predict the current target word by paying attention to the source sentence and both the left-side and right-side target context.

The paper is organized as follows, section 2 gives the overview of the data used in the shared task and preprocessing operations for the data, while section 3 describes our training techniques, including model architecture, span-level mask prediction, etc. Section 4 presents our experimental results. Finally, our conclusions are summarized in Section 5.

2 Data

In this section, we first introduce the datasets used to train our systems, then we introduce how to prepare the simulated training data for the WLAC shard task and describe the vocabulary for each language direction.

2.1 Datasets

As the WLAC shared task is a data-constrained task, we can only use the parallel corpora provided by the WLAC organizers for all four language directions. Specifically, we use UN Parallel Corpus V1.0[1] (WMT 2017) for Chinese ⇒ English and English ⇒ Chinese. For German ⇒ English and English ⇒ German, we use the WMT 14 dataset pre-processed by Stanford NLP Group[2]. Details of the training resources provided are shown in Table 1.

2.2 Simulated Training Data

Since the WLAC shared task only provides raw parallel corpora and does not provide supervised data, which complies with the WLAC shared task setting, we need to automatically construct supervised data from the raw parallel corpora.

Specifically, given a raw parallel sentence pair $(\boldsymbol{x}, \boldsymbol{y})$, where $\boldsymbol{x} = (x_1, ..., x_m)$ is the source sentence, $\boldsymbol{y} = (y_1, ..., y_n)$ is the reference target sentence, we would like to construct a target word w and its corresponding target context $\boldsymbol{c} = (\boldsymbol{c}_l, \boldsymbol{c}_r)$ and human-typed characters $\boldsymbol{t}$, where the translation pieces $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ are on the left and right side of the target word w.

According to Li et al. (2021), we first randomly sample a target word $w = \boldsymbol{y}_t$, and then we sample four types of context types:

- Zero-context: both $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$ are empty;
- Prefix: randomly sample a translation piece $\boldsymbol{c}_l = \boldsymbol{y}_{i:j}$ from $\boldsymbol{y}$, where $i < j < t$. The $\boldsymbol{c}_r$ is empty.
- Suffix: randomly sample a translation piece $\boldsymbol{c}_r = \boldsymbol{y}_{i:j}$ from $\boldsymbol{y}$, where $t < i < j$. The $\boldsymbol{c}_l$ is empty.
- Bi-context: sample $\boldsymbol{c}_l$ as in prefix, and sample $\boldsymbol{c}_r$ as in suffix.

Last but not least, we need to generate human-typed characters $\boldsymbol{t}$ for the target word w, we adopt a heuristic method - we randomly sample a position i in the target word w, where $0 < i < |w|$, and simulate human-typed characters $\boldsymbol{t} = w_{1:i}$. For languages like Chinese, the human input is the phonetic symbols of the word, we use pypinyin[3] to implement this conversion. So far, we get the tuple $(\boldsymbol{x}, \boldsymbol{c}, \boldsymbol{t}, w)$, which can be viewed as a simulated training example for the WLAC shared task.

2.3 Vocabulary

Considering that WLAC is a word-level task, we don't use tools to do any subword segmentation. We directly use Moses scripts[4] to tokenize English and German sentences, and jieba[5] for Chinese sentences. The vocabulary size for each language direction is shown in Table 2.

3 Word-Level AutoCompletion Systems

In this section, we mainly introduce the *Generate-then-Rerank* framework. Both the generator and the reranker's architecture are based on Transformer(Vaswani et al., 2017) with the modification that the decoder is bi-directional to leverage more context information. It is important to note that we borrow the idea from Li et al. (2021) that we view WLAC as a word prediction task and *only use human-typed characters* $\boldsymbol{t}$ *as hard constraints*.

3.1 Model Architecture: Transformer

The vanilla Transformer (Vaswani et al., 2017) adopts a sequence-to-sequence architecture consisting of an encoder and a decoder. Specifically, the encoder is a stack of L encoder blocks and each block consists of a multi-head self-attention module and a feed-forward network (FFN). The decoder is also a stack of L decoder blocks, the main differences between the Transformer encoder and Transformer decoder are mainly reflected in two aspects: First, in each decoder block, there is an additional cross-attention module between the multi-head self-attention module and the feed-forward network. Second, the multi-head self-attention modules in the decoder are uni-directional while they are bi-directional in the encoder.

In the neural machine translation task setting, given a source sentence $\boldsymbol{x}$ and a target sentence $\boldsymbol{y}$, the decoder generates $\boldsymbol{y}$ as:

$$P(\boldsymbol{y}|\boldsymbol{x};\theta) = \prod_{t=1}^{|\boldsymbol{y}|} P(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x};\theta) \qquad (1)$$

[3] https://github.com/mozillazg/python-pinyin

[4] https://github.com/moses-smt/mosesdecoder

[5] https://github.com/fxsjy/jieba

Thus, the Transformer model is typically trained by minimizing the cross entropy:

$$\mathcal{L}_{NMT} = -\sum_{t=1}^{|\boldsymbol{y}|} \log P(y_t|\boldsymbol{y}_{<t}, \boldsymbol{x}; \theta) \quad (2)$$

Since Transformer is designed for auto-regressive generation tasks, we cannot directly adopt it to the WLAC task, which is essentially a natural language understanding task. Inspired by the successful practice of Conditional Masked Language Modeling (Ghazvininejad et al., 2019) in non-autoregressive machine translation, we take the same idea to train our model for the WLAC shared task.

Bi-directional Decoder Our decoder's architecture is roughly the same as the standard Transformer decoder except that the multi-head self-attention sub-layer. The standard Transformer decoder can only attend the left-side target context, while in our model, it can attend to all target words and make use of both left-side and right-side context information to better predict the <*mask*> token.

3.2 Generator

Span-Level Mask Prediction The primitive object function for a simulated training example in Generator is as follows:

$$\mathcal{L}_G = -\log P(w|\boldsymbol{x}, \boldsymbol{c}; \theta_G) \quad (3)$$

In our preliminary experiments, we find that it is hard to train the generator because, in every mini-batch, a simulated training example provides *only one* training signal, which makes the model easy to overfit. The importance of the density of training signals has been discussed in the Pretrained Language Model(Clark et al., 2020). To this end, we adopt an efficient sampling approach —— Span-Level Mask Prediction. As described in section 2.2, once we get the tuple $(\boldsymbol{x}, \boldsymbol{c})$, we use it to predict all the missing words in the masked span between $\boldsymbol{c}_l$ and $\boldsymbol{c}_r$. In the Pretrained Language Model, Joshi et al. (2020) has adopted the same idea as in our work. But one major difference is that, unlike Joshi et al. (2020), we have to set the position id of the masked word to be the same; otherwise, there will be a large gap between the training stage and the inference stage.

3.3 Reranker

So far, we have modeled the WLAC task as a classification task, that is, an extreme classification task. Inspired by recent works to introduce label knowledge to enhance text representation (Yang et al., 2021; Ma et al., 2022), we propose to use a generator-reranker framework to solve the WLAC task. We use the generator to recall positive and negative labels and use a reranker to distinguish positive labels from these labels. Specifically, we use the same Transformer architecture as the generator. But the reranker's input and objective function are different from the generator.

Input We obtain top-K labels $\mathcal{W} = \{w_1, w_2, ..., w_K\}$ through ranking the scores generated by the generator. Then, for each candidate label w_i in $\mathcal{W}$, we replace the <*mask*> token with w_i. So the input tuple becomes $(\boldsymbol{x}, \boldsymbol{c}, w_i)$. And the multi-class classification head of the original decoder becomes a binary classification head, which is used to measure whether the candidate label w_i matches the source sentence and target context.

Objective Function The objective function is as follows.

$$\mathcal{L}_R = \begin{cases} -\log P(w_i, \boldsymbol{x}, \boldsymbol{c}; \theta_R), & \text{if } w_i = w \\ -(1 - \log P(w_i, \boldsymbol{x}, \boldsymbol{c}; \theta_R)), & \text{otherwise.} \end{cases} \quad (4)$$

3.4 Model Configuration

We implement our models with Fairseq toolkit(Ott et al., 2019)[6]. Our models follow the Transformer-Base architecture(Vaswani et al., 2017), the key model architecture configurations and training configurations are listed in Table 4 and Table 5. Each model is trained on 8 NVIDIA Tesla V100 GPUs, each of which has 32GB memory.

4 Experimental Results

We report experimental results in four language directions: Chinese ⇒ English, English ⇒ Chinese, German ⇒ English and English ⇒ German. Table 3 shows the main experimental results on the official test sets with automatic accuracy evaluation and human accuracy evaluation.

[6] https://github.com/facebookresearch/fairseq

learning rate (generator)	5e-3
learning rate (reranker)	1e-3
max tokens per batch	32k
optimizer	Adam

Table 5: Training configuration for our generator model and reranker model.

The performance of the generator is as expected, and as demonstrated in Li et al. (2021), without using the bi-directional decoder, the generator performs relatively poorly. Additionally, we conduct an ablation study on Chinese ⇒ English subtask to demonstrate the effectiveness of the span-level mask prediction, the model without leveraging the span-level mask prediction strategy performs poorly, with a drop of -10.1 in accuracy on the validation set.

However, the performance of the reranker is not as expected. We conjecture that this is due to the insufficiency of the training procedure of the reranker. Initializing reranker's weights with generator's weights or with PLM's weight will boost the performance of reranker, we leave this as future work.

5 Conclusion

This paper describes the IIGROUP's systems submitted to the Word-Level AutoCompletion task at WMT22. We adopt a *Generate-then-Rerank* framework. The experimental results demonstrate the effectiveness of the generator.

However, due to the lack of computing power and time, the results of our experiments don't show the effectiveness of our reranker. We discuss this issue in section 4 and we will try to solve this in future work.

Abstract

This paper presents the submissions of Huawei Translation Services Center (HW-TSC) to WMT 2022 Word-Level AutoCompletion Task. We propose an end-to-end autoregressive model with bi-context based on Transformer to solve the current task. The model uses a mixture of subword and character encoding units to realize the joint encoding of human input, the context of the target side and the decoded sequence, which ensures full utilization of information. We use one model to solve four types of data structures in the task. During training, we try using a machine translation model as the pre-trained model and fine-tune it for the task. We also add BERT-style MLM data at the fine-tuning stage to improve model performance. We participate in zh→en, en→de, and de→en directions and win the first place in all the three tracks. Particularly, we outperform the second place by more than 5% in terms of accuracy on the zh→en and en→de tracks. The result is buttressed by human evaluations as well, demonstrating the effectiveness of our model.

1 Introduction

In recent years, machine translation quality has improved significantly with advances in model architecture (Sutskever et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017), bilingual data availability, as well as data augmentation strategies (Liu et al., 2016; Freitag et al., 2017; Johnson et al., 2017; Zhang et al., 2018; Edunov et al., 2018; Wu et al., 2019; Li et al., 2019). In scenarios where machine translation is used to facilitate understanding, machine translation outputs can basically satisfy audience's demands. However, in areas where translation quality is crucial (such as translating product manual, patent description, etc.), post-editing is required. Techniques to improve post-editing efficiency are meaningful and necessary. Researches (Barrachina et al., 2009; Green et al., 2014; Knowles and Koehn, 2016; Santy et al., 2019) in this regard falls into this category of computer-aided translation (CAT).

Word-Level auto Completion, as a new task in WMT22, fall into this category as well. This task aims at auto-completing a target word given a source sentence, translation context, and a human-typed character sequence, so as to improve post-editing efficiency. Li et al. (2021) define the task in detail, offer comprehensive analysis and provide a baseline system.

For this task, we choose the subword-level modeling strategy (Kudo and Richardson, 2018). Comparing with word-level modeling, this strategy enables the usage of pre-trained models from other mainstream tasks, and solves the out-of-vocabulary (OOV) issues at the same time. As human-typed input is just several characters of the target word, the input is not suitable for subword segmentation. We use character-level encoding instead. Our final submission is an autoregressive model with bi-context, ensuring mixed encoding of characters and subwords.

In view of the possible discontinuity between the context and human-typed inputs in the target-side text, we use tags to wrap the inputs, and then encode jointly with the context, in conjunction with the autoregressively decoded pre-token sequence. The joint coding maximizes the usage of information without introducing additional RNN (Cho et al., 2014) or vocabulary reduction modules.

During training, we use a standard machine translation model as the pre-trained model, and fine-tune it for this task. We then add BERT-style Mask Language Model (MLM) (Devlin et al., 2018) data in the fine-tuning stage to enhance the language model capabilities of the decoder, thereby improving the overall model performance.

The inference mechanism is different from that of traditional NMT. In general, the entire decoder sequence must be used for encoding each token,

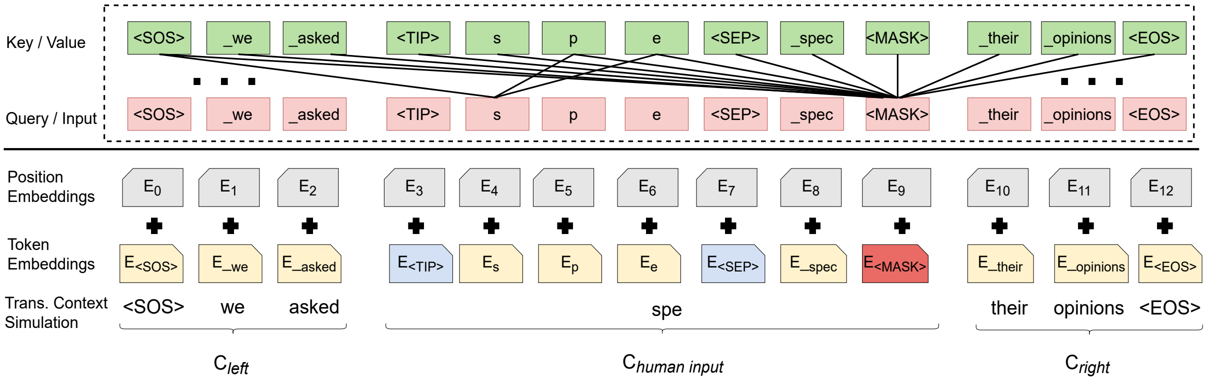

Figure 1: The input representation of our model's decoder. C_{left} and C_{right} are the context. E_s, E_p, E_e are the char embedding of human input "spe". <TIP> is the separator for human input and left context. <SEP> is the separator for human input and decoded sequence. <MASK> represents the potenial target word in this translation context.

which reduces the inference performance to a certain extent. However, given the model's parallel ability and the short decoding sequence (the number of subwords in a word), this issue is not very serious for this task and this strategy is applicable for practical use. Figure 1 shows the input representation of our model's decoder.

We submit results for three language directions. All of them achieve the highest accuracy. Our Zh→En and En→De submissions even outperform the second place by 5% in terms of accuracy, and get a good lead in human evaluation, demonstrating the effectiveness of our strategy.

2 Data Processing

Zh→En data for this task comes from UN V1.0 (about 15.9M) and En↔De data comes from WMT14 (about 4.5M). The task allows the use of additional monolingual data, but we add no additional data on the zh-en track given the amount of bilingual data available. An additional 24M monolingual data is used for the En-de track, and the data comes from the WMT news task as well. we generate synthetic parallel data by sampling BT (Edunov et al., 2018) for the En→De track and by beam BT for the Dn→En track. The specific reasons will be given later.

We follow basic strategies to cleanse the data, including: deduplication, garbled character filtering, XML conversion, and fast-align(Dyer et al., 2013), etc. The data sizes before and after data processing are shown in table 1.

As for subword, we employ sentencpiece on Zh→En track, and set the vocabulary size to 36k. On En→De track, we use the BPE algorithm, and set the vocabulary size to 32K.

Lang-Pair	Origin	Cleaned
Zh-En	15.9M	15.5M
En-De	4.5M	4.3M

Figure 2: The joint encoding of context and human input.

3 System design

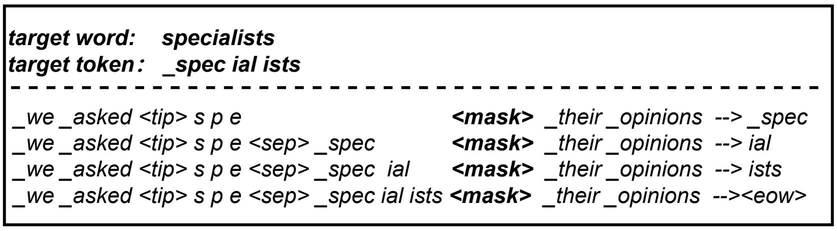
In this chapter, we introduce the model structure, training strategy, inference strategy and corresponding data generation strategy used for this task. Our model is based on the encoder-decoder architecture of the standard Transformer.

3.1 Model Structure

We use Transformer as our model architecture. For convenience, we only use a 25 encoder layers and 6 decoder layers deep model. The parameters of the model are the same as Transformer-big. We just change the post-layer-normalization to the pre-layer-normalization (Sun et al., 2019), and increase the number of encoder layers to 25.

3.2 Modeling Units

In general, we use a mixed encoding strategy that encoding subword-level and character-level information at the same time. To be more specific, the model conducts subword-level encoding on source and target context information, and character-level encoding on human-typed input, as it is just several characters of a word. Apparently, the model can



```
target word:    specialists
target token:   _spec ial ists
-----------------------------------------------------------------------
_we _asked <tip> s p e                           <mask>  _their _opinions  --> _spec
_we _asked <tip> s p e <sep> _spec               <mask>  _their _opinions  --> ial
_we _asked <tip> s p e <sep> _spec  ial          <mask>  _their _opinions  --> ists
_we _asked <tip> s p e <sep> _spec ial ists <mask>  _their _opinions  --><eow>
```

Figure 3: The process of data generation.

encode the two types of information at the same time.

3.3 Joint Encoding

In the above chapter, we discussed our modeling granularity for context and human-typed input. According to the settings of the task, context information and human-typed input information may be discontinuous. Here we insert the tag <tip> before and after the tip to wrap the human-typed input to distinguish the two. Schematic diagram is shown in Figure 2.

The context and human-typed input of the translation test can be jointly encoded, which ensures the maximum usage of information.

3.4 Autoregressive Decoding with Bi-context

In the task, there are four types of data: left-context, right-context, zero-context and bi-context. If we use four models to process these four types of data, the problem can be solved, but the task will be complicated. Instead, we can regard the first three types as special cases of the last type, so we directly design an autoregressive decoding strategy with bi-context, and use a single model to process all types of data.

To be more specific, decoding is performed with Mask token as the anchor point. The encoder encodes the source-side text. The mask, in conjunction with context and human-typed input, is encoded at the decoder side to predict the first subword of the target word. The first subword (pre-token) will be encoded as well. Then the model continues to use the mask for decoding until a complete word is decoded. The overall architecture diagram of the model decoder is shown in figure 1.

Here are two points: 1. The mask token replaces the second tip described in the previous section. The mask token is capable of distinguishing the human-typed input from other information and masking at the same time. 2. The newly added <sep> tag is responsible for distinguishing between human-typed input and decoded pre-token information.

3.5 Data Generation

Based on our previous coding strategy for various types of information, we first use the script provided by the organizer to generate word-level training data. Then, we use the subword-level model to perform subword processing on the source text and translation context. Regarding the target word, we add a tag <eow> at the end of word after subword segmentation. Assuming that the number of subwords is N, we generate N sets of training data to simulate the entire autoregressive process. We call the data as WLAC (Word Level Auto Completion) data to distinguish it from terms. A case study of the generation is show in Figure 3.

In the process of generating data, we also add some rules to improve efficiency. We remove sentences with too short target words or too long human-typed input by a given probability. In addition, we keep only 1/10 of the training samples of eos that predict the end of the sentence.

In order to effectively validate the performance of the model during training, we generate a test set using the same strategy. WMT19 news test is used for the Zh→En track, and WMT14 new-test is used for En↔De tracks. We do not use a filtering strategy when generating the test set.

4 Experiment

During the experiment, we first build a baseline based on the MT model in order to measure our model's performance more accurately. After that, in the training process, we adopt several strategies to improve the model performance, that is, fine-tuning a MT model and introducing BERT-style MLM data. Validation and debugging of these strategies are done on the Zh→En track. We use the finally determined strategy to train models for other tracks.

Lang-Pair	Baseline	MT-tune	Mix-tune	Average	Ensemble	WMT22
zh-en	62%	74%	77.19%	78.69%	78.96%	59.40%
en-de	-	dvivied	81.79%	82.86%	82.80%	62.06%
de-en	-	-	77.83%	79.05%	79.77%	63.82%

Table 2: The main results of our experiments. MT-tune refers to using WLAC data to fine-tune a standard MT model. MLM-Mix-tune refers to using WLAC and BERT-style MLM data to fine-tune the MT model.

4.1 Baseline based on the MT Model

First, we consider whether the current task can be solved by directly relying on the outputs by an MT model trained with bilingual data. By doing so, we lower the requirements of this strategy and regard a case as correct as long as the predicted word appears in the MT result.

We obtain an accuracy of 62.5% on the Zh→En track by using the above-mentioned approach. We use this as a benchmark for optimization. If our designed strategy cannot exceed this level of accuracy, the strategy fails.

4.2 MT Model Finetune

After obtaining the baseline MT model, we then fine-tune it using the generated WLAC data. It should be noted that the self-attention layer of the standard NMT model's decoder does not have the ability to generate attention to the right, and our decoder is a mask-based prediction model, so we need to break this limitation. This is also a gap between the two tasks.

4.3 BERT-Style MLM Data Fine-tune

In the fine-tuning stage on the basis of a MT model, through analyzing each type of data, we find that the the accuracy of prefix is higher than that of the suffix. We assume this is because there is no right-side information during the training a pre-trained NMT model. As a result, the model may learn right-context less efficiently than the left-context.

According to the task setting, the context of the target side is an incomplete fragment and is given randomly. At the same time, tips are not necessarily continuous, so the overall translation is relatively confusing. Source-side information is important so we deepen the number of encoding layers. In addition, using the mask as the decoding anchor causes the decoder to change from the standard language model mode to the mask language model mode. To address these issues, we add a same proportion of BERT-style MLM data with source-side information. Given the availability of original text, we enlarged the probability of the mask to 25%.

4.4 Average and Ensemble

Finally, we adopt commonly used strategies to improve the model performance, including averaging and ensemble, and we find that both of the strategies lead to performance improvement. Particularly, averaging brings significant improvement.

5 Result and Analysis

Due to time restriction, we only conduct detailed comparison experiments on the Zh→En track. En↔De tracks simply follows the final strategy we apply to the Zh→En track. The results are shown in Table 2.

First of all, the performance of the MT baseline we trained is very poor, indicating that the MT task is not well adapted to the current task. So we give up the idea of using the MT results to enhance the model performance.

After our constructed WLAC data is added, the model performance improves by nearly 12 points, indicating the effectiveness of our strategy. But it is worth noting that the En→De model does not converge after adding the ST/BT data. We assume that the quality of the ST data is not good. In addition, the target-side of WLAC data is confusing, resulting in training failure. So for the De→En model, we directly generate BT data based on beam search to avoid the issue.

After MLM data is added, we again obverse a significant improvement. The accuracy on the Zh→En reaches 77.19%. The En→De model, which was not converged at the previous stage, gains an accuracy of 81.79%. The results support our assumption that MLM data can enhance the language model ability of the decoder, while avoiding noise interference from the source-side text.

In the end, model averaging leads to improvements on all three tracks, and the improvement is more significant than ensemble. Ensemble leads to significant improvement on the De→En track but limited improvement on the other two tracks. We assume this is because the De→En model is not sufficiently trained due to time restriction.

6 Conclusion

In this paper, we detail our team's participation in the WMT22 word-level AutoComplete task. We first analyze the input and output, as well as challenges in this task. We notice that the modeling granularity of human-typed input and context information are different. Therefore, we propose modeling human-typed input at character-level and modeling context information at subword-level, explicitly distinguishing and jointly encoding the two, thereby maximizing information usage in the encoding stage. At the same time, there is a semantic discontinuity between context and human-typed input. We add tags to differentiate the two. Finally we propose an autoregressive model with bi-context to process four types of data at the same time. During training, we use an NMT model as the pre-trained model and fine-tune it for this task. BERT-style MLM data is also introduced to improve the model performance, and at the same time to solve the single-direction decoding issue of the self-attention model. In the end, our models are well adapted to the task and gain safe leads in both automatic and human evaluations.

Abstract

This paper describes the joint submission of Alibaba and Soochow University, TSMind, to the WMT 2022 Shared Task on Translation Suggestion (TS). We participate in the English ↔ German and English ↔ Chinese tasks. Basically, we utilize the model paradigm fine-tuning on the downstream tasks based on large-scale pre-trained models, which has recently achieved great success. We choose FAIR's WMT19 English ↔ German news translation system and MBART50 for English ↔ Chinese as our pre-trained models. Considering the task's condition of limited use of training data, we follow the data augmentation strategies proposed by Yang et al. (2021) to boost our TS model performance. The difference is that we further involve the dual conditional cross-entropy model and GPT-2 language model to filter augmented data. The leader board finally shows that our submissions are ranked first in three of four language directions in the Naive TS task of the WMT22 Translation Suggestion task.

1 Introduction

Computer-aided translation (CAT) (Barrachina et al., 2009; Green et al., 2014, 2015; Knowles and Koehn, 2016) has become more and more popular to help increase the quality of machine translation (Lopez, 2008; Koehn, 2009) result. It also improves the efficiency of translators by combining the results of machine translation and the content edited by translators in the process of translation or post-editing (Bowker, 2002; Lengyel and Ugray, 2004; Bowker and Fisher, 2010; Bowker, 2014; Chatterjee, 2019).

Post-editing based on machine translation is typical in CAT. Recent works (Domingo et al., 2016; González-Rubio et al., 2016; Peris et al., 2017) propose interactive protocols and algorithms so that humans and machines can collaborate during translation, and machines can automatically provide feedback on humans' edits. One interesting mode is Translation Suggestion (TS) (Yang et al., 2021), which offers alternatives for specific spans of words in the generated machine translation. It will be convenient if the model refines translation results in those specified locations with potential translation errors. Yang et al. (2021) released a benchmark dataset for TS, *WeTS*, which is one of the shared tasks in WMT22. At the same time, they proposed an end-to-end Transformer-like model for TS as the benchmark system.

However, the lack of many labeled TS data limits the training of a large Transformer model to some extent. Though Yang et al. (2021) have tried to utilize XLM-Roberta (Conneau et al., 2019) to initialize the encoder of the Transformer, the decoder has to be trained from scratch, which leads to relatively low BLEU scores for some specific TS spans. We investigate the potential of other encoder-decoder pre-trained models by experiments to see if there is still room for improvement. Finally, we have found that pre-trained Transformer NMT models could be suitable choices to be fine-tuned with the limited size of TS data. In addition, we applied similar data augmentation strategies proposed in Yang et al. (2021), but use the well-trained alignment models between source and target languages from Lu et al. (2020) to filter out high-quality augmented data. Our submissions are ranked first in three of four language directions in the WMT22 Translation Suggestion task.

2 The Model

We train a simple end-to-end Transformer model for each language pair to generate the translation suggestion candidates. The source sentence and the masked translation, in which an incorrect span requiring an alternative has been replaced with a special mask tokens in advance, are concatenated with a special separation token *[SEP]*. Afterward,

[*] indicates equal contribution.

Table 2: Number of parallel samples remained after filtering by length and cross-entropy quality score (Lu et al., 2020).

we feed the concatenated sequence as input of the Transformer encoder and the translation suggestion needs to be generated by the Transformer decoder. The model is trained in the same way of a normal translation model.

Considering that the TS task also relies on alignments of hidden representations between the source and the target language, a well-trained translation model can be a good starting point for TS model training. The weights of our model are initialized with a pre-trained Transformer NMT model. Then, a two-phase training pipeline is applied. In the first phase, the model is trained with pseudo corpus derived from data augmentation described in Section 3. In the second phase, we fine-tune the model with the real TS train data released by the organizers.

3 Data Augmentation

We follow the data augmentation methods provided by (Yang et al., 2021) to generate three types of pseudo data for TS model training: data sampled on the golden parallel corpus, data sampled on the pseudo parallel corpus, and data extracted with word alignment. However, the details of the pseudo data augmentation in this paper are slightly different from those of Yang et al. (2021). Full details are exhibited in the following subsections.

Algorithm 1 Algorithm of Phrase Align

```
Input: y, r, A
Output: p̂
Function GenerateAlign(y, r, A):
    $yt = size(\mathbf{y}), rt = size(\mathbf{r})$
    for $i \leftarrow 0$ to $yt$ do
        for $j \leftarrow i$ to $yt$ do
            for $a \leftarrow 0$ to $rt$ do
                for $b \leftarrow a$ to $rt$ do
                    if IsMatch(y, r,i, j, a, b, A) then
                        do
                            $i += 1; a += 1$
                        while $\mathbf{y}^i == \mathbf{r}^a$
                        do
                            $j -= 1; b -= 1$
                        while $\mathbf{y}^j == \mathbf{r}^b$
                        $\hat{\mathbf{p}}.add((\mathbf{y}^{i:j}, \mathbf{r}^{a:b}))$
    return $\hat{\mathbf{p}}$
Function IsMatch(y, r, i,j,a,b,A):
    for $ii \leftarrow i$ to $j$ do
        let T = $\{t_i | \mathbf{r}^{t_i}$ is aligned with $y^{ii}$ in $\mathbf{A}$ $\}$
        foreach $t_i \in T$ do
            if $t_i < a$ or $t_i > b$ then
                return False
    for $aa \leftarrow a$ to $b$ do
        let T = $\{t_a | \mathbf{r}^{aa}$ is aligned with $y^{t_a}$ in $\mathbf{A}$ $\}$
        foreach $t_a \in T$ do
            if $t_a < i$ or $t_a > j$ then
                return False
    return True
```

3.1 Sampling from golden parallel corpus

Raw parallel corpus is firstly filtered by the sentence length. All sentence pairs that have less than 20 words or more than 80 words on any side are removed.

Considering that there might be noise data in the corpus, we apply the dual conditional cross-entropy model (Lu et al., 2020) to obtain a quality score for each sample. Sentence pairs with low quality are

		All	revenue	of	the	system	…			
		0	1	2	3	4	5	6	7	…
All	0	*								
revenues	1		*							
from	2		*							
the	3			*	*					
system	4					*				
	5									
	6							*	*	
	…									

Figure 1: In this example, we have the alignment info between machine translation (MT) and reference sentences: 0-0, 1-1, 1-2, 2-3, 3-3 4-4, 6-6, 6-7, the phrase from $0 \sim 4$ in MT are aligned to $0 \sim 4$ in reference. The rectangle enclosed by the aligned phrases between MT and reference should satisfy that each row and each column has at least one *.

filtered.

Then we generate a pseudo corpus with the remained high-quality parallel corpus. ($\mathbf{x}$, $\mathbf{r}$) is marked as the sentence pair of the parallel corpus, where $\mathbf{x}$ is the source sentence and $\mathbf{r}$ is the golden reference. $\|\mathbf{r}\|$ represents the number of tokens in $\mathbf{r}$.

The first step is to randomly sample the length l to mask for the reference r from a uniform distribution:

$$l \sim U(1, \|\mathbf{r}\|) \tag{1}$$

Then a span with l tokens $\mathbf{r}^{i:j}$ is randomly selected by:

$$i \sim U(0, \|\mathbf{r}\| - l), \;\; j = i + l \tag{2}$$

Finally, we get the TS training data $(\mathbf{x}, \mathbf{r}^{\neg i:j}, r^{i:j})$ from each parallel sentence pair $(\mathbf{x}, \mathbf{r})$, where $\mathbf{r}^{\neg i:j}$ is denoted as the masked version of r, in which $\mathbf{r}^{i:j}$ is replaced with a mask token, e.g <MASK_REP>.

3.2 Sampling on Pseudo Parallel Corpus

In addition, the monolingual corpus is another source for data augmentation. We first filter the monolingual data with a language identification process. Then pseudo parallel corpus is generated with NMT models. Finally, TS training data can be generated as we do in Section 3.1.

3.3 Extracting with Word Alignment

In the task of TS, the labels for the masked span is always correct while the translation contexts of the span, $\mathbf{y}^{\neg i:j}$ are not error-free. Therefore, both of the above two types of pseudo data are biased from the task. In pseudo data sampled from golden parallel corpus, the translation contexts are error-free. And the labels of pseudo data from machine translation results are not always correct. To reduce the bias, another way of data augmentation is proposed in Yang et al. (2021). They utilize the alignment between the machine translation and the golden reference to generate pseudo-training samples for TS. We use the similar idea and the details of our alignment-based data augmentation algorithm are described as follows.

Given the triplet ($\mathbf{x}$, $\mathbf{y}$, $\mathbf{r}$) where $\mathbf{x}$ is the source sentence, $\mathbf{y}$ is the machine translation result generated by NMT models, and $\mathbf{r}$ is the reference, we need to find aligned segment pairs $(\mathbf{y}^{i:j}, \mathbf{r}^{a:b})$ between $\mathbf{y}$ and $\mathbf{r}$.

First, we use the Fast Align toolkit (Dyer et al., 2013) to extract token alignments between $\mathbf{y}$ and $\mathbf{r}$. The align result $\mathbf{A}$ is a list of aligned indexes in the format of i-a, which means token $\mathbf{y}^i$ is aligned to $\mathbf{r}^a$. With the token alignments, the next step is to extract aligned-phrase pairs, denoted as $\hat{\mathbf{p}}$. Figure 1 shows an example of an aligned phrase between MT and reference. The algorithm of the aligned-

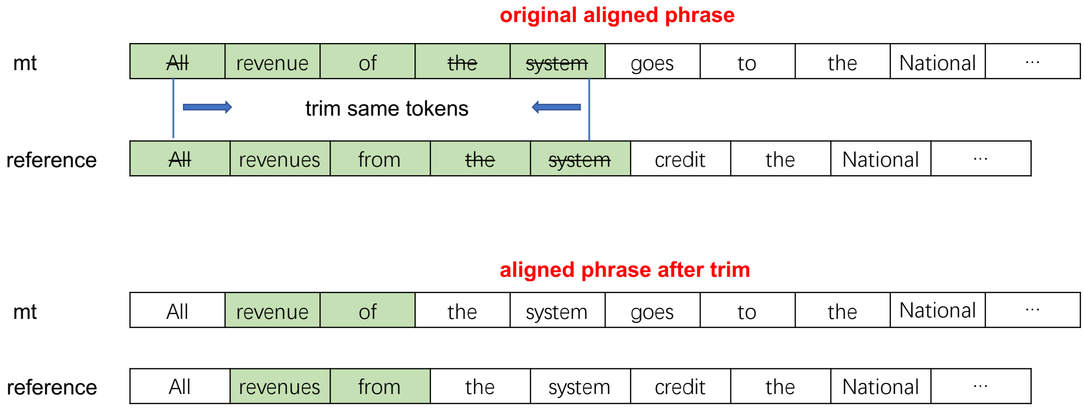

Figure 2: As shown in Figure 1, we get the original aligned phrase between MT and reference which are "All revenue of the system" and "All revenues from the system". We then trim the tokens that appear in both MT and reference to compress the aligned phrase. Finally, we get the trimmed aligned phrase: "revenue of" and "revenues from"

Method	En-De	De-En	En-Zh	Zh-En
TSMind	45.90	43.37	30.21	28.77
-w/o first-phase training	37.14	33.23	21.20	16.44
-w/o second-phase training	37.37	36.83	21.84	19.19

Table 3: Sacre-BLEU on the validation sets of Sub-Task 1 (Naive TS) of the WMT'22 Translation Suggestion Task.

phrase extraction is presented in Algorithm 1 from line 1 to line 13. The aligned phrases are a subset of SMT's phrase extraction (Koehn et al., 2003) with two restricts. 1) Each row and each column of a aligned phrase has at least one token aligned (a * in Figure 1); 2) We take only the longest phrase and the sub-phrases are not taken. After the original aligned phrase is obtained, we remove tokens that appear in both MT and reference to get the trimmed result as shown in Figure 2. We trim these common tokens because we want the model to focus more on the incorrect spans and its alternatives. The pseudo-code of the phrase-alignment is presented in the Algorithm 1. We denote the aligned phrase as $\mathbf{y}^{i:j}$ and $\mathbf{r}^{a:b}$, $\mathbf{y}^{\neg i:j}$ represents the masked version of $\mathbf{y}$ as described in Section 3.2.

Now we need to judge whether $\mathbf{r}^{a:b}$ is better than $\mathbf{y}^{i:j}$ in the context of $\mathbf{y}^{\neg i:j}$. We replace $\mathbf{y}^{i:j}$ with $\mathbf{r}^{a:b}$ in $\mathbf{y}$, and get another new sentence $\hat{\mathbf{y}}$. First, we use the dual conditional cross-entropy model as described in Section 3.1 to calculate the quality score of $(\mathbf{x}, \hat{\mathbf{y}})$. Then, the perplexity of $\hat{\mathbf{y}}$ and $\mathbf{y}$ are given by the language-specific GPT2 models (Schweter, 2020; Radford et al., 2019; Zhao et al., 2019) released on HuggingFace (Wolf et al., 2020) respectively. If the cross-entropy quality score of $(\mathbf{x}, \hat{\mathbf{y}})$ is smaller than the threshold of β_1 and the perplexity loss reduction value of $\mathbf{y} - \hat{\mathbf{y}}$ is at least β_2, then the translation $\hat{\mathbf{y}}$ is most likely better than $\mathbf{y}$. We can treat $\mathbf{y}^{\neg i:j}$ as the masked version of MT and $\mathbf{r}^{a:b}$ as the correct alternative. β_1 and β_2 are the hyper-parameters of the alignment.

Finally, we get the aligned training data ($\mathbf{x}$, $\mathbf{y}^{\neg i:j}$, $\mathbf{r}^{a:b}$) from the triplets $(\mathbf{x}, \mathbf{y}, \mathbf{r})$.

4 Experiment

4.1 Corpus and Setup

Parallel corpora for data augmentation in Section 3.1 and 3.3 and monolingual corpora for Section 3.2 are all downloaded from WMT22 general translation task[1]. For English ↔ German, WikiMatrix (Schwenk et al., 2021), News Commentary v16, Common Crawl Corpora, and Tilde MODEL Corpora (Rozis and Skadiņš, 2017) are used as parallel corpus. For English ↔ Chinese, parallel corpus we used includes UN Parallel Corpus V1.0 (Ziemski et al., 2016) and all parallel corpora from CCMT corpus (Yang et al., 2019) except for the casict2015 corpora. For monolingual corpora, News Commentary and News Crawl are used for all three languages, and Leipzig Corpora (Goldhahn et al., 2012) is also used for Chinese and German.

	En-De	De-En	En-Zh	Zh-En	Average
XLM-R	25.12	27.40	32.48	21.25	26.56
Naïve Transformer	28.15	30.08	35.01	24.20	29.36
Dual-source Transformer	28.09	30.23	35.10	24.29	29.43
SA-Transformer	29.48	31.20	**36.28**	25.51	30.62
TSMind	**47.44**	**45.02**	26.41	**31.78**	**37.66**

Table 4: Sacre-BLEU on the test sets of WeTS (Yang et al., 2021)

Then the filtering strategies proposed in Section 3.1 are applied to the raw parallel data. The number of data remained after every filtering step can be found in Table 2.

We download monolingual data from WMT22, and get a total of 45.02 million German, 14.68 million English and 10.01 million Chinese monolingual sentences.

For data augmentation in Sections 3.2 and 3.3, we use the NMT models for English ↔ German and English ↔ Chinese released by Yang et al. (2021)[2] to translate the source sentences. And the hyper-parameter β_1 and β_2 to filter aligned phrases are set to 2.5 and 0.05, respectively.

4.2 Model Training

As mentioned in Section 2, a well-trained NMT model is a good starting point for the TS model. For English ↔ German, we initialize the weights with the NMT models released by Ng et al. (2019) (Winner of WMT'19). For English ↔ Chinese, the one-to-many and many-to-one mBART50 models (Tang et al., 2020) are used.

We use the fairseq toolkit (Ott et al., 2019) to train and evaluate our model. Hyper-parameters are set to the same as examples in the fairseq toolkit except that we reset the learning rate at the beginning of the first phase training and beam size is set as 6 during inference.

4.3 Experimental Results

We evaluate the TSMind by calculating the Sacre-BLEU (Post, 2018) of the top-1 generated translation suggestion candidate on the golden reference. Results of the validation sets of WMT22 are shown in Table 3. Without first-phase training, we get much worse performances. This demonstrates that a large amount of pseudo corpora contributes much to the model. However, without the second-phase training (i.e. without the human-labeled data), we cannot obtain a good translation suggestion model with only pseudo corpora either. Therefore, the design of the two-phase training and the pseudo corpora are essential to set good translation suggestions.

Since the development set of WMT'22 is not the same as the test set used in Yang et al. (2021), to make a fair comparison, we also report the Sacre-BLEU on the test set of WeTS in Table 4. Results of all baseline systems are reported by Yang et al. (2021). TSMind outperforms the strong baseline, SA-Transformer, significantly with a gap of 7.04 BLEU on average for all four language pairs. We notice that TSMind does not perform well on the English to Chinese language pair. The reason might be that the pre-trained model we use is the one-to-many model of mBART50, and the multilingual decoder is not well-trained for Chinese. For example, on the English to Chinese news translation test set of WMT'20 (Barrault et al., 2020), mBART50 only achieves a Sacre-BLEU value of 30.79, while the Sacre-BLEU of state-of-the-art is 49.2.

5 Conclusion

In this paper, we present our translation suggestion systems, TSMind, for the WMT 2022 Translation Suggestion Task. Different from previous work, we use well-trained NMT models as the pre-trained models and applied a two-phase training strategy.

We explore three data augmentation strategies from previous work and utilize the dual conditional cross-entropy model to filter out low-quality augmented data. The leader board finally shows that our submissions are ranked first in three of four language directions in the Naive TS task of WMT22 Translation Suggestion task.

Abstract

This paper describes the Transn's submissions to the WMT2022 shared task on Translation Suggestion. Our team participated on two tasks: Naive Translation Suggestion and Translation Suggestion with Hints, focusing on two language directions Zh→En and En→Zh. Apart from the golden training data provided by the shared task, we utilized synthetic corpus to fine-tune on DeltaLM (ΔLM), which is a pre-trained encoder-decoder language model. We applied two-stage training strategy on ΔLM and several effective methods to generate synthetic corpus, which contribute a lot to the results. According to the official evaluation results in terms of BLEU scores, our submissions in Naive Translation Suggestion En→Zh and Translation Suggestion with Hints (both Zh→En and En→Zh) ranked 1st, and Naive Translation Suggestion Zh→En also achieved comparable result to the best score.

1 Introduction

Combining machine translation (MT) and human translation (HT) is becoming a popular way in translation practice, which uses a typical way of post edit (PE) – the human translators are asked to provide alternatives for the incorrect word spans in the results generated by MT (Green et al., 2013; Bahdanau et al., 2015; Vaswani et al., 2017; Zouhar et al., 2021; Yang et al., 2021). In order to improve the efficiency of PE, researchers proposed translation suggestion (TS) to provide the sub-segment suggestions for the annotated incorrect word spans, and experiments show that TS can substantially reduce translators' cognitive loads and the post-editing time (Wang et al., 2020; Lee et al., 2021; Yang et al., 2021).

This paper describes the contribution of Transn IOL Research to the WMT22 Translation Suggestion shared task, where systems were submitted to two tasks: 1) Naive Translation Suggestion; 2) Translation Suggestion with Hints. For both tasks we trained the models on pre-trained encoder-decoder language model ΔLM (Ma et al., 2021) with the corpus which were synthesized deliberately, then submitted the ensemble results of the trained models. Our main contributions are:

. We utilized the pre-trained language model ΔLM to generate TS, which gets good results on the shared tasks, and much lower computational budget than training from raw Transformers (Vaswani et al., 2017; Junczys-Dowmunt and Grundkiewicz, 2018; Yang et al., 2021) as well as better quality.

. Apart from the provided golden data annotated by expert translators, we proposed the constructing methods for silver and bronze data to train TS system based on parallel corpus and the NMT models provided by the shared tasks, which contributes a lot for the final results.

. Based on the Naive Translation Suggestion models, we proposed an effective algorithm for the task of Translation Suggestion with Hints, which improves BLEU scores significantly.

The rest of this paper is organized as below. Section 2 is a brief description for Translation Suggestion shared task of WMT2022. Section 3 presents our system, including data constructing and the training process with ΔLM. Section 4 reports experimental results in the participated language directions. Finally, we conclude our work in Section 5.

2 Translation Suggestion Tasks

Translation Suggestion is a new task on WMT2022, which includes two sub-tasks.

Task 1 - Naive Translation Suggestion: This sub-task focuses on the scenario where the user

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1205 - 1210
December 7-8, 2022 ©2022 Association for Computational Linguistics

selects the incorrect span of the MT sentence without entering any information, the model outputs the alternatives automatically. Consider the source sentence x, the MT sentence m, the incorrect span selected by the user as w, the alternative y and the model parameter θ, the naive TS can be formulated as: $P(y|x, m, w, \theta)$.

Task2 - Translation Suggestion with Hints: In actual applications, users usually have general ideas of what they want. If they are dissatisfied with all the suggestions provided by Naive TS, they are willing to enter some hints for the model to generate more accurate suggestions. Given the hints h provided by users, the sub-task 2 can be formulated as: $P(y|x, m, w, h, \theta)$. In this task, we take the $top - k$ initial characters of the alternative words as the hint, and the k is randomly selected for each example.

Task 1 includes 4 language directions (En⇔Zh and En⇔De) and Task 2 includes 2 language directions (En⇔Zh). We participated En⇔Zh language directions for both tasks.

3 Implemented Systems

We fine-tune the pre-trained language model ΔLM on synthetic data and the task golden data for Task1, then adjust N-best parameter along with an optimization algorithm for Task2. The details are described in this section.

3.1 Pre-trained Model

ΔLM is a pre-trained multilingual encoder-decoder model, which outperforms various strong baselines on both natural language generation and translation tasks (Ma et al., 2021). Its encoder and decoder are initialized with the pre-trained multilingual encoder InfoXLM (Chi et al., 2020), and trained in a self-supervised way. ΔLM's pre-training tasks include span corruption on monolingual data and translation span corruption on bilingual data. We choose ΔLM as the pre-trained model for TS task because the pre-training task of translation span corruption is similar to TS. The only difference is that ΔLM masks spans in target sentence as well as spans in source sentence on bilingual data, which follows the idea from mT6 (Chi et al., 2021), but TS only masks one span in target sentence.

We use ΔLM-base model in our experiments, which has 360M parameters, 12-6 encoder-decoder layers, 768 hidden size, 12 attention heads and 3072 FFN dimension.

3.2 Construct Synthetic Data

The golden data provided by the TS tasks are annotated by expert translators, which are expensive and labor-consuming. Since the 15k golden data are far from enough to fine-tune a ΔLM model, we propose several methods to construct synthetic data for TS on parallel corpus and the specified NMT models. These synthetic data are named as silver or bronze data according to its constructing complexity as well as effect contribution.

Silver Data Silver data are constructed on parallel corpus and additional models or tools. We implemented two kinds of silver data construction.

1) The data are obtained via difference comparison on MT and target sentences. Given a parallel corpus sentence pair of source and target sentence, we first translate the source sentence by the NMT model (which is used to generate the train/dev/test data of the TS task and released to all task participants), then compute edit distance (ED) between MT and target sentence to measure the cost of editing from MT to target. We choose ED metric of LCS (Longest Common Subsequence) (Bergroth et al., 2000), which means only insertion and deletion operations are allowed (not substitution operation). ED is usually calculated by dynamic programming, and it can indicate the words which are inserted or deleted from MT to target sentence by a trace-back approach. So we can get a TS span by concatenating all words between the first and last edited words in target sentence. Table 1 shows an example for it. This can be formulated as:

$$TS = diff(NMT(source), target) \quad (1)$$

Thus, $(source, target_{diff\_mask}, TS)$ is the constructed train data, and $target_{diff\_mask}$ is the masked translation where the TS span is replaced with a placeholder. If the edited parts in target sentence is too long, it will induce a long TS span and short masked translation, so we filter out such data by a threshold.

2) The data are constructed by masking special parts on target sentences. By browsing the golden TS train data, we found there were certain regularity. Apart from the haphazard TS spans, NEs (Named Entity) and non-translated elements (especially digits) inclined to be mistranslated. So we can focus on constructing synthetic data by masking and predicting NEs and non-translated elements in target sentences. We use spaCy[1] NER function

MT	4.6.1 Suspension for Contractor reasons
$target$	4.6.1 Suspension because of Contractor reasons
$difference$	4.6.1 Suspension <add>because</add> <del>for</del><add>of</add> Contractor reasons
TS	because of
$target_{diff\_mask}$	4.6.1 Suspension <mask> Contractor reasons

Table 1: An example of synthetic data by difference comparison on MT and target sentences.

to extract such spans in target sentences, and select NE labels of PERSON, LOC, ORG, PRODUCT, MONEY and QUANTITY. This can be formulated as:

$$TS = NER(target) \tag{2}$$

Thus, $(source, target_{NER\_mask}, TS)$ is the constructed train data, and $target_{NER\_mask}$ is the masked translation where the TS span is replaced with a placeholder.

Bronze Data Bronze data are sampled directly on parallel corpus. Sampling on parallel corpus is straightforward and simple but effective for TS model. This method is also used by (Yang et al., 2021). Given the sentence pair (source,target) in the parallel corpus, we denote $target^{\backslash i:j}$ as a masked version of target sentence where its fragment from position i to j is replaced with a placeholder ($1 \leq i \leq j \leq |target|$). The $target^{i:j}$ denotes the fragment of target from position i to j. We treat $target^{i:j}$ and $target^{\backslash i:j}$ as the TS and masked translation respectively. This can be formulated as:

$$TS = target^{i:j} \tag{3}$$

So we get the constructed train data $(source, target^{\backslash i:j}, TS)$.

When the target language is Chinese, we tokenize the target sentence by Jieba[2] before sampling on it.

3.3 Training Process

We perform two-stage fine-tuning on ΔLM for training the TS models. In the first stage, we use the silver and bronze train data to fine-turn on the original ΔLM model. In the second stage, we continue to fine-tune on the results of the first stage with the golden train data. Because there are much more train data and time consumption in the first stage than that of the second stage, we just train one model for stage 1, but train several models for stage 2 with different parameters considering the plan of model ensemble. The details will be described in Section 4.

3.4 Optimization Algorithm for TS Candidates with Hints

For Task2, we use the same models as that of Task1 to generate TS candidates, and the minor adjustment is just generating more outputs with a larger N-best value during predicting. Given TS candidates by the initial predicting order, our optimization algorithm is simple and effective. Firstly, each TS candidates is converted to a string consisting of the first character of the words in TS, and secondly, we compute LCS (Bergroth et al., 2000) between each string and the hint by the candidates order, then choose the longest LCS from the results. If there are multiple longest LCSs, just choose the first one by the candidates order. Finally, the TS candidate corresponding to the longest LCS is selected as the best TS.

For Chinese language, first of all the TS candidates should be converted to phonetic symbols word by word, then perform the above process. We use pypinyin[3] to get phonetic symbols of Chinese words.

4 Experiments

We present the performance of the implemented models on the dev and test datasets, as well as some additional analysis.

4.1 Data Used

In addition to the golden train and dev data provided by the TS tasks, other data we used to train TS models are from WMT22 general translation task[4], and just part of the bilingual data are used.

Data Used for Zh→En Direction The original parallel corpus for generating synthetic data are 14 million ParaCrawl v9 Zh⇔En and 15 million UN Parallel Corpus V1.0 Zh⇔En bilingual data. Following the data constructing methods in section 3.2, all of the constructed silver and bronze data are 110 million. We sampled 4 times on different posi-

Dataset	Stage	Zh→En	En→Zh
dev set	Stage 1	15.62	25.10
	Stage 2	28.15	38.08
test set	Stage 2	28.42	39.71

Table 2: BLEU of two stages on dev or test sets for Zh⇔En language directions

tions for every sentence when constructing bronze data.

Data Used for En→Zh Direction Besides the original parallel corpus of Zh→En direction, we added 6 million CCMT corpus. The data constructing methods are the same as Zh→En direction, and we finally got 120 million silver and bronze data.

4.2 Results of Task 1

Following the two-stage fine-tuning process described in section 3.3, Table 2 summarizes the results of Task 1 for Zh⇔En language directions.

On stage 1, we fine-tune ΔLM-base with the constructed silver and bronze data. All models are implemented on top of the open source toolkit Fairseq[5]. We train on 6 GeForce RTX 3090 GPUs. The optimizer is Adam (Kingma and Ba, 2014) with $\beta 1 = 0.9$ and $\beta 2 = 0.98$. The learning rate is 6e-5 with a warming-up step of 8000. The models are trained with the label smoothing cross-entropy, and the smoothing ratio is 0.1. All the dropout probabilities are set to 0.3. The gradient accumulation is used due to the high GPU memory consumption, and we set max-tokens = 1600 and update-freq = 64. To speed up the training process, we conduct training with half precision floating point (FP16). We validate on dev set every 1000 updates, and the early stop patience is 5. Under these training parameters, the model converges at epoch 3.

On stage 2, we use the golden train and dev data provided by the TS tasks, and continue to fine-tune on the checkpoint with the best validation performance of stage 1. Only a few training parameters were adjusted on stage 1. The learning rate is reduced to 3e-5. In order to apply model ensemble strategies, the dropout varies in [0.1, 0.2, 0.3], and the update-freq varies in [3, 4, 5] with the fixed max-tokens 1600. The submissions are ensemble results of all models trained on stage 2.

Dataset & parameter	Zh→En	En→Zh
test set, N-best=100	39.95	48.60

Table 3: BLEU of test set with hints when N-best=100

4.3 Results of Task 2

Task 2 intends to predict more accurate translation suggestions under additional hints. So we enlarge the N-best value gradually from 5 to 100 to generate more TS candidates, and search the optimal TS by the algorithm described in section 3.4. Figure 1 shows the results on dev set where the N-best value is set in [5, 10, 20, 30, 50, 80, 100]. It seems that the BLEU rises with the increase of N-best value, but the gains diminish when N-best exceeds 50.

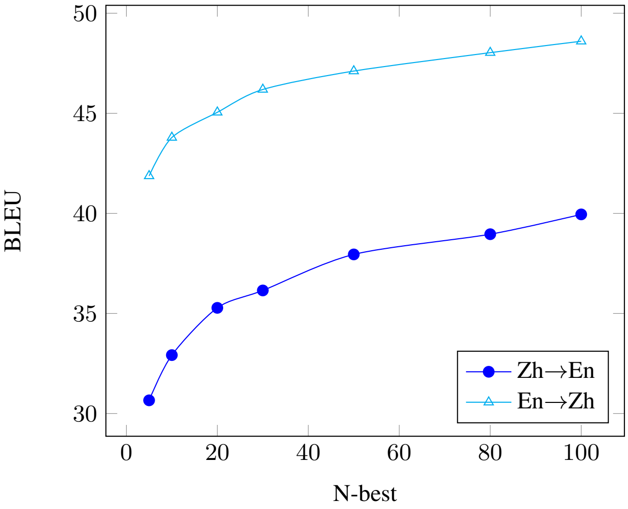

Figure 1: BLEU of dev set with hints for different N-best values

We get the final submissions on test set under N-best = 100, and the official BLEU scores are shown in Table 3 for Zh→En and En→Zh language directions.

4.4 Results Analysis Considering TS Accuracy

In practice, TS is designed to replace the incorrect span in target sentence during PE, so an absolutely accurate TS is important for post-editing translators. Therefore we analyze the accuracy indicator for TS in this section. Predicting an absolutely accurate TS relies heavily on TS length, then we analyze it based on different TS lengths, as well as top-k predictions, considering that instead of the top predicted TS, an accurate but top-k-located TS is also valuable for PE through the interactive options. Here top-k predictions are generated in the same

[5] https://github.com/facebookresearch/fairseq

TS Len		**=1**	**≤3**	**≤5**	**≤10**	**All**
dev TS, Num=2767 **(Proportion)**		**1279** **(46.2%)**	**2181** **(78.8%)**	**2488** **(89.9%)**	**2709** **(97.9%)**	**2767** **(100%)**
Top-1 predictions	Positive Num	657	900	931	949	950
	Accuracy	**51.4%**	**41.3%**	**37.4%**	**35.0%**	**34.3%**

	Accuracy	**73.7%**	**63.2%**	**57.6%**	**53.8%**	**52.7%**

Table 4: TS accuracy analysis on dev set for Zh→En language direction

way as the TS candidates in Section 3.4.

For Zh→En language direction, Table 4 shows that if there is just one word in TS, the accuracy is 51.4% for the top predictions; and the accuracy reaches 63.0% or 73.7% if we consider top-3 or top-5 predictions. Similarly, the accuracy is 41.3%, 53.1%, or 63.2% if considering top-1, top-3, or top-5 predictions respectively for the TSs no more than 3 words. The accuracy decreases gradually as the TS length increases. A significant finding is that even on the whole dev set, the accuracy still reaches 52.7% if we consider the top-5 predictions. Therefore, the accuracy indicator may help us determine when and how the TS options are activated.

4.5 Effects of Training Procedure and Synthetic Data

The two-stage fine-tuning procedure is essential for our results. If stage 1 is not applied, which means just fine-tuning ΔLM on the golden data, we get very low BLEU scores, i.e., 2.19 in Zh→En language direction on dev set. If stage 2 is not applied and just fine-tuning ΔLM on the synthetic silver and bronze data, the BLEU scores are 15.62 in Zh→En and 25.10 in En→Zh (see Table 2), with a decrease of about 13 BLEU score than the full two-stage fine-tuning procedure.

The effects of the synthetic silver and bronze data are also analyzed. Table 5 lists the results in Zh→En language direction for the single silver or bronze data on stage 1 and stage2. It shows that the silver synthetic data plays a more important role for the final performance than the bronze data.

Systems	**Zh→En**	
	Stage 1	**Stage 2**
silver & bronze data	15.62	28.15
only silver data	13.53	26.11
only bronze data	10.24	24.06

Table 5: Effects of the synthetic silver and bronze data for Zh→En language direction on dev set

5 Conclusions

We present the Transn IOL Research submissions of the WMT2022 shared task on Translation Suggestion. Our system is implemented with two-stage fine-tuning on ΔLM, which is a pre-trained encoder-decoder language model. To improve the performance, we construct synthetic data by difference comparison, named-entity masking and random sampling on parallel corpus. We propose an effective algorithm to choose optimal translation suggestion with hints. The accuracy indicator of TS is also analyzed for more efficient PE in practice. On the participated 4 tracks of En⇔Zh language directions, we achieved best scores on 3 tracks and comparable result on another track.

Effective translation suggestions benefit a lot for post editing. In the future, we plan to research field related and fine-grained TS models to improve system performance, and will integrate these advanced techniques in our translation practice.

Abstract

Translation suggestion (TS) models are used to automatically provide alternative suggestions for incorrect spans in sentences generated by machine translation. This paper introduces the system used in our submission to the WMT'22 Translation Suggestion shared task. Our system is based on the ensemble of different translation architectures, including Transformer, SA-Transformer, and DynamicConv. We use three strategies to construct synthetic data from parallel corpora to compensate for the lack of supervised data. In addition, we introduce a multi-phase pre-training strategy, adding an additional pre-training phase with in-domain data. We rank second and third on the English-German and English-Chinese bidirectional tasks, respectively.

1 Introduction

Translation suggestion (TS) is a scheme to simplify Post-editing (PE) by automatically providing alternative suggestions for incorrect spans in machine translation outputs. Yang et al. (2021) formally define TS and build a high-quality dataset with human annotation, establishing a benchmark for TS. Based on the machine translation framework, the TS system takes the spliced source sentence $\mathbf{x}$ and the translation sentence $\tilde{\mathbf{m}}$ as the input, where the incorrect span of $\tilde{\mathbf{m}}$ is masked, and its output is the correct alternative $\mathbf{y}$ of the incorrect span. The TS task is still in the primary research stage, to spur the research on this task, WMT released the translation suggestion shared task.

This WMT'22 shared task consists of two subtasks: Naive Translation Suggestion and Translation Suggestion with Hints. We participate in the former, which publishes the bidirectional translation suggestion task for two language pairs, English-Chinese and English-German, and we participate in all language pairs.

Our TS systems are built based on several machine translation models, including Transformer (Vaswani et al., 2017), SA-Transformer (Yang et al., 2021), and DynamicConv (Wu et al., 2018). To make up for the lack of training data, we use parallel corpora to construct synthetic data, based on three strategies. Firstly, we randomly sample a sub-segment in each target sentence of the golden parallel data, mask the sampled sub-segment to simulate an incorrect span, and use the sub-segment as an alternative suggestion. Secondly, the same strategy as above is used for pseudo-parallel data with the target side substituted by machine translation results. Finally, we use a quality estimation (QE) model (Zheng et al., 2021) to estimate the translation quality of words in each translation output sentence and select the span with low confidence for masking, and then, we utilize an alignment tool to find the sub-segment corresponding to the span in the reference sentence and use it as the alternative suggestion for the span.

Considering that there is a domain difference between the synthetic corpus and the human-annotated corpus, we add an additional pre-training phase. Specifically, we train a discriminator and use it to filter sentences from the synthetic corpus that are close to the golden corpus, which we deem as in-domain data. After pre-training with large-scale synthetic data, we perform an additional pre-training with in-domain data, thereby reducing the domain gap. We will describe our system in detail in Section 3.

2 Related Work

The translation suggestion (TS) task is an important part of post-editing (PE), which combines machine translation (MT) and human translation (HT), and improves the quality of translation by correcting incorrect spans in machine translation outputs by human translators. To simplify PE, some early scholars have studied translation prediction (Green

[*] Yufeng Chen is the corresponding author.

Proceedings of the Seventh Conference on Machine Translation (WMT), pages 1211 - 1216
December 7-8, 2022 ©2022 Association for Computational Linguistics

et al. (2014), Knowles and Koehn (2016)), which provides predictions for the next word (or phrase) when given a prefix. And some scholars have also studied prediction with the hints of translators (Huang et al., 2015).

In recent years, some scholars have devoted themselves to researching methods to provide suggestions to human translators. Santy et al. (2019) present a proof-of-concept interactive translation system that provides human translators with instant hints and suggestions. Lee et al. (2021) utilize two quality estimation models and a translation suggestion model to provide alternatives for specific words or phrases for correction. Yang et al. (2021) propose a transformer model based on segment-aware self-attention, provide strategies for constructing synthetic corpora, and released the human-annotated golden corpus of TS, which became a benchmark for TS tasks.

3 Method

In this section, we describe the translation suggestion system, followed by our strategies for building synthetic corpora, and finally the details of the additional pre-training phase.

3.1 Translation Suggestion System

As defined by Yang et al. (2021), given the source sentence $\mathbf{x}$, its translation sentence $\mathbf{m}$, the incorrect span $\mathbf{w}$ in $\mathbf{m}$, and its corresponding correct translation $\mathbf{y}$, the translation suggestion task first masks the incorrect span $\mathbf{w}$ in $\mathbf{m}$ to get $\mathbf{m}^{-\mathbf{w}}$, and then maximizes the following conditional probabilities:

$$p(\mathbf{y}|\mathbf{x}, \mathbf{m}^{-\mathbf{w}}; \boldsymbol{\theta}) \quad (1)$$

where $\boldsymbol{\theta}$ is the parameters of the model.

The construction of the TS system is based on common machine translation models. We introduce the models used in our TS system below:

- **Transformer-base (Vaswani et al., 2017).** The naive transformer model. The encoding and decoding layers are both set to 6, the word embedding size is set to 512, and the attention head is set to 8.

- **Transformer-big (Vaswani et al., 2017).** The widened transformer model. The encoding and decoding layers are both set to 6, the word embedding size is set to 1024, and the attention head is set to 16.

- **SA-Transformer (Yang et al., 2021).** The segment-aware transformer model, which replaces the self-attention of the naive transformer with the segment-aware self-attention, further injects segment information into the self-attention, so that it behaves differently according to the segment information of the token. Its parameter settings are the same as those of Transformer-base.

- **DynamicConv (Wu et al., 2018).** The dynamic convolution model that predicts a different convolution kernel at every time-step. We set both encoding gated linear unit (GLU) and decoding GLU to 1 in the experiment.

3.2 Build Synthetic Corpora

Since there are few golden corpora available for training, it is necessary to build a synthetic corpus to make up for the lack of data. We build synthetic data through the following three strategies and use the mixed data for model pre-training.

3.2.1 Building on Golden Parallel Data

Following the method of Yang et al. (2021), we construct synthetic data on the large-scale golden parallel corpus. Given a sentence pair $\mathbf{x} = \{x_1, x_2, \ldots, x_n\}$ and $\mathbf{r} = \{r_1, r_2, \ldots, r_m\}$ from the golden parallel corpus, we randomly sample a sub-segment $\mathbf{w} = \{r_i, r_{i+1}, \ldots, r_j\}$ of $\mathbf{r}$, we mask the sub-segment in sentence $\mathbf{r}$ to get $\mathbf{r}^{-\mathbf{w}} = \{r_1, r_2, \ldots, r_{i-1}, [\text{MASK}], r_{j+1}, \ldots, r_m\}$, and use $\mathbf{w}$ as an alternative suggestion. We perform statistics on the length of golden data to determine the length of masked spans, which is more in line with the golden distribution.

3.2.2 Building on Pseudo Parallel Data

The prediction of alternative suggestions requires the translation context, which cannot be provided by the golden parallel corpus. Therefore, we use the MT model provided by the shared task to infer the source of the large-scale parallel corpus to generate the pseudo-parallel corpus. Then we still follow Yang et al. (2021) and use the same way as described in Section 3.2.1 to construct synthetic data on the pseudo corpora consisting of source sentences and machine translation output sentences.

3.2.3 Building with Quality Estimation

The TS task is to predict the correct alternative proposal given the translation context. However, when sampling on the golden parallel corpus, the context

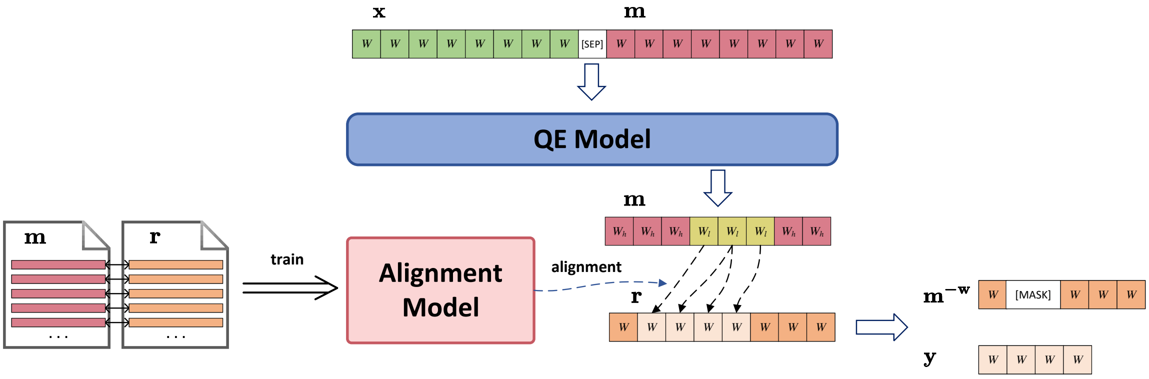

Figure 1: Schematic diagram of building synthetic corpora with quality estimation. $\mathbf{x}$ is the source sentence, $\mathbf{m}$ is the machine translation sentence, $\mathbf{r}$ is the reference sentence, and W_h and W_l represent words with high and low confidence, respectively.

does not match the translation output, and when sampling on the pseudo-parallel corpus, the alternative suggestions may be incorrect. Therefore, the above two construction strategies are not optimal.

We explore a method that is closer to the real scenarios, as shown in Figure 1. First, the word-level translation quality estimation (QE) model is used to estimate the confidence of the words in each translation sentence, and the continuous span with low confidence (that is, poor translation) is selected. Then, the translation sentence is aligned with the reference sentence through the alignment model, and the sub-segment corresponding to the span in the reference is selected as an alternative suggestion.

More specifically, we use a masked language model as our QE model, following the method of Zheng et al. (2021). To train the QE model, we splice the source sentence $\mathbf{x}_i$ and the reference sentence $\mathbf{r}_i$ of the large-scale golden parallel corpus, where some words in $\mathbf{r}_i$ are masked to get $\mathbf{r}_i^{-w}$, and the QE model is optimized to minimize the following loss function:

$$\mathcal{L} = -\sum_{i=1}^{N} \log p(\mathbf{r}_i^{w} | \mathbf{x}_i, \mathbf{r}_i^{-w}; \boldsymbol{\theta}) \qquad (2)$$

where N is the number of golden parallel sentences, $\mathbf{r}_i^{w}$ is the masked part of the reference sentence and $\boldsymbol{\theta}$ is the model parameter.

During inference, the source and translation sentences of the pseudo-parallel corpus are spliced and fed into the QE model. The model scores the word of the translation sentence according to the recovery probability of it after being masked, and words with lower scores are considered poor translations.

After that, we train a word alignment model (Lai et al., 2022) using the translated sentences and reference sentences. To ensure high alignment quality, we filter out sentences with lengths less than 5 and greater than 100 and randomly sample 5M sentence pairs for training. We use the trained alignment model to align the machine translation sentence and the reference sentence. The sub-segment in the reference that aligns with the poorly translated span described above is selected as an alternative suggestion.

3.3 Additional Pre-Training Phase with In-Domain Data

The sources of data used to construct large-scale synthetic corpus and human-annotated golden corpus are domain different. To bridge this difference, we introduce an additional pre-training stage. We filter data similar to the golden corpus as in-domain data, which are used as pre-training for the next phase after pre-training model with a large-scale synthetic corpus.

In particular, we use BERT (Devlin et al., 2019) to construct a discriminator to identify in-domain data. The discriminator consists of a binary classifier trained to distinguish between in-domain and out-of-domain sentences. The source sentences from the golden corpus as positive examples and source sentences from the synthetic corpus as negative examples are used to train this discriminator. We upsample the golden corpus by 10 times, and randomly subsample the same amount of sentences from the synthetic corpus. For each input source sentence, the discriminator predicts the probability that the sentence is in-domain. Sentences with probabilities greater than a certain threshold are

Direction	Train	Valid	Test

discriminated as in-domain sentences.

After the above two phases of pre-training, we use the human-annotated golden corpus for fine-tuning and test the final model.

4 Experiments and Results

4.1 Setup

We have submitted English-Chinese (en-zh) and English-German (en-de) bidirectional translation suggestion tasks. We mix en-zh data from WMT'19 and WikiMatrix, and en-de data from WMT'14 and WikiMatrix, respectively, to construct a synthetic dataset. We use the golden Train, Valid and Test set provided by this shared task, and the data statistics are shown in Table 1. We follow Yang et al. (2021) to preprocess the data, and mix the data constructed by the three strategies described in Section 3.2 as our large-scale synthetic data. The statistics of the constructed large-scale (LS) synthetic data and in-domain (IND) synthetic data are shown in Table 2. Note that for the experiments in the en-zh translation direction, we do not apply the construction strategy with QE and the pre-training phase with in-domain data. All our models are implemented based on Fairseq (Ott et al., 2019). We use the same data on each model for two phases of pre-training and fine-tuning.

Table 5: BLEU scores on the development set for systems under different models in the English-German direction.

4.2 Results

We report the results of our method on the development and test set of the translation suggestion task of WMT'22. SacreBLEU[1] is used to compute the BLEU score as quality estimates relative to a human reference. We report the experimental results of our system and the baseline system (Yang et al., 2021) on the test set in Table 3, and for the baseline system, we directly use their experimental results.

As can be seen from Table 3, our system beats the baseline system in three translation directions, especially in the en-de direction, where our system surpasses the baseline by 13.13 BLEU.

We also report the results of the system on the development set of English-German translation directions to analyze the effectiveness of different models and strategies. In Table 4, we show the results of the system based on the SA-Transformer model under different strategies. "Do nothing" means we only train with the provided training set. It can be seen that the strategy of constructing synthetic data with quality estimation (QE) and the additional pre-training with the in-domain (IND) data stage can

[1] https://github.com/mjpost/sacrebleu

bring about a great improvement.

In Table 5, we present the results of systems based on different models and the model ensemble. It can be seen that in the case of the single-model system, the Transformer-big and DynamicConv models achieve better results. Besides, the ensemble model brings obvious improvement and achieves the best results.

5 Conclusion

We describe our contribution to the Translation Suggestion Shared Task of WMT'22. We propose a strategy to construct synthetic data with the quality estimation model to make the constructed data closer to the real scenarios. Furthermore, we introduce an additional phase of pre-training with in-domain data to reduce the gap between synthetic corpus and golden corpus. Experimental results demonstrate the effectiveness of our strategy. Considering the heavy labor of annotating TS data, we think data augmentation is the most important strategy that should be addressed. In the future, we will put more effort into the data generation method, to make the most of openly-accessible parallel data.

Limitations

The strategy of constructing synthetic data based on quality estimation proposed in this paper can automatically sample the incorrectly translated spans in the translations, and find the correct alternative suggestions through the alignment. It is a solution that conforms to real scenarios, and the experimental results have also proved that it is effective. However, our approach to generating synthetic data via QE still has some limitations. First, the quality estimation and alignment phases require a large additional time overhead. And second, the segments from the reference sentences may not fit into the context of the masked translation sentences due to grammar constraints. We hope to explore better solutions in future research.

Acknowledgements

The research work descried in this paper has been supported by the National Key R&D Program of China (2020AAA0108001) and the National Nature Science Foundation of China (No. 61976016, 61976015, and 61876198). The authors would like to thank the WMT'22 shared task organizers for organizing this competition and for providing open source code and models, as well as the anonymous reviewers for their valuable comments and suggestions to improve this paper.
